A paper was also read, entitled, "*Further Particulars of the Fall of the Cold Bokkeveld Meteorite.*" By Thomas Maclear, Esq., F.R.S., in a letter to Sir J. F. W. Herschel, Bart.—This communication, which is supplementary to the one already made to the Society by Mr. Maclear, contains reports, supported by affidavits, of the circumstances attending the fall of a meteoric mass in a valley near the Cape of Good Hope. The attention of the witnesses had been excited by a loud explosion which took place in the air, previous to the descent of the aerolite, and which was attended by a blue stream of smoke, extending from north to west. Some of the fragments which had been seen to fall, and which had penetrated into the earth, were picked up by the witnesses. One of them falling on grass caused it to smoke: and was too hot to admit of being touched. The mass which was sent to England by H.M.S. *Scout*, weighed, when first picked up, four pounds. The paper is accompanied by a map of the district, showing the course of the aerolite.

A paper was also read, entitled, "*An account of the Shooting Stars of* 1095 *and* 1243." By Sir Francis Palgrave, K.H.—The author gives citations from several chronicles of the middle ages, descriptive of the remarkable appearance of shooting stars which occurred on the 4th of April, 1095, on the testimony of independent witnesses both in France and England. One of them describes them as "falling like a shower of rain from heaven upon the earth:" and in another case, a bystander, having noted the spot where the aerolite fell, "cast water upon it, which was raised in steam, with a great noise of boiling." The Chronicle of Rheims describes the appearance as if all the stars in heaven were driven, like dust, before the wind. A distinct account of the shooting stars of July 26th, 1293, is given by Matthew Paris.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

Monday, 30th March, 1840, W. R. Hamilton, Esq. in the chair. George Gutch, Esq. Fellow, presented 10 guineas for the purchase of books.

The following papers were read :—

On Garden Walls, by J. B. Watson, Fellow.

A paper from Mr. Jenkins "*on Talacre Stone.*"

I have the pleasure of offering to your notice a stone quarry in North Wales, whose produce is now importing into London, two cargoes having already arrived; and, unless I am much mistaken, the introduction of this stone to the British architects will prove a valuable boon. The quarries are situated on the coast of Flintshire, within a mile of the point of Air, at the mouth of the estuary of the Dee, and adjoining the grounds of Talacre Hall, the seat of Sir Edward Mostyn, Bart.

The mineralogical character of this stone is that of silicious sand-stone, with an argillo-silicious cement. It is of great density, a cubic foot weighing 150¼ lbs., is worked with great ease, and being remarkably free from hard untractable veins and soft places, is capable of a very smooth surface, a fine arris, and the most delicate carving. The closeness of its texture and fineness of its grain, render it very desirable for external work in a large city, as it prevents the soot from adhering to it, and thus clogging up the mouldings and carvings, reducing them to an undistinguishable mass of blackness, a fault justly complained of in the Bath and Portland stones.

For landings and steps, the Talacre stone far excels the very best kinds of Yorkshire stone, as it is superior in strength, and not liable to scale in the unsightly manner that so frequently destroys the appearance of the finest pavements of Yorkshire stone, as may be seen near the Post Office, and in the Temple; and as the quarries are now in the possession of a London company (the Talacre Coal and Iron Company,) an abundant supply of large sized stone may be expected.

Its colour is very uniform, and, to my taste, has a beautiful *tone*, which eminently fits it for interior finishings, especially in the Gothic style.

Its durability may be seen in the shrine of St. Winifred's well, at Holywell, in Flintshire, which was constructed of this stone in the 15th century, and, though exposed to the humidity of the air, incident to the neighbourhood of mountains and an arm of the sea, as well as to the clouds of sulphurous smoke from the numerous works on the stream issuing from that celebrated spring, yet still preserves its rich and delicate carvings in a very perfect state. Many other ancient buildings in the neighbourhood have been constructed or ornamented with this stone, as the ancient mansion in the village of Llanasa, with its curious carved porch, erected in 1642, the carvings and ashlar of which are still very perfect, the quoins of Rhyddlan and Denbigh Castles, built the latter end of the 13th century; and among modern buildings, Talacre Hall, the seat of Sir Edward Mostyn, Bart., the masonry of which is the admiration of all. I may mention that the chimney pieces of this mansion, in the Gothic style, are carved in this stone, and have a very beautiful effect.

The following is the result of an experiment made on the comparative strength of the Talacre stone with best Yorkshire.

A piece of Talacre stone, 2 ft. 6½ in. long, 3¾ in. wide, and 2 in. thick, bore, for several minutes, a weight of	4	2	1
Best Yorkshire of the same size broke immediately with a pressure of	4	0	11

I may add that, from the proximity of the quarries to the new harbour of Port Talacre, this stone can be brought to London at a price little, if at all, exceeding that of Yorkshire stone.

Mr. Donaldson read a paper "*On various extraordinary tombs, recently brought to light at the ancient city of Cære, and described in a work of much learning and research, forwarded to the Society by its author, the Cavaliere Canina, an Honorary and Corresponding Member.*

About half way on the road between Rome and Civitâ Vecchia, is the village of Cervetri, or Cerveteri, the site of the ancient Cære, where some judicious excavations have brought to light a tomb, which seems at once to prove the affinity of the ancient inhabitants of these parts with the Greeks, and affords a confirmation of the supposition of their common origin, derived from other discoveries of an analogous nature. Immediately contiguous to Cervetri is a platform of considerable extent, on which was doubtless the ancient Cære, surrounded once, it is presumed, with walls. Within a short distance of the precinct marked by the supposed line of wall are a number of tombs, one of which is that now about to be explained. It evidently bears the proofs of two distinct epochs of construction, as the original edifice, which forms the centre, consisted of a solitary chamber in the body of a circular mass surmounted by a mound of earth. This was subsequently enlarged by another ring of solid masonry, containing various cells, also surmounted by a larger mound of earth. This addition so effectually closed from observation the inner chamber, that it has remained, until the present period, undespoiled of its precious relics; while the outer chambers have been robbed of every object that they once contained, from their entrances being immediately exposed to view. The original tomb consists of a circular mass about 82 feet in diameter, having apparently an outer ring of solid masonry, and a central pillar of construction, which ran up to the top, and served to support the mound of earth, which formed the conical part of the tumulus; and probably it was surmounted externally by a pedestal, on the top of which was a statue, or some object allusive to the deceased. The sepulchral chambers consisted of an outer gallery, about 30 feet long, and 5 ft. 8 in. wide, and 11 ft. 2 in. high, at the further end of which were two oval-formed chambers, about 11 ft. 6 in. long, by 9 ft. wide, on the right and left, rudely worked out of the solid mass. At the extremity of the outer gallery is a wall with a small aperture in it, opening into another gallery about two-thirds the length of the first one, or 20 feet, and 4 ft. 3 in. wide. The walls of the galleries seem to be formed of a rude solid perpendicular construction, about 5 feet high, above which are three overhanging courses, with horizontal joints, or beds, forming an inclined roof on each side. Another uppermost course is perpendicular, and leaves a kind of square channel, about 18 inches wide and 15 inches high, running the whole length. The walls of the oval chambers seem to be worked out of the rude solid mass, and do not present the appearance of any regular courses of stone. There were smaller chambers in the periphery of the outer construction, formed in a similar manner, and when it was deemed desirable, at a subsequent period, to procure greater accommodation for the family, it seems to have been effected by enlarging the circumference and extending the smaller chambers. But it is remarkable that the large gallery or chamber in the original mass was not carried out, as though there was the wish to hold it sacred as the deposit of the chief of the family, and to secure it from intrusion by closing up its entrance. It will be seen that the construction of the walls of the galleries is similar to that of the subterraneous chamber at Mycenæ, commonly called the Treasury of Atreus, or Tomb of Agamemnon, and illustrated in the supplementary volume to Stuart's Athens. The courses are horizontal, and gathering over each other gradually towards the apex of the roof, and cut away so as to give the inner face a concave appearance. But another remarkable instance of this peculiar construction of ancient art, exists at Rome in the Mamertine Prison, the lower cell of which was once evidently built in the same manner, the upper part having subsequently been cut off, and the arch surmounting it constructed as a regular arch with concentric courses. Mr. Donaldson then described the various objects which were found in this tomb. In the first gallery next the door was a brazier placed on an iron tripod, and close to it a bronze censer for perfumes, and next to that another brazier. Further in was a four-wheeled car, upon which was borne the corpse laid on the bronze bed; and there remained many fragments of the wood of which it was formed, and of the bronze with which it was ornamented. Near the entrance to the right hand oval chamber was a bronze bedstead, on which lay the body of the defunct, evidenced from the bones on the floor and traces of stains produced by the decomposition of the flesh. There were two small iron altars, one at the head and the other at the foot of the bedstead, and about two dozen small earthenware figures on the floor round the three outer sides of the bedstead, several shields, a bundle of arrows; and these, with some cuirasses, which once hung on the walls, prove this to have been the sepulchral chamber of a warrior. In the channel in the roof were suspended from nails some bronze vases and dishes. The inner gallery seems to have been appropriated as the sepulchral chamber of a female. When first discovered, it was found to be encumbered with the ruins of one of the side walls, which had fallen in; but upon removing the rubbish and dirt, various articles in gold and silver were found among the remains of the body, which had been deposited at the further end. A small silver bucket, and a cup without handles, various bronze cups and vases, proper for scents and perfumes, were also discovered. The two oval chambers to the right and left of the outer gallery, were evidently of a subsequent period, and were formed in a very rude and rough manner, as though added with great haste. The chamber on the left contained various cups and other objects of bronze, and in that to the right were found numerous little terra-cotta figures similar to those in the outer gallery, near the funeral bedstead, and some earthen vases, in one of which were deposited burnt bones and ashes, remains, doubtless, of some member of the same family, and, it is to be inferred, of a period somewhat subsequent to the outer chamber, as in that the body had not been burnt, a practice of later introduction. Canina is of opinion, from an observation of the various bronze objects found in these tombs, and engraved with representations of combats and huntings of animals, and none of which represented the events that occurred at Troy, that this tomb must have been erected before this important period of Greek history, a supposition which gains strength, from the peculiar form of the Greek characters of the inscriptions. It may therefore be concluded, that this tumulus must be about 3,000 years old, and was erected during the period that the Pelasgi held possession of the country.

April 27.—The Marquis of Northampton in the Chair.

Signor Gasparo Fossati, architect to the Emperor of Russia, was elected an Honorary and Corresponding Member.

Some Roman remains from Watling Street, were exhibited by Mr. Fowler

A paper was read, "*On the Classification of Egyptian Architecture,*" by Mr. George Alexander, the tendency of which was to show, that many buildings, usually attributed to the earlier Egyptian or Pharaonic dynasties, were in reality much more recent, being erected during the Ptolemaic and Roman rule in Egypt; which gave rise to some observations by Mr. Hamilton and Sir Gardner Wilkinson, who were present.

A paper was also read, entitled,

"*Remarks on the question raised by Sir Gardnor Wilkinson respecting the origin of the Vertical Line in Architecture, and the Return to the Horizontal Line after the "Revival.*" By George Godwin, jun., F.R.S. & S.A.*

At a recent meeting of the Institute of Architects, Sir Gardnor Wilkinson laid before the members some pertinent remarks, concerning the appearance of the vertical line in architecture at an earlier period than is generally ascribed to its introduction—remarks which, while they prove the acuteness of his observation, and cannot but lead to the exercise of thought on the part of those who are engaged in the study of architectural history, serve as evidence of the writer's interest in our proceedings, and entitle him to our thanks. I should be sorry, then, if they were allowed to pass unnoticed, and am tempted, in order that this may not be the case, to offer at once a few observations on the subject. I feel some diffidence, I must confess, in coming before you on this occasion, because there are many others present much better qualified to respond satisfactorily to the inquiry; indeed, I should not have done so, could I have been certain that any individual would have offered himself for the task. Experience, however, teaching that the only certain way to have one's wants and wishes fulfilled, is to bestir oneself in carrying them out personally, I have stepped into the breach, and must plead the goodness of the intention as an excuse.

The bearing of Sir Gardnor Wilkinson's general argument was to the effect that the vertical line, admitted to be the principal feature distinguishing Gothic, or what has been termed *Church Architecture* from the Greek style, whereof the predominance of horizontal lines is a characteristic—originated at a much earlier date than the style it now distinguishes, and is to be found extensively in the ruins of ancient Rome. Further, that after the revival of the classic style in Italy, although the vertical line was still used throughout the *churches* of Christian Rome, we do not perceive it in the numerous and splendid palazzi which arose there and in other parts of Italy, but that the horizontal line is in them again made predominant. And the question he then put was, "what was the origin of the vertical style in ancient Rome, and the return to the horizontal style in the palaces of modern Italy."

What Sir Gardnor Wilkinson means by the vertical line in ancient Rome, and the appearance which it offered, are very clearly pointed out in the following sentence extracted from his paper:—

"In an arch of triumph, a Roman composition, though the mouldings and many other details are borrowed from the Greek, the vertical line commences with the pedestal of the columns appended to its side, and extending upwards with the column, breaks through the entablature, which it obliges to come forward to carry out and mark its direction, requires a projection of the attic to correspond with the capital above the cornice, and terminates in a statue; thus continuing it uninterruptedly from the base to the summit of the building."

Now it appears to me, that this mode of arrangement may be ascribed simply to the introduction of the ARCH as a chief feature in construction, and the decline, if not original want, of pure taste on the part of the Roman people. In Greece, and in the earlier sacred edifices of Rome, built before the introduction of the arch, and in imitation of those of Greece, columns bore the beams of wood or blocks of stone forming the upper part of the building, and were a constituent portion of the fabric. When, however, it became necessary to cover in larger spaces than could be conveniently spanned by single beams or blocks reaching from pillar to pillar, and the principle of the arch became generally understood and acted upon, a continued wall from which the arch might spring became requisite, and took the place of columns. The Romans, however, who, if I may venture to say it, had little real appreciation of harmony and fitness, (with a love of which the Greeks as a people were thoroughly imbued,) could not consent to abandon columns, but used them in the shape of accessories in nearly all structures the destination of which would allow of their introduction. They were placed against the faces of buildings—attached to but not made a portion of them. Probably where a great projection was not advisable, the height of the columns (as by that of course the diameter must have been regulated,) was lessened, and a pedestal (*column's foot*) was used to raise them to the required elevation. Something to bind the upper part of the column to the building was, however, requisite, and the entablature, then surrounding the structure itself, may have been brought out for that purpose over each of the columns. These, of themselves, namely columns bearing nothing, performing no office, but simply standing before a building with which they seemed to have little connexion, must have failed to give pleasure even to the least educated minds; offering, however, as they did, a convenient plinth for vases, or sculptured figures, these were found in some degree to lessen the objection, and therefore it is not surprising that they were usually thus terminated, sometimes with and sometimes without, the intervention of a similar projection of the attic under the figure.

In examining a Roman arch of triumph, that of Septimus Severus for instance, as well as many others, the probability of this position becomes very striking. And throughout the buildings of Rome so long as columnar decorations were employed, this mode of arrangement seems to have been almost necessarily followed.

Sir Gardnor Wilkinson says that wherever deviation from Greek models was allowable, the vertical line constantly predominates, "and to such an extent, that even a Greek entablature is sacrificed to this their favourite sentiment, being broken up into detached parts and compelled to project and recede, in order to allow the vertical line to pass continuously through it to the summit of the building."

This seems to me, but I mention it with great deference, to invest the use of the vertical line by the Romans with a little too much importance. I am compelled to think, a desire for its use was not the cause of the introduction of breaks and recesses, but that its own appearance, as well as these breaks, were the accidental effect of the employment of adventitious columnar decoration in situations where considerations of expense or convenience prevented the use of a continuous entablature. Although it is probable that when once the vertical line was strongly marked in a façade, the natural love of harmony in mind which finds annoyance in the constant recurrence of discordant lines, would induce subsequent arrangements in unison with the prevailing character.

Immediately on the *revival*, we find columnar decoration indulged in, even with less restraint from good taste than before, producing in nearly all cases, whether in Italy, France, or England, the predominance of the vertical line. The cupola of the church of *Santa Maria del Fiore*, at Florence, by Brunelleschi, and the church dedicated to St. Francis at Rimini, by Alberti, both in the 15th century—the Basilica of Vicenza by Palladio, in the 16th—the principal façade of St. Peter's at Rome, by Maderno, at the beginning of the 17th—and the hospital of the *Invalides* in Paris, by Mansart, in the 18th—may all be referred to as instances. In our own metropolis, Inigo Jones, at the Banquetting House, Whitehall, and Wren at St. Paul's Cathedral, afford us examples: and to bring the duration of this mode of arrangement up to the present time, I may mention Messrs. Cockerell and Richardson's design for the Exchange, submitted to the Gresham Committee, in the chief front of which it strikingly prevails.

Returning, however, for a moment to Italy at the period of the revival, we find that works of the same artists wherein adventitious columnar decoration was not introduced, display the horizontal line predominant, witness for example the façade of the Pitti Palace at Florence, by Brunelleschi, and the greater number of the numerous palatial residences at Rome and elsewhere, which render Italy as eminent for the possession of modern works of architectural skill as she is for the remains of her ancient glories. This predominance of the horizontal line however was not quite universal. In the Palace of the Chancery at Rome, for example, the vertical line is nearly continuous throughout the façade, although the entablature is unbroken. I will not pretend now to enter upon an examination of the feeling and motive of the architecture of this period, although it is a subject full of interest, and well worthy of what it has not yet sufficiently received, namely, investigation and analysis: should what has been said chance to lead to this very desirable result on the part of a qualified investigator, the profession will be greatly indebted to Sir Gardnor Wilkinson.

* We are glad to learn that the *Société Libre des Beaux Arts*, at their last annual meeting, awarded a silver medal to Mr. Godwin, as author of "The Churches of London."—EDITOR OF C. E. & A. JOURNAL.

New Mouth of the Vistula.—In consequence of the early breaking up of the ice in the Vistula, and the flood occasioned by the late heavy rains, the river was choked up a mile and a half above the city of Dantzic, whence it takes its course to the westward. The left bank of the river is here bounded by a dyke, which protects the fruitful low country behind it; the right bank is, however, without any such artificial protection, because its immediate neighbourhood consists of unfruitful sand land, and of a road of sand-hills or downs, for a distance of several German miles, which separates the river from the sea in such a decided manner, that it never appeared possible to any one that from that side any danger was to be apprehended from the water in the Vistula. But it happened on the night of the 31st of January, when it was expected that every moment the water would run over the dykes on the left bank of the river, and produce a most dreadful inundation, that the stream, encumbered with heavy masses of ice, took its course over the right bank, and attained the sand hills. These being from forty to sixty feet high, stopped the water, but the current undermined them just at the place where those hills merely consist of loose sand, and are the narrowest. As soon as they gave way, the accumulated mass of water and the heavy ice found their way through this new opening with indescribable force, and made a broad and deep channel into the sea. To stop this new natural mouth is impossible, and if it could be done, no one would feel inclined to do it. About thirty years ago, the plan was proposed by members of the governmen to form exactly the new mouth for the river which has just been made by a natural cause. Thus a great expence has been saved, and a great benefit o erated at the same time, by this occurrence. As regards the influence which this event may have on the communication of the town of Dantzic with the Port Fairwater, and also with Poland and the interior of the country, there is not the least ground to apprehend any interruption. We by no means lose the navigableness of the old Vistula, which, henceforward as before, will bring the Polish barges and the timber transports to our town. Its depth is likewise sufficient in its whole length to bear vessels of the same magnitude as before. Neither does the occurrence make any change whatever in the communication of that town with the sea-port.—*Morning Chronicle.*

EARL DE GREY'S CONVERZATIONE.

On Thursday evening the 21st ult., Earl De Grey opened his house in St. James's Square, for the reception of the Royal Institute of British Architects, of which Society his Lordship is the President. In addition to the members of the Institute, the splendid suite of apartments was crowded by a numerous and brilliant assembly of the patrons and professors of every branch of the arts and sciences, among whom we noticed the Marquis of Lansdowne, Lord Stuart de Rothesay, Lord Bughersh, Sir Edward Cust, Mr. Gally Knight, and Mr. Rogers, Sir Martin Shee, Sir Richard Westmacott, Sir Francis Chantry, Sir David Wilkie, Mr. Martin, Mr. Copley Fielding, Sir Gardner Wilkinson, Sir Henry Ellis, Sir Frederick Madden, Mr. Walker, Mr. Brunel, Mr. Babbage, Mr. Allan Cunningham, &c. &c. Her Grace the Duchess of Northumberland and a select party of ladies of rank were also present. The attention of the visitors was attracted by a display of works of art from the portfolios of Mr. Stanfield, Mr. Joseph Nash, and other artists of eminence, and by some beautiful specimens of the Dagnerrotype and electrotype.

MR. WALKER'S CONVERZATIONE.

On Wednesday evening the 27th ultimo, Mr. Walker, the President of the Institution of Civil Engineers, invited a large number of scientific gentlemen to a converzatione held at his house in Great George-street, the rooms were crowded at an early hour of the evening, we have not witnessed so large an assembly of the scientific and literati during the season. The company were entertained by a display of numerous works of art, drawings and models of new inventions, a few of which we shall just take a glance at. The portfolios of drawings by Scannell, Tomkins, Landseer, and Lake Price were much admired, so also the elaborate work on the Alhambra by Owen Jones. There was exhibited an excellent specimen of electrotype taken from an engraving of Byron, the original engraving was shown from which the electrotype was produced, the first is in relief, and for the purpose of taking off impressions, a second electrotype is obliged to be taken off from the first, which brings this last impression to the same appearance as the original plate; there were also shown two impressions, one taken from the original plate, and the other from the second electrotype, both of them were so much alike, that it was with difficulty any difference could be detected.—There was a fine representation in stained glass of Mary Queen of Scots and Knox, by Messrs. Hoadley and Oldfield.—In the model room was exhibited a beautiful set of 8 models of Mr. Brunel's block machinery at Portsmouth, showing the different operations the block passed through from the square block of wood to its completion.—Mr. Rennie's trapeziod paddle-wheel attracted considerable notice, likewise the beautiful models of Mr. Samuel Seaward's marine atmospheric steam-engines, also his slide valves by which the eduction valve is opened before the induction valve, thereby allowing a better and more rapid escape of the steam to the condenser, and producing a better vacuum; his brine detector which exhibits the quantity of salt with which water in marine boilers is impregnated, is of great advantage to the engineer, by the aid of which he is enabled to judge the proper times it is necessary to *blow off*, for the purpose of cleansing the boilers of the salts which are deposited at the bottom, which if not attended to, very soon destroys the metal.—Another very ingenious model was that of Mr. Davison's refrigerator, lately constructed at Messrs. Truman's brewery, a vertical cylinder which contains several tubes, is filled with a stream of cold water, constantly flowing through it, which surrounds the tubes; there is also a blast of cold air forced through the interior of the tubes by the aid of a fan blower—the hot liquor is admitted into an open chamber on the top of the cylinder and allowed to gradually overflow the tubes which project above the bottom of the open chamber, and trickle down the interior side of the tubes, thus it is cooled by the combined operation of cold water coming in contact with the outside of the tubes, and the cold blast up the centre of their interior, by the time the hot liquor has arrived at the bottom, it is sufficiently cooled to be conveyed into the working tuns.—There was a model of Messrs. Maudslays and Field's double cylinder steam-engine, described in a late number of the Journal.—Mr. Milne's hydrostatic gas regulator, by the aid of which the lights are always kept at one height and intensity.—The patent omnibus, if we may judge correctly by the model, appears to be a cumbersome machine, and likely to monopolize the whole of the streets in the city, if many are to be introduced.—There were likewise several models of machines and apparatus connected with railways and steam navigation, by Mr. Curtis, Mr. Cottam, Mr. England, Mr. Greener, and others.—A very neat letter balance by Professor Willis attracted notice.—Some specimens of drawing paper made by Mr. Ranson's patent machinery were exhibited, by which drawing paper may be had in unlimited lengths and in any width up to 4 feet, and also of any degree of fineness or quality.—Mr. Bielefeld's Papier-Mâché ornaments, particularly a Corinthian capital, were objects worthy of notice.—Some specimens of bricks and tiles, made by Bakewell's press, showed the superiority of bricks made by this machine over those of the ordinary kind. Besides what we have already enumerated, there were objects of considerable interest distributed through all the rooms, not forgetting the beautiful models and drawings of works in progress under the directions of Mr. Walker in all parts of the kingdom.

We can truly say that we never saw a party more satisfied than the one of this evening, with the judicious combination of social and scientific arrangements, and the select, yet abundant materials for intellectual, as well as hospitable entertainment provided by the worthy President.

Among the numerous distinguished individuals present, we recognized Earl de Grey, the President of the Institute of British Architects, Lord Western, Lord Lowther, Lord Blayntyre, Sir Robert Peel, Sir Henry Parnel, Sir John Rennie, Sir Duncan M'Dougal, Sir John Rae Reid, Sir George Murray, Sir John Scott Lillie, Sir W. Pearson, Sir H. Ellis, Sir W. Burnett, Sir W. Riddell, Sir James Duke, Sir Hesketh Fleetwood, Sir John Barrow, Sir David Wilkie, Sir Peter Laurie, Mr. Hodges, M.P., Mr. Handley, M.P., Mr. Baines, M.P., Mr. Pease, M.P., Professor Willis, Mr. Babbage, Major Anderson, Col. Colby, Col. Paisley, Col. Thompson, Dr. Reid, Dr. Field, Dr. Roget, Sergeants Spankie and Adams, Mr. Barry, Mr. Tite, Mr. Hardwicke, Mr. Blore, Mr. Basevi, Mr. Donaldson, Mr. Fowler, Mr. Kendall, Mr. Stephanoff, Mr. Landseer, Mr. Stone, and a great number of architects, artists, and most of the members of the Institution of Civil Engineers.

NOTES OF THE MONTH.

The Royal Exchange competition has been decided in favour of Mr. Tite, so that we suppose the works will now go on. Mr. Cockerell his competitor is exhibiting a model of his design in the Old Jewry.—Mr. Barry, as if he were not satisfied with providing for the legislature, has now been engaged in making designs for the new Courts of Law, proposed to be erected in the square of Lincoln's Inn Fields, the expenses to be mainly defrayed from the Suitor's Fund. This plan has received the approbation of the lawyers, and will doubtless be carried into effect, giving the architect the opportunity of adding another colossal building to the architectural contributions of the Victoria era.—The area in Trafalgar-square is now a scene of activity, the footpath which connects the Strand with Cockspur-street, has been brought considerably nearer to the Whitehall side, thus adding a large space to the former enclosure, which we trust will be laid out so as to agree in character with the National Gallery, to which it might be made to give a greater appearance of elevation.—A diminished grant has been taken for the buildings of the British Museum, so that they must linger on in the old style.

In addition to the information which we conveyed last month about the Daguerreotype, we may mention that the attempt to produce permanent engravings so as to admit of impressions being taken, has perfectly succeeded.

Among the men of science, whose loss we have sustained may be mentioned Poisson, the eminent French mathematician, and Sir Robert Seppings.—Sir Robert was surveyor to the navy for nearly fifty years, during which time he was the means of introducing many improvements into the navy, worthy of his own invention, as the circular bow and stern, the system of diagonal bracing, of scarfing short pieces, of making frigate timber applicable to line of battle ships, and the use of the iron knees.—Mr. Whitwell, the architect of the unfortunate Brunswick Theatre, also died recently, but as we hope to attain some particulars respecting him, we shall defer any farther notice of his services.—We may mention among the professional losses, and as a very severe one, the unfortunate destruction of a great part of York Minster by fire, arising from carelessness. We feel pretty sure however that this national monument will be restored.

Durability of Iron Boats.—The question of the durability of iron vessels, of their little liability to accident, and of the ease with which damage done to them may be repaired, appears to be very clearly proved from the experience which has already been obtained on these points; and this is no little, for there are boats built by Mr. Laird in both North and South America—in all parts of India and on the Euphrates and the Indus—in Egypt, on the Nile—and in the Mediterranean—on the Vistula, on the Shannon, and on the Thames. One of these boats on the Savannah has been constantly at work for these last six years without any repair; which is a great test, if we consider the frequent constant caulkings required to preserve a timber-built ship. There is also a steam-yacht built of iron, the Glow-worm, the property of Asheton Smith, Esq. This vessel has made the passage from Bristol to Carnarvon, a distance of 210 miles, in 18 hours. In the report to the House of Commons on steam-vessel accidents, we find the following stated of the Garryowen, one of these vessels:—"We went ashore about two cables' length to the eastward of the pier (Kilrush), and struck very heavy for the first hour. The ground under our weather-bilge was rather soft clay, covered with shingle and loose stones, some of them pretty large. Under our inside, or lee-bilge, the ground was very hard, being a footpath at low water. I was greatly afraid she would be very much injured by it in her bottom, but I am happy to say she has not received any injury; in fact, her bottom is as perfect and as good as on the day she left Liverpool—not a single rivet started, nor a rivet-head flown off. If an oak vessel, with the cargo I had on deck, was to go on shore where the Garryowen did, and get such a hammering, they would have a different story to tell. * * Out of 27 vessels that got ashore that night, the Garryowen is the only one that is not damaged more or less." Colonel Chesney, the commander of the Euphrates expedition, writes thus of the iron vessels which were employed on that service:—"It is but right to tell you that the iron vessels constructed by you far exceeded my expectations, as well as those of the naval officers employed in the late expedition, who would one and all bear testimony anywhere to their extraordinary solidity; indeed, it was often repeated by Lieut. Cleveland, and the others, that any wooden vessel must have been destroyed before the service was one-half completed, whereas the Euphrates was as perfect when they laid her up at Bagdad as the first day she was floated.—*Mr. Cruise, United Service Journal for May.*

QUERIES.

A correspondent is desirous of having some comparison between Sneeze Wood, Right Yellow Wood and Els, and those in use with us, such as Fir, Oak, &c. The woods alluded to may be found in 3rd Vol. Royal Engineers, "Bridge across the River Kat." A. P.

STEAM NAVIGATION.

Oscillating Marine Engines.—This description of engine is daily becoming more generally known and adopted; their great advantage is the extreme lightness and the small space they occupy in a vessel; in both these important particulars the saving is nearly one-half. For vessels of limited draft or for shallow water, they must ultimately become in general use. During the last month we attended the trials of two new steam-vessels, fitted with oscillating engines manufactured by Messrs. Penn & Son, of Greenwich, who have devoted to this class of engine considerable attention, and have fitted up no less than 17 pairs of them; they have not been known to fail in a single instance, and are the admiration of all parties who have witnessed their performance, for the beauty of the workmanship, and the accuracy with which they work, particularly those on board the iron steamers plying on the River Thames above bridge. Messrs. Penn have always found this description of engine give a result fully equal to their dimensions, in comparison with others of the ordinary construction. The first vessel whose performance we witnessed last month was the *Courier*, an iron steamer, built by Messrs. Ditchburn & Mare, of Blackwall, intended to run on the Elbe between Hamburgh and Magdeburgh, 158 feet long at the water line, and 20 feet beam; draught of water, with engines, boilers filled with water, and 15 tons of coke, is only 19 inches in midships, and 14 inches at stem and stern. The engines have cylinders 34 inches diameter, with a 3 feet stroke, and make 27 strokes per minute, and are estimated at 32 horses power each. The weight of engines and boilers filled with water is 37 tons 15 cwt. The paddle-wheels are 15 feet diameter, with float-boards 8 feet long and 13¾ inches wide. The second vessel whose performance we witnessed was the *Queen Victoria*, a new timber-built vessel, constructed by Mr. Thompson, of Rotherhithe. She is 90 ft. long, 13 ft. 9 in. beam, and 2 ft. 9 in. draught of water, fitted with a pair of oscillating engines of 15 horses power each; the weight of the engines with boiler filled with water is only 15 tons, being 10 cwt. to the horse power; the total length of engine-room is 19 ft. 6 in. The speed of this vessel is very little inferior to the Gravesend boats, and is by far the fastest of her power ever produced. She ran the mile at Long Reach, with the tide, in 4 minutes and 50 seconds, and against the tide in 6 minutes 36 seconds, giving an average speed of 10¾ miles per hour. This boat is intended to run between Hungerford and Woolwich.

Race between the "Ruby" Gravesend steamer (oak built), and the "Orwell" and "Sons of the Thames" iron steamers.

SIR—As there has been of late much attention drawn to the subject of iron steam vessels, which are announced as possessing great advantage over those of wood, and as I have perceived various notices of the progress of different vessels of this class in your Journal, I shall feel obliged by your giving insertion to the following account of a run which took place on Saturday, May 2nd, between the Ruby, and two of the crack iron steamers.

I should premise that the Ruby has now commenced running for the fourth season, and that no vessel has yet been found that can compete with her. She is timber-built of English oak plank, upon the improved diagonal plan adopted by the Diamond and Woolwich Companies—a plan I have no hesitation in saying is stronger, more durable, and superior to that of any combination of iron whatever. She has never been caulked since the day she was launched, nor a farthing laid out in repairs, and her lines are as true as when they were first laid down on the shipwright's floor.

As the Ruby has been lying by some time to refit for the season, the owners of the two iron boats alluded to, took the opportunity of announcing their respective craft as the fastest vessels in the kingdom, but the Ruby has again taken her place as number one, and like a giant refreshed with sleep, goes better and faster than ever, and the victory she has achieved over the Orwell and Sons of the Thames will no doubt cause their respective partisans to alter their tone for the future.

Your's, &c. A. BILLINGS,
Manager of the Diamond Steam-boat Company.

Race between the "Ruby" and the "Orwell."—1st Trial. On Saturday, at 8 p. m., the Ruby got under weigh from Blackwall, and proceeded slowly down the river, to enable the Orwell to come up, as she was to start from London at eight o'clock. The Ruby went half speed down to Long Reach, no "Orwell" in sight, then tried the mile one hour after flood, spring tide, came back as far as the Halfway House, and discovered the Orwell coming down with plenty of smoke and steam; turned round the Ruby, and went on quarter speed till the Orwell was just four boats astern at Erith, off Cold Harbour Point. Set off full speed, with strong flood tide, two hours flood, (the reasen of placing the Ruby ahead was the fear of hugging, as both were near the shore). The Ruby's engines went off in fine style,—31 strokes, and she soon began to draw away perceptibly from the Orwell, (the Orwell's people at this time hoisted the jack at the main;) however, when off Purfleet the Ruby had gained a quarter of a mile upon the latter vessel, the jack was hauled down, and the Ruby, as the conqueror, hoisted hers, the Ruby gradually gained upon her antagonist, till she stopped at Gravesend Town Pier, when, by observations made, the Orwell was 1½ miles astern, and by time 8 minutes as she passed the Town Pier, thus beating the Orwell in a run of 14 miles about 1½ miles, the distance of four boats length to be deducted, which was the distance the Ruby was ahead when the race began. The Ruby ran the whole distance against a strong flood tide and ahead, in one hour and ten minutes, being seven minutes less time than the Orwell.

Second trial from Gravesend.—The Ruby having stopped ten minutes at Gravesend Town Pier, allowed the Orwell time to come up on the opposite shore and pass Tilbury Fort, when she again started for the chace, and by the time the Ruby had crossed the river against the strong flood in the stream, the Orwell was one mile ahead. The Ruby then ran on for forty-five minutes, in which time she caught the Orwell, and went right by her neck and neck, (you might have tossed a biscuit from one vessel to the other,) headed her by a quarter of a mile, turned round and was back to Gravesend in seventy minutes. In this second race she beat the Orwell one mile in 45 minutes: from the above it will appear that the Ruby, against tide, is full 1½ miles per hour faster than her antagonist.

Race with the "Sons of the Thames."—The Ruby waited at Gravesend till 4 o'clock, and then started up the river to meet the Sons of the Thames. The latter vessel and the Mercury left London at 5 p. m., and at 40 minutes past five they were both discerned at the bottom of Woolwich Reach, the Sons of the Thames full a quarter of a mile ahead of the Mercury. Some colliers being in the stream prevented the Ruby being turned round so soon as she ought to have been, so that when the vessel was got round with her head down, the Sons of the Thames was a quarter of a mile ahead, and the Mercury was just alongside, all three going full speed, and the tide running down strong. It was now evident by the Ruby drawing away from the Mercury, that she was gaining fast upon the Sons of the Thames, which vessel the Ruby came up to in 15 minutes, when the Sons of the Thames had a half minute stop, and the Ruby shot by her, and continued to gain upon her till the arrival at Gravesend Town Pier, when the Ruby was one mile ahead. It should be observed that at Greenhithe, the Sons of the Thames had another short stop, but as she was going all the time with the tide, both these stoppages could not have made more than one minute's difference. The whole distance was done by the Ruby, from the bottom of Woolwich Reach in 55 minutes.

General Remarks.—It is right to observe, that during the above races, the Orwell apparently had 100 persons on board, and the Sons of the Thame about 50, whilst the Ruby had none but her crew. To some this may appeas an advantage for the Ruby, but the advantage would have been more ir favour of the Ruby if she had had 200 persons on board, as her paddles would then have had more hold of the water, and the vessel would have consequently gone faster; as during the race the Ruby's engines were overrunning their speed for want of proper resistance to the wheels. The Ruby's best speed is when she has 300 persons on board; in proof of which, the Ruby started from Gravesend on Sunday night last, with 300 passengers on board, half an hour after the Sons of the Thames had left, and arrived at London Bridge within three minutes of the time that the latter reached there, the Ruby thus beating the Sons of the Thames 27 minutes in the whole distance, which was entirely against a strong ebb tide. A. B.

The "Elbe" Steamer.—The "Elbe" steamer, which arrived lately from Dunkirk, for the purpose of getting her machinery put on board by Mr. Borrie, of the Tay Foundry, made a trial trip, on Saturday 2nd ult., to prove the efficiency of her engines. She left the West Protection Wall at one o'clock p. m., with about sixty-five of Mr. Borrie's friends on board, for whom he had prepared ample cheer. She proceeded down the river,—rounded the Bell Rock,—run to the Buoy of Tay in fifty-five minutes, being a distance of 12 miles; and from the Bell Rock to the Harbour in two hours and a quarter—a distance of 24 miles—having the ebb tide against her in coming up the river. The vessel was built by Mr. Malo, of Dunkirk, and it was the general impression on board that both the builder and engineer had performed their parts well, and had, between them, furnished a very superior steamer—a fact of which, indeed, they were then witnessing the proofs. The engines (of 160 horse power) were much admired by several professional gentlemen on board for smoothness of action, their elegant and substantial construction, and high finish. The "Elbe" is about 500 tons burden, and belongs to the Dunkirk and Hamburgh Steam Navigation Company. She will shortly join "The Nord"—(fitted out in the early part of last season by Mr. Borrie)—on the Dunkirk and Hamburgh station.—The great increase in the trade of building and fitting up steam ships at Dundee, has rendered the starting of marine engines, at one time a rare, now a very common occurrence amongst us; and —not unmindful of the merits of Mr. Borrie's brother engineers in this place —we have much pleasure in stating that both they and he, from their profound knowledge, great experience, and integrity in fulfilling their engagements in the best and most satisfactory manner, do honour to their profession and to Dundee. On the present occasion, we are specially glad to bear testimony to the steady advancement of Mr. Borrie's well-earned reputation in every department of engineering; and to notice the gratifying fact, that his eminence as a marine engineer has now attracted the attention of Government. The great crane, erected by Mr. Borrie last season, according to the designs of James Leslie, Esq., engineer of the harbour, affords, in connection with our spacious docks, facilities equal, if not superior, to any in Great Britain, for the fitting up of the largest class steamers; and we are happy to learn that Mr. Borrie will, in all probability, be the first to profit by his own labours and enterprise at the port of Dundee.—*Dundee Chronicle.*

TRANSATLANTIC STEAMERS.

Comparison of the passages of the four lines of Sailing Packet Ships between Liverpool and New York, with those of the Transatlantic Steam Ships, during the year 1839.

Sailing Ships.	Longest Outward.	Shortest Outward.	Average Outward.	Longest Homeward.	Shortest Homeward.	Average Homeward.
	Days.	Days.	Days.	Days.	Days.	Days.
Old or Black Ball Line ..	48 0	22 0	33 17	36 0	18 0	22 12
Dramatic Line	38 0	23 0	30 12	25 0	17 0	20 12
Star Line	45 0	27 0	36 0	28 0	21 0	24 0
Swallow-tail Line	45 0	28 0	35 0	31 0	17 0	22 12
Steam Ships.						
Great Western	21 12	13 0	16 12	15 0	12 6	13 9
British Queen	20 9	14 21	17 8	21 12	13 12	16 12
Liverpool	18 12	16 0	17 4	27 0	13 18	15 16
Average of all the Sailing Ships	44 0	25 0	34 $1\frac{1}{4}$	30 0	18 6	
Average of all the Steam Ships	20 3	14 15	17 0	21 4	13 4	15 $4\frac{1}{4}$
Difference in favour of the Steam Ships	23 21	10 9	17 $1\frac{1}{4}$	8 20	5 2	7 $13\frac{1}{4}$

The immense superiority, in point of speed, of the Steam Ships, will be fully evident on inspection of the above table; where the difference in the first instance is more than half; in the second almost three-fifths; in the third more than half; in the fourth more than a quarter; in the fifth near a third; and in the sixth more than a third.

It must, however, be borne in mind that the Transatlantic Steam Ships are yet in their infancy, whilst the sailing ships are perfection; there being no faster ships on the face of the globe than the New York and Liverpool Liners.

Steam Navigation in Germany.—Besides the generally good roads, steam-boats and railway lines are, of late, facilitating interior communication in most parts of Germany. Everybody in England knows the steam-boat communications on the Rhine, which for several years past have poured out a mighty stream of English travellers along the western parts of Germany and Switzerland. In the course of this summer, (1840,) the banks of the Elbe, Saxony, Bohemia, and the whole central part of Germany, will be as easily admissible to the tourist, as the banks of the Rhine have hitherto been. Perhaps a few words on this subject may prove acceptable to persons intending to take a trip or a journey to countries comparatively not so generally known. From London or Hull to Hamburgh steam-boats are regularly running several times every week. Hamburgh is situated about eighty miles inland, on the navigable Elbe. From Hamburgh to Magdeburgh, the journey is performed on board steam-boats, offering the best accommodations. The distance, by the river, is about 250 English miles. From Magdeburgh to Leipsic a railway is constructing; it will be opened in its whole length, in the early part of this summer: the journey—about seventy-four miles—will then be performed in three or four hours. From Leipsic to Dresden a railway has been in operation for more than a year: the distance—seventy-one miles and a quarter—is performed in about $3\frac{1}{2}$ hours. From Dresden another line of steam-boats run, about fifty miles, as far as Tetschen, in Bohemia, where you find yourself at a few hours' journey from Prague and Toplitz, as well as in the vicinity of Carlsbad, Frezonsbad, and the other celebrated and fashionable Bohemian watering places, which may all all now be reached without any fatigue, or any great expense, five days after embarking from England. From Prague to Brün the distance is about sixty miles, where the traveller will find excellent public coaches, or can take for private use, at any time and at moderate prices, stage coaches, kept always in readiness by all the post-administrations throughout the Austrian Empire, for the accommodation of families travelling without their own carriages. From Brün to Vienna, the journey—about eighty-five miles—is performed in four or five hours, by a railway which has been in operation for upwards of a year. From Vienna the steam-boats on the Danube run through Hungary to the Turkish frontiers, and the Black Sea, in communication with those plying to Constantinople, Odessa, Trebizonde, &c. In two months, when the whole Magdeburgh-Leipsic Railway is opened, a person may travel from England to Vienna, or to Constantinople by steam, with the exception of a distance of about eighty miles, comprising the two sections of road from Tetschen to Prague, and from Prague to Brün, where neither railway nor steam-boat conveyance is as yet established.—*Athenæum.*

PROGRESS OF RAILWAYS.

Bristol and Exeter Railway.—It is expected that a portion of the Bristol and Exeter Railway, as far as Bridgewater, will be opened in the course of the present year. We understand that the works are proceeding with great activity.—*Railway Times.*

BLACKWALL RAILWAY.

Considerable exertions are being made to open that part of the railway from the Minories to Blackwall on the 18th inst., the anniversary of the battle of Waterloo, when it is expected that his Grace the Duke of Wellington will be present; one line of railway is nearly completed from end to end, *the railway* is carried on a viaduct from the Minories to the West India Docks, thence it is continued on an embankment, until it immerges into a shallow cutting near the terminus at Brunswick Wharf, and terminates under a shed covered with an iron roof, similar to that of the terminus of the London and Birmingham Railway at Euston-square; adjoining the shed is a spacious building for the offices, of the Italian style of architecture, and forms a prominent feature from the river, it is erected from the designs of Mr. Tite the architect, President of the Architectural Society; the Blackwall terminus is most conveniently adapted for steam-boats, being situated on Brunswick Wharf, alongside which the largest class steamers can embark and disembark passengers at all times of the tide, and there are already 2 Gravesend steamers announced for starting from this spot as soon as the railway is opened, and no doubt many others will follow; it is more than probable, before another year passes over, all the steamers which now start from below bridge will make the Blackwall terminus the starting place, thereby avoiding the most dangerous part of the voyage through the Pool, and save in time about three quarters of an hour; by this means the Gravesend boats will be able to make two trips each way every day, and we have no doubt it will also be found the most advantageous route to Woolwich, which can be done by railway, and steamers across the river within three quarters of an hour from the Minories to Woolwich.

To afford every facility for the conveyance of passengers, two classes of carriages have been provided, part of which are already delivered; the first class are enclosed, painted blue, finished very tastefully, and emblazoned with the Arms of the City, and the East and West India Dock Companies, at the same time there is no superfluous ornament or extravagance about them—the second class carriages are open at the sides, and are not provided with seats; the passengers will be obliged to stand during the short time that they are being conveyed, which it is expected will be in about nine or ten minutes; it is stated that the fares will be very trifling, for the first class carriages 6*d.*, and the second class 4*d.*

The breadth of the viaduct on the top is 24 feet in clear of the coping stone or cornice, and 28 feet out and out. The arches on the top are covered with asphalte to prevent the percolation of wet through the brickwork. The rails are light in consequence of being relieved of the heavy locomotive, the form is T shaped, and 5 inches deep, they are laid to a 5 feet 1 inch gauge, on transverse sleepers of English fir, 3 feet apart, upon which the chairs are spiked—the rail is secured to the chair in rather a novel manner, a hole is pierced through one of the arms of the chair at right angles to the rail, in which an iron ball about the size of a bullet is dropped and rests against the rail, an iron key or wedge is then driven through an aperture in the same arm of the chair parallel to the rail, which fixes and presses the ball firmly against the latter, this method of fixing prevents any lateral vibration of the rail, and at the same time it allows the free expansion and contraction of the metal. Down the centre of each railway are fixed the pulleys upon which the tail ropes will traverse, placed 30 feet apart; they are 30 inches diameter, and 8 inches wide across the sheave, the rim is lined with rope matting to prevent any noise from the rapid motion of the rope passing over them; the axles turn upon plummer blocks fixed on an iron curb, and over each bearing is a small box for grease to lubricate the axles; the pulleys are fixed vertically throughout the line, both in the straight part and the curves, for the latter they are of a different shape to the others, being 30 inches diameter on one side, and 36 inches on the other; the rim is formed like the outside of the mouth of a large bell.—In the last month's *Journal*, p. 178, is described how the railway is to be worked, by what is technically termed tail ropes, that is, a rope at each terminus is attached to the carriages, and as the rope is coiled up at one end of the railway by the aid of steam-engines, it draws the carriages, and at the same time the rope at the other end is being unwound, thus by the time the forward rope, with the carriage, is wound up at the station at Blackwall, the rope of the station at the Minories is unwound, it is then ready to draw the carriages from the Blackwall terminus back to the Minories. For this purpose there are four of these ropes, two to each line—they are each $3\frac{1}{2}$ miles long, and $5\frac{3}{4}$ inches diameter, and are worked by two pairs of marine engines at each end of the line, those at the Blackwall terminus are 70 horses power each engine, manufactured by Mr. Barnes, and at the Minories station each engine is 112 horses power, manufactured by Messrs. Maudslays and Field, the latter are of greater power than the former, in consequence of the railway being principally upon the ascent from Blackwall to the Minories; each rope is worked by one pair of engines, the power is tranferred from the engines by means of spur wheels which turn an immense wheel or iron pulley 14 feet diameter in the clear, and 22 feet out and out, and 3 ft. 6 in. wide on the outer circumference, and about 21 inches at the inner circumference,—round this wheel is coiled the rope just described. The engines at the Minories station have each a marine boiler of large dimensions; and those of Blackwall, one pair have three Cornish oval boilers, and the other pair two marine boilers. The engine house at Blackwall is on a level with the railway, and at the Minories it is below the railway, under the arches. The whole of the works do considerable credit to the respective contractors, and to the indefatigable zeal of the engineers, Mr. George Stephenson and Mr. Bidder.

The North Midland Railway.

The North Midland Railway, which forms a communication between Leeds and Derby, was partially opened for traffic on Monday, 11th ult. On Saturday morning, preparatory to that opening, the Directors took a trip along the line, starting from Derby, and traversing to about within eleven miles from the terminus at Leeds. But, although the line is in a condition to be traversed from Derby to the immediate neighbourhood of Wakefield, the portion open to the public extends only from Derby to Rotherham, a distance of about 40 miles, giving, by means of the Sheffield and Rotherham Railway, an uninterrupted railway communication from Sheffield to Derby; from thence by the Midland Counties Railway to Nottingham and Leicester; and by the Birmingham and Derby Railway, to Birmingham and London.

The railway station at Derby is a wonderfully extensive place, which astonishes every person on arriving there for the first time. The length of buildings and covered way now erecting extend, we believe, 1050 feet. So stupendous and magnificent does every thing appear, that imagination almost leads passengers to suppose they are arrived at a market-place for steam engines. The buildings comprise a handsome hall, offices, refreshment and waiting rooms, with requisite conveniences, 230 feet long, 3 stories high, with a façade wall extending each way 110 feet, with openings for the departure of passengers on their arrival. The platform the whole length is formed by large Yorkshire stone landings of a superior quality. The passengers' shed extends the whole length of the walls and buildings, which is covered by a light iron roof of 42 feet span. The centre part of the passengers' shed is 56 feet span, and one bay 42 feet, are also covered, in the whole about 450 feet in length, and supported by handsome iron columns, 22 feet high from the top of the rails.

The arrangements for the lines of rails with the requisite number of turntables are on an extensive scale, and appear to be well adapted for the traffic and depôt for the Company's carriages.

In addition to these buildings there is an engine-house with 16 sides, 134 feet across, with a conical roof and lanthern rising to 54 feet above the floor from the top of the columns, which are 18 feet high; this building is approached by two wings 48 feet long, over which will be a reservoir of water for the supply of the engines, &c.

The preparations for the repairs of the Company's engines and carriages bear the same proportion, the shops averaging 160 feet long each, by 70 feet wide, three stories high, and smith's furnaces to each in connexion with other buildings.

When the extensive nature of these works is considered, and that they have only been 9 months in hand, the greatest praise is due to Mr. Jackson, the contractor, for the despatch employed, and the stability and beauty of these structures, which, in connexion with the other stations on the line, reflect the greatest credit on the taste and skill of Mr. Thompson, the Company's architect.—*Abridged from the Derby Reporter.*

Cheltenham and Great Western Union Railway. Engineer's Report, read at the last Half-Yearly Meeting on the 30th April.

Gentlemen—Notwithstanding the many causes of delay which have arisen, all the principal works between the Lansdowne Bridge, at Cheltenham, and the proposed station at Gloucester, have been completed. Two bridges, which are three-quarters finished, and about 20,000 yards of earthwork for the approaches to one of these, namely, the Badgeworth Road Bridge, together with the trimming and soiling of slopes at several places, are all that now remains to be done to complete the whole of this portion of the line, preparatory to the laying the ballast and the permanent way.

The excavation for the junction between the Birmingham and Gloucester Company's station at Cheltenham and the main line at Lansdowne Bridge, has been commenced, and upwards of 49,000 yards of ballast are prepared and set aside.

The cuttings and embankments upon this district, although consisting principally of clay, have not suffered much during the late wet season, and there is now every appearance of the works standing well.

The five permanent shafts of the Saperton Tunnel, referred to in the last Report, have been completed; the sixth, which will be the least in depth, and in other respects the easiest in construction, has not been commenced, in consequence of the taking possession of any land, at that part, involving, by the arrangements with the proprietor, the previous purchase of the whole of the land required for the works generally in the same parish, and which expense you deemed it unnecessary at present to incur.

Between Cirencester and the junction with the Great Western Railway at Swindon, the works have, generally speaking, been actively proceeded with during the last half-year.

Of the masonry of bridges and culverts, which is of course principally summer work, upwards of 3000 yards have been executed, and 7,500 remain unfinished, independently of the covered way, which contains about 5,500 yards, and which is just commenced.

Of the 900,000 yards of earthwork, which, as was stated at the last meeting, then remained to be moved, 400,000 have been excavated, and formed into embankment; and there remain, consequently, 500,000 only, to complete the work.

Upon the whole extent of the works in this district, both the cuttings and embankments have stood remarkably well; the few and slight symptoms of slipping, which occurred on one single part only, have been entirely remedied, and the slopes are now in excellent condition.

Although the average performance, however, has thus, upon a total distance of 17 miles, been such as would, calculating at the same rate, and allowing but moderately for the great advantages of the summer season, ensure the completion of the whole during the next five or six months, this average rate has not been equally maintained upon all the contracts.

The works of the Cirencester branch to Kemble are in a forward state, and might easily be finished during the next August; and the contractor for that part of the line extending from the Great Western Railway to the Red Lion at Minety, a distance of upwards of nine miles, would be able to complete the work, including the laying of the permanent way, by the month of September. An embankment of about 160,000 yards, contract, No. 2, is the principal work to be executed on the remainder of the line; and if very great exertions were used, there can be little doubt that the whole might be brought into profitable work with the commencement of the year 1841, or even by the end of the present year: while, in the mean time, the nine miles before referred to, forming part of a continuous line in conjunction with the Great Western Railway, might be brought into operation at a still earlier period.

The prospect of the early opening of the Great Western Railway, up to Swindon, which may be expected during the latter end of the present year, and the great state of forwardness of several miles at that extremity of your line, would render a successful effort highly valuable. These exertions would, of course, necessarily demand a proportionably rapid expenditure of the capital of the Company—an expenditure, however, which would be unquestionably economical in the end. I am, Gentlemen, your's obediently,

I. K. Brunel, Engineer.

Great Western Railway.—The works in the neighbourhood of Bath are proceeding with very great activity. The foundation of the pier in the centre of the Avon, near the Old Bridge, having been properly laid, operations have been commenced on the Widcombe side of the water. In the Ham gardens the erection of the arches on which the Bath depôt will be situated, is being rapidly proceeded with; whilst some steps have been taken towards erecting the viaduct across the Dolemead and Pulteney road. The tunnel at the top of Raby-place is likewise being finished in a very rapid manner. Towards Hampton the works are of a heavy character, and the utmost despatch is, therefore, observable in that quarter. The workmen have made great progress in the necessary excavations for turning the course of the canal immediately opposite the Cleveland Baths. The embankments for the permanent way are here in a forward state; while, near Hampton church, and in the meadows beyond, the contractors have been very active, and operations have been commenced throughout the extent of the line to Bathford. Altogether, there seems no reason why the line between Bath and Bristol should not be opened towards the close of this summer; and we hear that the Bristol directors have been taking measures which, it is hoped, will secure the opening of their division, and consequently of the entire line, in the middle of next year.—*Wilts Independent.* The opening of the extended line to Steventon, a distance of 52 miles from London, is announced to take place on the 1st of next month. We are happy to find that there is every probability of this grand undertaking being opened between Bristol and Bath early in September. The permanent way has been laid down in the neighbourhood of Keynsham to a considerable extent, and the locomotive engine is at work. Between Keynsham and Bristol the road is all formed, and except finishing off the head of No. 3 tunnel, is in a perfect state. The beautiful elliptic Gothic-arched bridge across the Avon, near the station, is completed, and presents a most splendid appearance. The work does infinite credit to the contractors, Messrs. Wilcox and Son.—*Bristol Mirror.*

Preston and Wyre Railway.—This line of railway, it is expected, will be opened to the public on the 1st or 2nd of July next—the North Union Company finding locomotive power and carriages. Above 1,000 men are engaged in the various works in progress at Fleetwood, among which may be mentioned an hotel, intended to be one of the finest buildings of the kind in the kingdom. A quay of considerable length, the foundation of which rests on iron piles, is also in progress. A light-house, on Mitchell's patent screw principle, has been erected on the end of a sand bank, about two miles out to sea, and will be lighted in the course of next month. The house and lantern stand from 60 to 70 feet high. Captain Denham, R.N., has been for some time busily engaged taking bearings for two other light-houses, which are intended shortly to be commenced. It is intended so to lower the bar, by dredging, that there shall never be less than 12 feet water at low water high spring tides, from the sea direct into the harbour, which can readily be effected. The town of Fleetwood has been tastefully laid out by Decimus Burton, Esq., of London, and a considerable number of houses are in progress.—*Lancaster Guardian.*

Birmingham and Gloucester Railway.—We can now confidently state that the Birmingham and Gloucester Railway will be opened on or before the 1st of July next, from Barnt Green, eleven miles from this town, to Cheltenham. Conveyances will be furnished by the company to perform the intermediate distance, and by the end of the year it is fully calculated that the whole line will be completed, and opened to the public from Birmingham to Cheltenham. —*Midland Counties Herald.*

Northern and Eastern Railway.—A correspondent informs us that the opening of the first portion of the Northern and Eastern Railway will take place at least two months sooner than was anticipated—namely, in August next. We learn from other quarters, that the greatest energy is displayed in the prosecution of the works.—*Ibid.*

Manchester and Birmingham Railway.—The exertions of the various contractors, on this line of railway, at the temporary Manchester terminus, in Travis-street, London-road, have, for the last four or five weeks, been quite astonishing. Since the 1st of April, no fewer than six more arches, of thirty-three feet span, have been completed, besides another skew bridge. The magnitude, or rather the extent of the work, may in some measure be estimated, when it is stated that the arches and bridge have consumed nearly seven millions of bricks. The immense scaffolding or centering, rendered necessary for the erection of the iron skew bridge, which has so justly attracted public notice, has this week been removed, and this noble mechanical structure, which has certainly not its equal in the kingdom—perhaps not in the world, may now be seen to the best possible advantage. Mr. Buck, the company's engineer, has, it is said, the rare merit of designing this extraordinary work of art. The permanent rails are now in the course of being laid; the mode of doing which presents to the eye of the scientific man a degree of firmness and probable durability not perhaps equalled, or even nearly approached, by any other railway line in the kingdom. The rails, remarkably heavy, are fifteen feet in length, and laid on longitudinal pieces of Kyanised timber, the scantling of which is twelve inches by six inches. There are besides transverse pieces, also Kyanised, ten inches by five inches, and screwed to the longitudinal ones every three feet, so that it may with safety be pronounced impossible that the rails, when once truly and firmly fixed in their chairs, can ever afterwards be other than completely parallel to each other; a circumstance that cannot fail to give a motion to the carriages so thoroughly easy and agreeable, as to bid defiance to all attempts at improvements on the plan. When the arches, now 110 in number, are extended to the intended permanent station, Piccadilly, near the Infirmary, the entire length of the viaduct on brick arches will exceed two miles: and the quantity of timber that will be consumed in laying the rails for this length only, will exceed 20,000 cubic feet. It is intended to open the railway, as far as Stockport, on the 29th May.—*Manchester Chronicle.*

Lancaster and Preston Junction Railway.—This railway will be opened for the conveyance of passengers, and of traffic, on Whit-Monday. The works proceed at the Lancaster terminus with considerable activity. A single line of rails has been laid down as far as Galgate, and during the past week a number of men have been despatched to the contract of Messrs. M'Mahon, which, it is rumoured, the Directors intend to take into their own hands, in order to ensure the completion by the 6th of next month, which otherwise is more than problematical.—*Railway Times.*

Paris and Rouen Railway.—The contract entered into between the Southampton Railroad Company and that between Paris and Rouen has been signed, and the works will be commenced immediately. The present railroad from St. Germain will form the nucleus, and from the same point it is imagined the railroad to Belgium might be commenced, and hence that goods could be forwarded directly from Rouen to Brussels, without having to pass through the French capital.—*Globe.*

Glasgow and Ayr Railway.—The most active exertions are making along the line in order to effect the completion of the whole line by the end of July. Betwixt Kilwinning and Dalry the cutting and embanking is carried on during the night as well as the day; and the contractor of this lot, hitherto in the most backward state, is proceeding with the greatest vigour and success. Considerable progress has been made in overcoming the difficulties of the so called bottomless meadow, which has required so much deposit in the embanking. The most formidable part of it yet remaining extends to about three hundred yards; and it is singular to observe that as the earth is poured on the embankment, the surface on both sides is heaved up to a considerab e extent. As the workmen proceed, they find each new piece of embankment to sink during the night, which depression they have to restore by fresh portions of surface material. Having once surmounted this obstacle, their task will be comparatively easy, as the embankment at this part of the line is only three feet. The meadow which lies betwixt Kilbirnie and Lochwinnoch Lochs, is supposed to have been at one time also covered with water, but it was not considered to have retained so much moisture as to cause such extra labour to make it properly *terra firma*, otherwise some change would have been made on the line, by which it might have been avoided. The lodging-houses in Kilwinning, Dalry, and Beith, are crowded with labourers employed on the railway, whose expenditure must be felt in a considerable degree by those villages. The iron-works at Dalry are in the progress of building, and appear to be on a very extensive scale.—*Glasgow Courier.*

ENGINEERING WORKS.

The Royal George.—Col. Pasley began his proceedings for the removal of the wreck of the Royal George on the 1st of last month, but up to the 12th nothing very remarkable was effected. Two guns, the rudder, and a considerable quantity of timber, were recovered; but as these were merely the fragments of last year's work which the inclemency of the season prevented the engineers from picking up, no serious measures were deemed necessary till Tuesday, 12 ultimo. At eight o'clock in the morning, the red flags at Spithead announced that a great explosion was to be attempted; and at eleven one of those huge cylinders which have formerly been described, filled with 2116 lb. of gunpowder, was lowered to the bottom. One of Col. Pasley's divers (George Hall) who has acquired great expertness in these operations, descended his rope-ladder a little in advance of the cylinder, and succeeded in fixing it securely to one of the lower gudgeons or braces on the rudder-post, within six or eight feet of the keel. The diver having remounted, and the vessels being withdrawn to a safe distance, the enormous charge was ignited by means of the voltaic apparatus. Within less than two seconds after the shock was felt, the sea rose over the spot to the height of about 15 feet, or not quite half so high as it did on occasion of the great explosions last year—a difference ascribable, probably, to the cylinder on the present occasion having been placed under the hull instead of alongside it. The commotion in the water, however, was so great as to cause the lumps and lighters to pitch and roll at a great rate. The whole surface of the sea for several hundred yards round was presently covered with dead fish and small fragments of the cylinder. Amongst these were innumerable tallow candles, and a mass of butter a foot and a half in length, evidently driven up from the purser's store-room. As soon as the vast commotion in the water had subsided, and the boats had returned from the universal scramble for the candles and dead fish, the diver proceeded again to the bottom, and soon reported that the whole stern of the ship had been driven to pieces, and that, so far as he could ascertain, there was now a free and wide channel directly fore and aft the ship, from stem to stern, through which both the flood and ebb tides will rush, and thus the mud with which the hull of the Royal George has been silted for half a century, will be washed out, and the way cleared for Col. Pasley's further operations.

Staffordshire and Worcestershire Canal Company.—This company, having purchased of the Moat Colliery Company the unexpired term of their lease of the river Sowe, up to this town, have this week employed no less than 150 men in improving and making navigable for heavily laden vessels, that part of it between this town and Radford Bridge. The work has been actively proceeded with, the bed of the river being lowered in some parts about two feet, widened or narrowed as required, and thoroughly cleansed. This improvement has been effected with the view of opening a market for Lord Hatherton's and other collieries at Church Bridge, near Cannock, to which place a branch from the canal is in progress, at an estimated expense of £20,000. It is expected that the branch will be completed by the end of the present summer; so that the inhabitants of this town may reasonably expect both a cheaper and better supply of the necessary article of fuel.—*Staffordshire Gazette.*

Portsmouth Dockyard.—A Board of Admiralty, consisting of Earl Minto and Sir W. Parker, lately visited the port. Several material points have called their Lordships' attention to this neighbourhood: in the first place, the floating bridge approaches required their inspection, in which they were assisted by their engineer, Captain Brandreth; and we have no doubt that all matters in dispute will be satisfactorily arranged for the company, and advantageously for the public. We have reason to think that Mr. Lindegren's projecting premises will be purchased and thrown open, by which means upwards of 60 feet of high water beach will be available to the watermen; care, however, should be taken that the new beach be properly formed, for, as the situation is removed from the operation of the tidal influence on the shingle, nature will provide nothing but mud to land on, unless the engineer shall exercise his art and procure a more hardened substance.

NEW CHURCHES, &c

Dorsetshire.—The foundation stone of the new church at Ash was laid on Wednesday, 13th ult., by the Rev. R. Oakman, the vicar, in the presence of a very large company, comprising about 2,000 of the nobility, gentry, and yeomanry of the county.—*Dorset County Chronicle.*

Nottingham.—The beautiful church of St. Mary, which has justly excited so much admiration from antiquaries, has been completely restored, at an expense of 3,000*l.*, which sum was raised by subscription; and Mr T. Wright, of Upton-hall, has purchased and presented to the church a beautiful Crucifixion, by Fra Bartolomeo, and one of his finest works, as an altar-piece.—*Nottingham Herald.*

Essex.—North and south transepts are now in progress at the parish church of Messing, near Colchester, under the direction of John Burges Watson, Esq., of 39, Manchester-street, London. The style is early English; there is a beautiful eastern window in stained glass and of great antiquity, supposed to have been of Dutch origin, and is an object of attraction to visitors; it is also contemplated to have a new tower and spire, for which designs have been furnished.

Sisters of Mercy in Birmingham.—John Hardman, Esq., of Handsworth, has generously allotted to the use of this establishment, a piece of land opposite his own dwelling; and a convent is now in progress, from the designs of A. W. Pugin, Esq., the architect of St. Chad's Church. The conventual buildings will consist of chapel, cloister, community room, refectory, offices, and private chambers, or, as the are technically termed, cells; to which will be added a refectory, school-room, and suitable apartments for about thirty female orphan children. The plan of the building is based chiefly upon that of "Brown's Hospital" in Stamford; and, as Mr. Pugin studies propriety of destination in all his edifices, we have reason to know that the one in question will not only be ornamental and picturesque, but in every respect *conventual*—in fact, the only entire building, with purely conventual features, in the country.—*Midland Counties Herald.*

Staffordshire.—The new church of St. James', at Handsworth, was consecrated on the 22nd April last. It is built in the early Gothic style, with a tower of three stories at the west end, it contains 926 sittings, of which 518 are free. Mr. Richard Robinson of Wolverhampton, was the contractor, for the sum of £2,500,—and Robert Ebbels, Esq., the architect.

MISCELLANEA.

Artificial Asphalte.—The substitution of boiling coal tar instead of water, with crushed caustic lime and screened gravel or sharp sand, in the usual proportions for making concrete, forms an admirable asphalte, perhaps equal to the foreign asphalte. C. F. P.

Wood Pavement.—A considerable length of the Strand is now being paved with wood; the blocks are hexagonal, 9 inches deep, and 9 inches across at right angles to the sides; the upper edge is chamfered all round, to form a groove to prevent the horses from slipping. The wood is laid on a bed of broken granite, and to us it appears that the work is being done in a very clumsy and unsatisfactory manner.

Asphalte.—This material has been used in lining the reservoirs and tanks of the Southampton Railway, and found to answer very well; it has also been used for covering terraces—in some situations it has not been very successful, but in others it is perfectly water-proof. An additional length of the footway in Whitehall has been laid with this material.

Thames Tunnel.—The Company have obtained another Act of Parliament, which empowers them to purchase the property on the Middlesex side of the river necessary for the approaches; the works will now proceed with rapidity. The tunnel is completed to within 50 feet of the wharf at Wapping, and preparations are making to commence immediately the sinking of the shaft on the Middlesex side of the river. The formation of the new shaft, as well as the remaining portion of the tunnel, will be carried on at the same time, and it is expected that in about four months they will be completed. Not less than 150 workmen are at present engaged in finishing the interior of the western arch roadway, preparatory to its being opened, in the first instance, as a thoroughfare for foot passengers.

To consume the smoke from a boiler furnace.—Let the fresh coals be put into the furnace as near to the door as possible, and leave the door open for a space of two or three inches to allow cold air to enter, this will keep down the greater part of the smoke which will be consumed; the same may be applied to marine engines. This method will be found as efficacious as any patent that has yet been taken out. M.

Safety Valve to Steam Boilers.—At a meeting of the Society of Arts, on Wednesday, May 6th, the gold Isis medal was awarded to Mr. Robert M'Ewen, for a mercurial gauge which answers the double purpose of an indicator of steam-pressure and a safety-valve for engine boilers. The novelty of the invention consists in the employment of a mercurial tube as a safe-vent for the steam, these tubes having hitherto been used only as indicators of pressure, and of a length sufficient to allow the steam to acquire a dangerous degree of pressure, without giving any other notice of the fact than what may be observed by the eye. As the action of Mr. M'Ewen's safety-valve depends on a purely *physical* principle, viz., the opposition of the elastic force of steam to the static pressure of mercury without a *mechanical* obstruction of any kind, it affords a free vent for the steam when its pressure exceeds the limit, corresponding to the length to which the tubes are adjusted, according to the strength of the boiler.

India Coal.—Dr. Hutchison, of the Madras artillery, has drawn up a report on the coal-fields recently discovered in the vicinity of Mergui, by which it appears that this coal is easy of access, lying at no great depth beneath the surface, so that shafts may be sunk without difficulty. For its conveyance there seems to be every facility, the river being adjacent, and a land carriage of one mile only being required. It is not stated whether the quality of the coal has been tested by experiment, but we presume it to be the same of which Dr. Heifer spoke so highly in his communications. Steamers will begin to ply between the different ports in the bay of Bengal: and the immediate coal depôts between the Presidencies and Suez will be more plentifully supplied, and at a cheaper rate. The effect these circumstances will produce on the destinies of India can scarcely be estimated.—*East India Magazine.*

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 28TH APRIL TO 23RD MAY, 1840.

William Crane Wilkins, of Long Acre, Lamp Manufacturer, and Matthew Samuel Kendrick, of the same place, Lamp Maker, for "*certain improvements in lighting and in lamps.*"—Sealed April 28; six months for enrolment.

John Inkson, of Ryder Street, Saint James', Gentleman, for "*improvements in apparatus for consuming gas for the purpose of light.*" Communicated by a foreigner residing abroad.—April 30; six months.

Orlando Jones, of the City Road, Accountant, for "*improvements in treating or operating on farinaceous matter to obtain starch and other products, and in manufacturing starch.*"—April 30; six months.

William Pierce, of James Place, Hoxton, Ironmonger, for "*improvements in the construction of locks and keys.*"—May 2; six months.

Arthur Wall, of Bermondsey, Surgeon, for "*a new composition for the prevention of corrosion in metals, and for other purposes.*"—May 2; six months.

Thomas Gadd Matthews, of Bristol, Merchant, and Robert Leonard, of the same place, Merchant, for "*certain improvements in machinery or apparatus for sawing, rasping, or dividing dye, woods, or tanners' bark.*"—May 5; six months.

William Newton, of Chancery Lane, Patent Agent, for "*an improved apparatus and process for producing sculptured forms, figures, or devices in marble, and other hard substances.*" Communicated by a foreigner residing abroad.—May 5; six months.

George Mackay, of Mark Lane, Ship Broker, for "*certain improvements in rotatory engines.*" Communicated by a foreigner residing abroad.—May 5; six months.

William Beetson, of Brick Lane, Old Street, Brass Founder, for "*improvements in stuffing-boxes applicable to water-closets, pumps, and cocks.*"—May 5; six months.

Frank Hills, of Deptford, Kent, Manufacturing Chemist, for "*certain improvements in the construction of steam-boilers and engines, and of locomotive carriages.*"—May 5; six months.

Bernard Aube, of Coleman Street Buildings, Gentleman, for "*improvements in the preparation of wool for the manufacturer of woollen and other stuffs.*"—May 7; six months.

Thomas Walker, of Galashiels, in the county of Selkirk, Mechanic, for "*improvements in apparatus applicable to feeding machinery employed in carding, scribbling, or teazing fibrous materials.*"—May 7; six months.

Henry Holland, of Darwin Street, Birmingham, Umbrella Furniture Maker, for "*improvements in the manufacture of umbrellas and parasols.*"—May 7; six months.

Henry Montague Grover, of Boveney, Buckinghamshire, Clerk, for "*an improved method of retarding and stopping railway trains.*"—May 7; six months.

Miles Berry, of Chancery Lane, Patent Agent, for "*certain improvements in treating, refining, and purifying oils.*" Communicated by a foreigner residing abroad.—May 9; six months.

Auguste Moinan, of Philpot Terrace, Edgware Road, Clock Maker, for "*certain improvements in the construction of time-keepers.*"—May 9; six months.

Rice Harris, of Birmingham, Gentleman, for "*certain improvements in cylinders, plates, and blocks, used in printing and embossing.*"—May 12; six months.

George John Newberry, of Cripplegate Buildings, Manufacturer, for "*certain improvements in rendering silk, cotton, woollen, linen, and other fabrics, waterproof.*"—May 12; six months.

Henry Dircks, of Liverpool, Engineer, for "*certain improvements in the construction of locomotive steam-engines, and in wheels to be used on rail and other ways, parts of which improvements are applicable to steam-engines generally.*"—May 12; six months.

John Davidson, of Leith Walk, Edinburgh, for "*an improvement in the method of preserving salt.*"—May 12; six months.

Peter Bradshaw, of Dean, near Rimbolton, Bedford, Gentleman, for "*improvements in dibbling corn and seed.*"—May 12; six months.

James Walton, of Sowerby Bridge, Halifax, Cloth Dresser, for "*improvements in the manufacture of beds, mattresses, pillows, cushions, pads, and other articles of a similar nature, and in materials for packing.*"—May 12; six months.

Richard Foote, of Faversham, Kent, Watch Maker, for "*improvements in alarums.*"—May 12; six months.

John Joseph Mechi, of Leadenhall Street, Cutler, for "*an improved method of lighting buildings.*"—May 12; two months.

Bryan J'Anson Bromwich, of Clifton-on-Teme, Worcester, Gentleman, for "*improvements in stirrup-irons.*"—May 13; six months.

Henry Ernest, of Gordon Street, Middlesex, Gentleman, for "*certain improvements in the manufacture of machines, usually called beer-engines.*"—May 13; six months.

William Hannis Taylor, of Norfolk Street, Strand, Esquire, for "*certain improvements in the mode of forming or manufacturing staves, shingles, and laths, and the machinery used for that purpose.*"—May 20; six months.

William Bush, of Camberwell, Merchant, for "*improvements in fire-arms and in cartridges.*" Communicated by a foreigner residing abroad.—May 20; six months.

James Buchanan, of Glasgow, Merchant, for "*certain improvements in the machinery applicable to the preparing, twisting, and spinning, and also in the mode of preparing, twisting, and spinning, of hemp, flax, and other fibrous substances, and certain improvements in the mode of applying tar or other preservative to rope and other yarns.*"—May 22; six months.

James Callard Davies, of College Place, Camden Town, Jeweller, for "*an improved clock or time-piece.*"—May 23; six months.

TO CORRESPONDENTS.

If W. B. *will favour us with the particulars of the addition to Thorney Abbey, we will insert them next month.*

S. P.'s *method of constructing a Bridge is impracticable, it is like building castles in the air, his communication will be left at our office.*

We thank Mr. Plank *for his correction, it will be forwarded to the author of the paper.*

Mr. Phillip's *communication is unavoidably postponed, together with some others.*

"Amicus" *is not aware of the difficulties and delays in getting the reports he mentions, we have inserted some in the present Journal.*

"*Report on the plans for preventing accidents on board of steam vessels,*" *we had intended to have given this month, but in consequence of an over pressure of matter, we are compelled to postpone it for the next Journal.*

We are obliged to Capt. P. *for his communication, the extracts from Palladio we have not inserted, as the work is accessible to most architects—his other paper explaining how increased buoyancy might be obtained by filling the sides of vessels with gas in reservoirs, we think is impracticable, as the weight of the reservoirs containing the gas and the increased ballast at the bottom of the vessel, will more than counterbalance the buoyancy of the gas.*

The communication from Mr. Nicholson's reply to Mr. Buck, &c., was received too late in the month for the present Journal, we will not fail inserting it next month.

Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," *No. 11, Parliament Street, Westminster.*

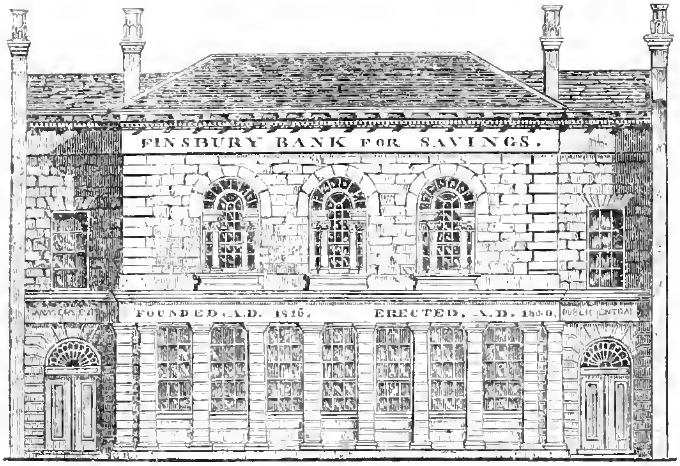
Books for review must be sent early in the month, communications on or before the 20th (if with wood-cuts, earlier), and advertisements on or before the 25th instant.

The First Volume may be had, bound in cloth and lettered in gold, Price 17*s*.

*** The Second Volume may also be had, Price 20*s*.

FINSBURY SAVINGS' BANK.

ARCHITECT, ALFRED BARTHOLOMEW.



THE sum allowed for the erection of this building was only £2850, which, taking into consideration its size, is not 50 per cent. upon the ratio of cost of any other of the savings' banks of the metropolis; the consequence is, that it is neither built externally of the materials, nor finished internally in the style, which the architect of it desired: a previous design was prepared by him for a larger and superior building, to be finished externally with Portland stone, internally fitted up in a handsome manner, and with the novelty of an entire fire-proof construction, the particulars of which are to be found in Mr. Bartholomew's "Specifications for Practical Architecture," just published. The absolute tender for the difference between external stucco and Portland stone (the frontage remaining the same), was less than 5 per cent. upon the cost of the original design, and less than 7 per cent. upon the reduced one; and the fire-proof construction added only about 6 per cent. to the cost.

The frontage of the building extends 72 feet, and consists of a range of seven large windows, for the admission of a great body of light to the offices, between ten rusticated pilasters, 13 ft. 6 in. high, which are diminished. They are surmounted by an entablature; above is a range of three Palladian windows (lighting a board-room), flanked by long rustic quoins, and surmounted by a fascia and a bold cornice, from the outer edge of which commences the slope of the roof, which has a sunk or concealed gutter. At the sides of the pilastrade before mentioned, are rusticated wings, containing the entrances, each 6 feet wide, above which the building retires, so as to detach it from the adjoining houses. All the fascias are made very broad, for the purpose of receiving inscriptions to be visible at a considerable distance.

The interior of the building, which is totally destitute of every description of decoration, contains a public office 30 feet long, three private offices, a strong-room, a depositors' waiting-hall 44 feet long, two entrance halls, each 11 feet 8 inches by 20 feet, a board-room 30 feet by 14 feet, two staircases, and besides these thirteen domestic apartments, most of which are concealed from view in order to avoid as much as possible the meanness of many small external windows.

All the proportions of this building have suffered from retrenchment, and it is thus rendered in dimension, having regard to its business, twice as large as any similar establishment.

The external cornices and chimneys are not yet finished.

The sum allowed for this building was so restricted, that the architect chose to be at some part of the expense of the external decorations of it, rather than suffer it to undergo farther mutilation.

ON THE PRESENT STATE OF THE ART OF GLASS PAINTING IN ENGLAND AND FRANCE, AND ON THE NECESSITY FOR EFFORTS IN ITS FAVOUR.

BY GEORGE GODWIN, JUN., F.R.S. & S.A.*

THE extraordinary degree of apathy universally manifested with regard to the well-being and progress of an art, the admirable results of which throughout a period of at least five or six hundred years are scattered over the whole of Europe, is so much to be lamented, and calls so loudly for exertion on the part of those who feel its importance, that I am induced to raise earnestly a feeble voice in its behalf. And I do this without any fear of the imputation of vanity or self-confidence, and with a strong hope that however weak the advocate, some good may be effected by the effort. Many men with earnest wishes and strong inward promptings, avoid speaking out simply through feelings of their own want of importance and dread lest interference on their part may be construed into presumption, or at the best be entirely disregarded. This I am disposed to think is an evil and should be combatted, experience showing that a word uttered in due season, however humble and weak the utterer, may, and often does, have effects which could not possibly have been calculated upon: and further, that an individual, however unimportant who with strong conviction iterates, and reiterates the necessity of a certain step will be sure of finding a response in the public mind, provided his statement be founded in truth, and sooner or later will most probably effect his purpose. This introduction is a little too pompous for the very brief remarks which follow, but nevertheless perhaps, may not be deemed useless or impertinent.

To bring together and relate the circumstances attending the progress of the art of painting, and staining glass from the foundation of Constantinople, where it attained a certain degree of excellence, and whence, there seems reason to believe, it was brought to Rome, and afterwards by our Norman, if not our Saxon, ancestors to England, would be a pleasant task, but as all the facts are well known, the repetition might prove tiresome. In the 14th and 15th centuries the art reached great perfection in England, and ultimately became so popular that stained glass was not merely used for ecclesiastical purposes, but as an essential feature of decoration in domestic architecture. At the Reformation the onward progress of glass painting was checked, and many fine specimens of it were destroyed as evidences and encouragers of superstition. Further ravages were made in the reign of Charles I. and during the continuance of the Commonwealth; indeed it seems surprising, bent as the Puritans were upon its destruction, that so much yet remains,

> "Innumerable of stains and splendid dyes.
> As are the tiger-moths deep damask'd wings."

to prove its power in exciting holy emotions; "to add new lustre to religious light," and a further charm to the many inherent beauties of those numerous buildings in the pointed style of architecture scattered over England, of which we have just right to be proud.

Dallaway in the first edition of his "Observations on English Architecture,"† gives a valuable list of the various professors of the art of painting on glass, who practised in England from the period of the restoration of the reigning family up to the year 1805, when Francis Egington died,—a man of celebrity in the exercise of the art, who had been established near Birmingham.

A little time previous to this date, Charles Muss came to London to obtain employment as a colourer of prints. He lodged at the house of an individual who painted upon china for Messrs. Mortlock, and was induced by accident, on the death of his landlord, to undertake the completion of some work of this description which had been left unfinished. Succeeding in this he became a china painter, and ultimately a glass painter, and was employed in that capacity for many years by Mr. Collins of the Strand. He afterwards executed a number of works in his own name,—of which one of the finest that I know is a window in the church of St. Mary at Redriff. Muss had a number of pupils, some of whom are now practising: as for example Mr. Nixon and Mr. Hoadley. Backler, who painted the window at St. George's church in the Borough, was another of his scholars, as was also Mr. John Martin—since so deservedly celebrated in another branch of art; a man of whom it may be said, in a parenthesis, our age will boast hereafter.‡ A work in stained glass from his hands is, I believe, to be

* The substance of this paper was read at the Royal Institute of British Architects. June 1, 1840.

† London, 1806.

‡ "It is only when we are skeletons that we are boxed and ticketed, and prized and shown."—*W. S. Landor.*

found at Lord Listowel's, at Kensington. The peculiarity to be observed in paintings of the Muss school, (I think it may also be termed the *defect*,) is the great degree of opacity given to some of the colours; whereas in the best works of the artists of the middle ages all the colours are more or less translucent. Of all Muss's living pupils Mr. Nixon, of the firm of Ward and Nixon, has perhaps most entirely abandoned this peculiarity, and the result apparent in such of the works executed by this firm as I have examined, is of an exceedingly satisfactory nature.

The branch of glass painting now most encouraged appears to me, although of itself charming, a departure from the special character of this art. I allude to the imitation of oil paintings on single plates of glass, or of plates composed of very few large pieces,—such for example as the copy of "Belshazzar's Feast," and others of Martin's wonderful conceptions, which have been so well executed by Messrs. Hoadley and Oldfield.

Dallaway says that Thomas Jervais, who died in 1801, was the first who was distinguished for exquisitely finishing small subjects, since which time this department of the art has been much studied and has been brought to a point of great excellence. In productions of this sort a variety of colours are fused into the same piece of glass, and it becomes almost impossible to obtain with such certainty equal effects of colour, as when each tint is on a separate piece of glass, although this style has undoubtedly its own advantages. In the works of the earlier manner the colours are nearly always on separate pieces, the various morsels being united by leaden or copper bands, and shaded with brown. A hardness of outline resulted, and a great excellence in drawing was not easily attainable, but there is nevertheless about them a character peculiarly their own which should not willingly be lost in decorating ecclesiastical structures of the style of the middle ages. Of course we should not give up the power we possess through our improved mechanical skill, to avoid injurious joinings where this can be done without diminution of excellence in other respects; what I would simply express is, my conviction that to endeavour to make stained glass appear to be anything else than stained glass is not desirable.

An error, as it appears to me, is sometimes committed in placing copies of the later Italian masters in the windows of structures erected in the earlier pointed styles of art. Our improved taste has made us feel that to place an Italian altar-piece in a Gothic church is to violate propriety and destroy harmony. Why should the filling-in of the windows escape the general law that all portions of a building avowedly in imitation of the works of a particular period should be congruous. The windows ought unquestionably to accord with the building itself, both as regards their design and the technical peculiarities which mark the genuine works of the period imitated.

Mr. Willement, whose works are well known to all who have inquired into the subject, is justly celebrated for his imitations of the efforts of the earlier artists in stained glass, and of these no other example need be given than the principal window in St. Dunstan's church, Fleet-street, executed by him a few years since. This window was presented to the parish by the Messrs. Hoare.*

In France at this time the art of painting on glass is making satisfactory, although but gradual, advances. During the period of the first revolution the abhorrence of every thing connected with royalty which prevailed, led to the suppression of the government establishment for the manufacture of glass and china at Sèvres, and to the destruction of numerous fine specimens of its skill. While many glass windows were broken and melted down in the vain belief that as gold was employed in the preparation of some of the colours, it could be extracted and made available. Buonaparte sought to re-establish the manufactory on its former footing, but found that, although they possessed all the written details of the processes, France which had produced so many noble works in stained glass, and the most perfect existing history of its progress and manufacture, was unable then to furnish artists capable of regaining for the establishment any of its former reputation. The art however was still exercised, but so little progress was made that prior to the year 1825, the practice of it appears to have been confined to this royal establishment at Sèvres, fame, not profit, being the object aimed at, and even there great success does not seem to have attended their efforts, if we may judge from the following circumstance. A window of painted glass was completed at Sèvres in 1827, for the church of *Notre Dame de Lorette*, and when fixed, which did not occur until some years afterwards, in consequence of the building remaining unfinished, it was declared to be a *chef d'œuvre* of modern art. In less than eighteen months however, as I am informed by a correspondent, the colours had faded so considerably as to render the window a public monument of failure, and permission to take it down was in consequence applied for. The dampness of the building was the cause assigned for the mishap, but insomuch as the carcass had been erected many years, this could not have been very excessive: and whether so or not, this failure could not have occurred had the colours been properly fused into the glass. Want of effect in some of the works executed at Sèvres has been attributed to the employment without modification, of the same mode of operation as is successfully adopted for porcelain. The bases of the colours are the same for one as for the other; but glass, in consequence of its translucent nature, requires that the tints should be much more intense than it is necessary they should be for china, which is opaque.

We have said that, prior to 1825, the art of painting on glass was nearly confined to the establishment at Sèvres. In that year Monsieur le Comte de Chabrol, then Préfet of the Seine, entered into correspondence with Mr. Jones, a pupil of our countryman, Charles Muss, already mentioned, the result of which was that Mr. Jones went to Paris with the intention of forming a government establishment for painting upon and staining glass, in which pecuniary profit was to be regarded as a main consideration. Immediately on the arrival of Mr. Jones, M. de Chabrol was virulently attacked for affording encouragement to a foreigner "to the injury of native talent," and for four years the question was violently agitated without any result. At the end of that time, fatigued by the continued opposition to which he had been subjected, Mr. Jones abandoned the idea of a government establishment, and devoted his energies to forming and carrying on with success a private undertaking. He proposed to the proprietors of the glass works at Choisy le Roi, two leagues from Paris, to establish a department for staining and painting on glass, in conjunction with the other operations. They assented to his views, affairs were put *en train*, and success has attended the attempt. Nearly all the persons at present employed in it have been educated to it by Mr. Jones, and, in consequence, work well together, a circumstance which, in connexion with the opportunities he possesses for making experiments at small cost, and the comparatively trifling expence of the recipient in France, places stained and painted glass within the means of a much larger class of persons there than it is in England. Green, blue, or red glass, for example, may be bought in Paris for 1½ franc per foot, purple for 2 or 2½ francs, and ruby for 3 francs. Progress in the art of staining glass appears to have been greatly aided by M. Bontems, the director of the works at Choisy, who has devoted much time to the attainment of the ruby coloured glass of which such magnificent specimens are to be found in earlier works. I am informed he has succeeded, after repeated experiments, in obtaining it at a much cheaper rate than formerly by the use of oxide of copper instead of oxide of gold, and without any diminution of excellence. The experience of English glass stainers is opposed to this statement, as all ruby coloured glass prepared here from copper is inferior. I am not able, however, on this point to do more than repeat what I am told. M. Bontems has recently visited the costly establishments of the King of Bavaria at Munich, where, although he found, as he considered it, an inferiority on the whole, he gained much information. The princely magnificence of the King of Bavaria in all matters that relate to art, and the extraordinary results he has produced in his little capital, will serve to throw a halo round his name in the pages of future historians..

The establishment at Choisy possesses an advantage in the friendly co-operation of some artists of talent, not glass painters. In order to render a design effective on glass, such changes and alterations from the original picture are sometimes necessary, as would be entirely objected to by painters nervously careful of their fame, so that it is sometimes difficult to find artists of ability willing to exert their talents for the purposes of glass-painting, as they must be subservient in a certain degree to him who has the execution of the work, and on whom of course depends the effect to be produced. The last works exhibited in Paris by the Choisy establishment were designed by M. Adolphe Fries, a warm friend of the undertaking, and obtained much commendation. It is hardly necessary to say that since the successful issue of the experiment at Choisy le Roi, attempts have been made to form other similar establishments, but, being ill conducted, have, for the most part, failed. Men were even seduced from Choisy by golden promises to aid the undertaking; but the directing mind being absent, found themselves powerless.

The works at Sèvres are chiefly limited to the supply of government wants. The only window lately executed by them which I have seen, is in the cathedral at *Eu*, near Dieppe. This was the gift of the King of the French, who, on more occasions than one, has evinced a strong desire to advance the arts in his kingdom.

* Although this paper does not pretend to give the names of *all* the professors of glass painting practising in England; (unfortunately necessarily few), the writer cannot omit to mention Mr. Millar, who has executed a number of works at Stonyhurst, and Mr. Wilmshurst whose large production "The Field of the Cloth of Gold" was destroyed by fire.

Circumstances are much more favourable in France to the progress of the art of glass painting than they are in England. The material is so much cheaper, and the remuneration expected by artists for their labour is so much less, even after making all allowances for the difference in the value of money in the two countries, that the greatest obstacles in the way of experimental essays amongst us do not exist there.

It is really to be desired that some efforts will shortly be made in England by men in authority, to prevent the decay of an art so beautiful and so valuable as this which we are now considering. Its present languid state is most deplorable to behold, and cannot but terminate fatally unless means be taken to inspirit and invigorate those who are engaged in it. It is not asked that government should form large and expensive establishments for this purpose, as at Munich, such a course is not necessary, perhaps, even, it would be unadvisable; but it does appear exceedingly desirable that they should, by occasional commissions and discriminating assistance, draw public attention to the subject, raise the hopes of its professors, and offer some inducement for increased exertion on their part. In consequence of the improved state of chemical and physical science, we have the means of producing works in painted glass superior to anything that has yet been done, were proper encouragement afforded to develop our resources; unfortunately, a directly contrary opinion prevails, and this fact, therefore, cannot be insisted on too vehemently.*

Concerning the importance of stained glass,

> " glass of thousand colourings,
> Through which the deepened glories once could enter,
> Streaming from off the sun like seraphs' wings."

to increase the solemnity of an ecclesiastical building, and induce holy and religious feelings—apart from its influence as a work of art—none disagree; and yet, in consequence of the niggardly and ill-advised system of church building pursued at this time, few of the new edifices which are rising in all directions—mean, contracted, and poverty-stricken—afford any specimens of it. If government were to set an example by the bestowal of a few windows, there are many individuals and public bodies who might be persuaded to follow it. In early times, when funds were needed for the erection of places of worship, the mendicant monks promised all who would subscribe, that they should be represented in stained glass,—that they should

> " knely before Christ in compas of gold,
> In the wyde windowe westward, wel neigh in the middell."

Notwithstanding it be pandering to the vanity and pride of frail humanity, we would promise this and more than this, to all who were willing to aid in the improvement of our churches, and to forward an art which has such claims upon the moralist and the man of taste: and we would point out that, by assisting to implant a knowledge and a love of art in the minds of their fellow men, they were advancing their welfare, raising them in the scale of beings, and effecting a national good.

Let us hope that better times than the present are in store for the lovers of this particular art—or rather, let us not be contented with simply hoping, but diligently set our own shoulders to the wheel, and vigorously assist to bring about that which we all admit to be so desirable.

* It may be remarked here, that care should be employed by painters in the selection of glass for their works. Glass, as now made for ordinary purposes, is ill-suited for painting on. A few years ago, admirable glass for this object was obtainable from a factory at Dumbarton, which is not now in operation.

MEDIEVAL ARCHITECTURE IN FRANCE.—No. 2.

(Continued from page 145.)

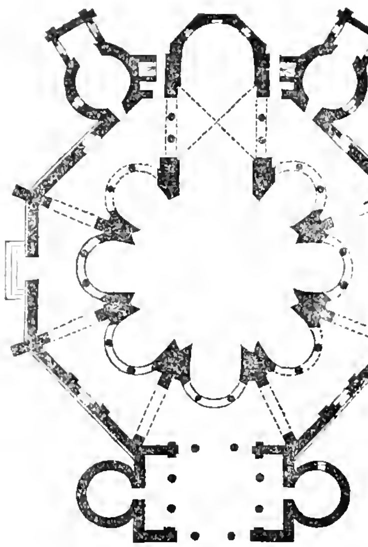
BYZANTINE STYLE.

Throughout a great part of the existence of what is called Gothic architecture, the Byzantine style flourished in France, both in distinct monuments, and as influencing other styles. In order to appreciate the character of this influence, we have considered it necessary not to limit ourselves to the examples afforded by France, seldom pure, but to investigate its history in other countries, so that thus we may be enabled to see the extent to which it has acted on other schools of art. It must be recollected that it was not until the eleventh century that the Greek and Latin churches were completely separated, while, during the whole period Constantinople contested with Rome for the supremacy. Down to that epoch Constantinople might be regarded with more propriety as the common centre of the Christian church than Rome, most of the general councils being held in the eastern empire, which was the great seat of learning. The bishops of Rome and Constantinople long contended for the jurisdiction over the provinces to the north of the Danube, and that the Greek patriarch was not without his influence, may be seen in many of the monuments to the north of the Alps. In France and in Germany, the examples of the Byzantine style are only partial, but in the Slavonic countries it is the predominant type to this day.

PLANS.

The first portion of the subject to which we shall call attention are the dispositions adopted in the arrangement of the ground plan of eastern churches, which, as was seen in the preceding article, completely altered the system copied from the Roman temples. Eusebius, in his life of Constantine,* describes some of the principal churches erected by this emperor and his mother in different provinces of his dominions. They were mostly circular or octagonal, and surmounted by lofty domes. Thus was constructed the great church of Antioch, dedicated to the Virgin, and called the Golden Temple, erected by this prince in the twenty-second year of his reign; it was in the form of an octagon, surrounded with exedræ and chapels. In the exedræ and in the porch it was lawful to bury. The church of the Ascension, built by St. Helena, mother of Constantine, upon the Mount of Olives, was circular, as is proved by the plan drawn on wax in the 8th century, and engraved in the *Acta Sanctorum*. This temple and the church of the Holy Sepulchre, are the reputed types of several churches built by the crusaders in their native countries. The churches of St. Marcellin and St. Constantius at Rome, are similar in their arrangements and were surmounted with cupolas of stone or pottery like the Syrian monuments before mentioned.

Fig. 6.—Church of St. Vital at Ravenna.

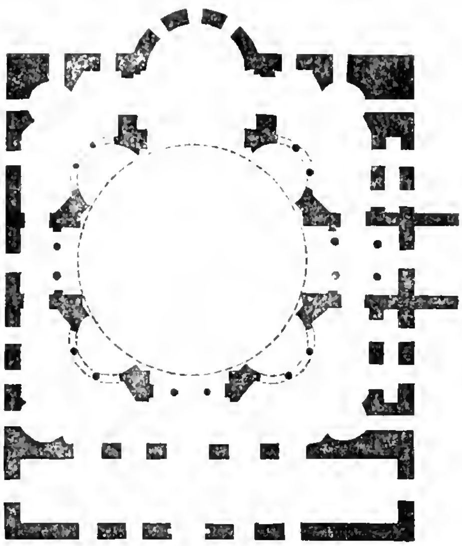


One of the nearest approaches to the description of Eusebius is the church of St. Vitalis, at Ravenna, founded in 534, while that city was still the seat of the Greek exarchs. Its plan is that of an octagon having semicircular chapels and *exedræ* on several points of its perimeter, or it may be described as round outside and octagonal within. A gallery on the first floor, running round the central area, is the *gynæceum*, or gallery for women, who, in the primitive church, as in the eastern churches to this day, were separated from the rest of the congregation. A hemispherical cupola, raised a great height from the ground, covers the building, and lights it by means of windows cut in the base. Pendents or brackets support the vault at the points where the re-entering angles of the polygon prevent it from being placed directly on the wall. The Greek architect, in constructing this building, has had recourse to a system, of which this is an early example.† Feeling the necessity for extreme lightness, since the cupola is supported mainly by brackets, he has used pieces of pottery in the shape of a bottle without a bottom. These vessels, placed in contact, form first the base of the cupola, then the curve, being continued without interruption, and in spiral, until they reach

* Eusebius, Vita Constantini, l. iii, c. 50; and Abulfareius.
† Another is to be found in the octagon baptistery at Ravenna, built in 540.

the top. The inside, as observed in our last number (p. 141), is covered with cement, decorated with mosaics on a gold ground. To the round churches of France we have already alluded at p. 143.

Fig. 7.—Church of Sergius and Bacchus at Constantinople.



We now proceed to consider the works of a later date, from the 6th to the 13th century, when we come to the church of Sergius and Bacchus, now called by the Turks *Chutchuk agia Sophia*, or Little Sancta Sophia. This was built by Justinian, as was the large church of Sancta Sophia. The architects were Anthemius of Thrales and Isodore of Miletus. In the central area the plan is the same as at Ravenna, the same polygon and the same semicircular arrangements; on the first floor is the *gynecœum*, running round the nave. Like the church of Ravenna, it is adorned with columns of valuable stone, surmounted with Byzantine capitals. The whole is covered with a cupola. A modification is, however, introduced into the plan; the exterior is a square, enclosing the central octagon. The church of Sancta Sophia is also square externally, and the arrangement of the interior preserves all the leading features of that of Sergius and Bacchus. The example of Sancta Sophia affected art everywhere, and the square system was adopted in every part of the east, to the exclusion of the circle and the octagon. The two succeeding engravings, Figs. 8 & 9, of the Panagia Lycodimo, and Cathedral at Athens, illustrate this. The Panagia Lycodimo is towards Mount Hymettus, on the west of the city; the Cathedral is now the public library.

Fig. 8.—The Panagia Lycomido at Athens.

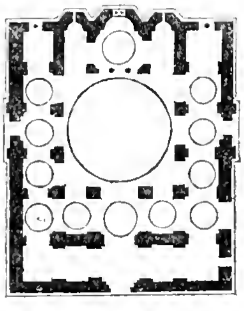


Fig. 9.—The Cathedral of Athens.

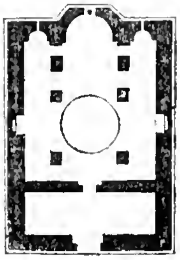
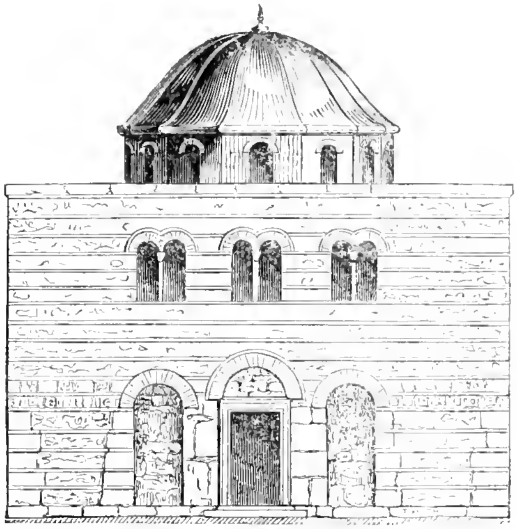


The plan of the *Ecs Miazin*, or the Three Churches, at Erivan, in Persia, one of the most celebrated Christian monuments of Asia, published by Chardin in his Persian travels, resembles the Cathedral of Athens. The only difference is in the form of the *narthex* or porch, which is square and open on three sides, whilst generally the vestibules occupy the whole breadth of the building. The *Ecs Miazin* has also a salient *absis* on each of its two lateral faces.

We may observe that it is from these models the Turks have borrowed the form of their mosques. Thus, also, they adopt a *Temenos* or square area isolating the building, and on the boundary of which are the residences of the officiating ministers and the tombs of their predecessors.*

ELEVATIONS.

Fig. 10.—Front of the Panagia Lycodimo at Athens.



The earliest Greek churches have a very simple front, a large mass, bounded at top by a horizontal line, without any pediment to indicate the inclination of the roof, carpentry not being used in Byzantine architecture, as cupolas and terraces only were used to cover in the building. Eusebius,† describing the basilica of the Apostles, says that rails cut out of gilt bronze were used to decorate the upper terrace, called the *Solarium*. It may be supposed from that, that the faces of the building were surmounted with horizontal cornices. The churches of Sergius and Bacchus, of Sancta Sophia, and of the Panagia Lycodimo (represented above), are all of the same kind; the square form being apparently preserved as late as the eighth and ninth centuries. These Byzantine churches are badly crowned, the upper entablature being composed only of a few mouldings, in which bricks are so placed as to form salient angles, and through which gutters are cut at different distances to carry off the water from the terraces or domes.

The first floor is generally marked on the front by a certain number of windows lighting the *gyneceum*. In the church of Sancta Sophia these windows are of large dimensions, semi-circular, and divided into three parts by two columns, which hold thin slabs or plates of stone, pierced with holes to let in the light.

Under the windows of the first story, or women's gallery, are placed the doors giving admission to the *narthex*, or porch. These doors are generally formed of lintels and door-posts, ornamented with elaborate mouldings, much in the style of the antique. Over the lintel a full arch, sometimes of stone and sometimes of brick, protects the door from the pressure of the superincumbent structure. The *narthex* was the place devoted to the catechumens, but in some of the later edifices it was used as a *gyneceum*, and thus the men entered the church by the north and south doors (*Noteiomeros*, *Boreiomeros*).

The early Byzantine basilicas have only a single dome, as in that of

* Around the temple was a large space, on each of the sides of which were raised porticoes, connected together. Besides the basins (for purification) of the basilica, there were the habitations of the guardians supported by the porticoes, which they equalled in extent."—Eusebius in the Life of Constantine, l. xiv, c. 58, describing the Church of the Apostles, built at Byzantium by Constantine. We may, perhaps, find here the origin of the monastic cloister attached to our cathedrals.

† Eusebius, l. iv, c. 58.

Sergius and Bacchus at Constantinople. Sancta Sophia, in the same city, has a large central dome, and two semi-cupolas which cover the two curved portions situated to the east and west of the nave. These primitive domes are generally very heavy and cumbrous in form, differing from those which were erected later and elevated on tambours. A great number of small arched windows, very near each other, are cut through the base of the domes, and serve to light the interior. The effect of the light is so brilliant, that the cupola seems as it were isolated from the building. The cupola of Sancta Sophia, upwards of 120 feet in diameter, not being properly poised over the four main piers, in consequence of gathering the spandrils into too small a compass, exhibited, in less than 25 years, symptoms of approaching downfall, and the piers were accordingly strengthened on the outside.

Eusebius, Paul the Silent, and other authors, agree in describing the dome of the Church of the Apostles as being covered with dazzling gilt bronze, to keep off the rain.

Fig. 11.—Church of Mone tes Koras at Constantinople.

Another system of decoration succeeded this, and was much copied in Europe, as may be seen in St. Mark, at Venice, begun in 996. In this system the horizontal line, as bounding the front, was entirely given up, and was replaced by an arched line marking the extrados of the vaults. In the Greek islands are to be commonly seen, little chapels with a cradle-like roof covering the only nave, and secured with cement or sheet-lead. Where the building consists of several aisles, as most of the large Byzantine edifices at Constantinople, the roof has a festoon-like appearance, like so many round-covered trunks placed side by side.

Thus the exterior shows, as it were, the skeleton of the building, every series of arches in the building having the extrados delineated outside. So in the church of *Mone tes Koras*, (the House of the Virgin,) at Constantinople, represented above; the front consists of five great arches, and as another lateral series of arches runs across to form the *narthex*, this portion of the edifice is terminated at each end by one of these arches.

The domes which were erected at this period were more hemispherical, and the windows instead of being in the base of the cupola are formed in a tambour or cylindrical base, on which it rests. At this period too the domes began to increase in number and be added to the grand one forming the centre of the cross. In the church of the Pantocrator they crown the transepts and the anterior part of the nave, in that of St. Theodosia, now the mosque of the Rose, in the Fanar, the port of Constantinople, four secondary cupolas of the same form as the central one, but smaller, are raised at the four corners of the building. In some a dome is raised on the *narthex* as in the churches of the Pantocrator and Mone tes Koras. That of the Theotocos, near Solimanieh, has three placed symmetrically, one in the centre, and one at each end. The capitals of the columns in the Greek churches were placed on round shafts, and were little more than square blocks, tapered downwards, and adorned with foliage or basket work.

About the time of the Venetian Conquests began a union of Byzantine and Roman architecture, which is not one of the least curious forms of the style. Here is again restored the influence of the west, and pediments indicate the inclination of the roof, although the Greeks never used carpentry in their ancient churches. One of the finest examples of this period is the *Ecs Miazin*, a Christian temple of Erivan, published by Chardin, and more recently by M. Dubois. Of this style is also the building which down to 1827 was used as the cathedral of Athens.

Fig. 12.—Cathedral of Athens.

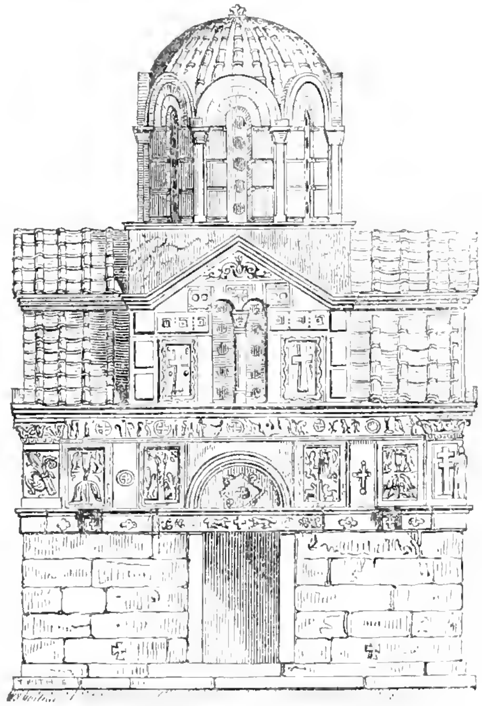


Fig. 13.—Notre Dame at Poitiers.

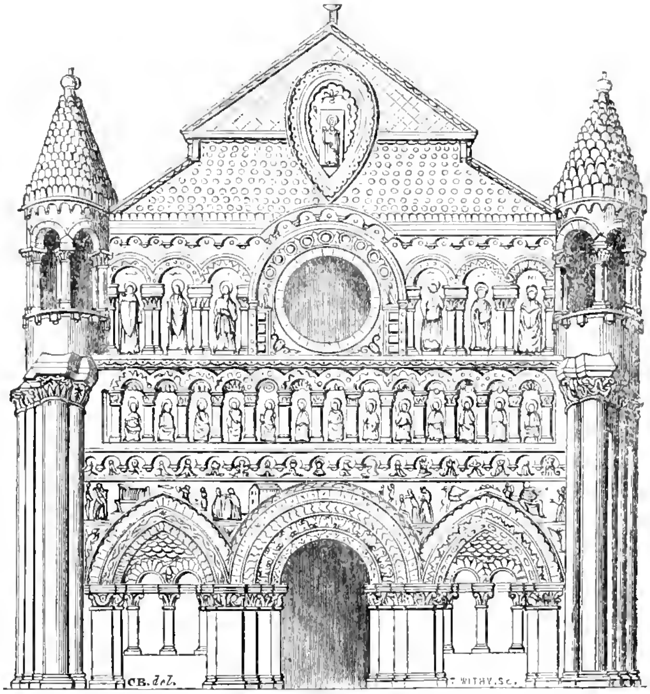


The figure above although partaking largely of the Roman, yet shows to what an extent the influence of the Byzantine school was felt, though in this case the interior presents much more points of resemblance than the outside. Our engraving, it must be observed, represents Notre Dame at Poitiers, not as it now is, but as it was before the gallery was broken through to enlarge the great window. This gallery although a type of the Gyneceum, is so far from being spacious, that in very few cases in the west of Europe, is there any communication through it. At Toscanella in the Roman States, and in the cathedral of Pisa, the original form is however preserved.

(To be continued.)

EXHIBITION—ROYAL ACADEMY.

(Continued from page 189.)

Among the practical jokes played off by the hanging committee in the architectural room, is that of placing a bird's-eye view where one must first get up a ladder in order to look down upon it, or in fact to look at it at all: which is no doubt exceedingly waggish and droll, but carrying the joke rather too far—at all events far above our heads: not that we care about it, because we have no relish whatever for drawings which carry us up into the clouds, in order to show us buildings as they would appear, viewed from a balloon. In itself the circumstance may be of little or no moment as far as the subject so placed is concerned, but it is certainly odd to meet with such blundering doings within the walls of a Royal Academy; where it certainly does bespeak a reprehensible systematic inattention to every thing connected with architecture. Lest we ourselves, however, should here be accused of inattention to our subject, we will resume our task of criticism by noticing two designs which we can heartily commend, and one of which we are glad to perceive is about to be executed. They are Nos. 1030 and 1050, both by Mr. J. W. Wild, and both for churches: the first being the "New Church, Streatham," to be executed under his superintendence; and the other a "Design for the Church proposed to be built at Paddington." They are neither Gothic nor Norman,—though the application of the round arch assimilates them somewhat to the latter: but in a style which has far more of the Lombardic character, and which, as shown is marked by picturesqueness no less than by simplicity, owing to the unusual breadth of surface and fewness of parts, on which account the Streatham church more particularly forms so striking a contrast to the impoverished, yet would-be-fine structures of the kind that have sprung up of late years in and around the metropolis, differing more or less from each other in their patterns, but all pretty much on a par as to taste, and exhibiting the same jog-trot outline system in design. Here we have at least some freshness of ideas and of mode of treatment,—a departure from the hackneyed track, into a better and more artist like one. Of course we can speak only as to general character of external design and style, for the perspective allows us to see only fronts of the two buildings distinctly, consequently we cannot undertake to say whether their character is satisfactorily kept up throughout: neither can we judge very accurately as to dimensions. The composition of the façade of the first-mentioned of the two designs, is quite Lombardic in outline and arrangement, being divided into three compartments, the centre one of which rises higher than the other two, and terminates in a gable, while the side ones are covered by half gables, not forming continuations of the principal one, but terminating lower down, before that commences. In each compartment is an arched recess or porch, containing—if we mistake not, a square headed door; and above the centre entrance is a large circular or rose window filled with two intersecting triangles, and bordered with coloured rays around its external margin. This polychrome effect is intended, we presume, to be produced by brick-work; and if so, we question if it will prove altogether so pleasing in execution as it does in the drawing, because in the latter it is particularly soft and delicate, whereas both the hue and texture of red brick, even when of superior quality, do not recommend as a material for ornament, however suitable it may be in certain styles, as a ground for embellishment in stone-work. Still though we have great doubts as to the result, we will not prejudge the experiment; on the contrary, we shall be glad to discover that our *misgivings* are *mistakings* also.

The church proposed for Paddington is similar to the other in style, but of a more ambitious character, being apparently considerably more extensive, unless the parts themselves are upon a smaller scale, and being surmounted by a cupola on an elevated tambour at the intersection of the transepts. Putting cost out of the question, it was most probably this latter circumstance, combined with the unusual and not particularly English physiognomy of the whole, that caused this design to be rejected incontinently. Perhaps, too, it may have been considered exceptionable as having too Roman Catholic a look,—for Catholicism happens to be just now one of the pet bug-bears of the day; just as if, while it is losing ground everywhere else, it is likely to gain ground in the land of John Bullism. We know not who is to be the architect of the church at Paddington,—have not, in fact learned if an ultimate decision is yet made, but the building will, we apprehend, not startle us by architectural innovations.

Turning from Mr. Wild's drawings to one for a similar purpose, No. 992, "The *approved* design for the New Church now about to be erected in the Liberty of the Rolls," we may tolerably plainly see what kind of things suit the taste and notions of those who are entrusted with the power of deciding on such occasions. That 'approved' does not exactly mean the most worthy to be approved, or carry with it an idea of superiority is evident enough—at least to ourselves, and in the present instance because we happen to have seen two other designs sent in for the same building, either of which was immeasurably better than this approved one: therefore it is a piece of good luck for it that neither of them are here exhibited, else we should most assuredly enter into some very 'odorous' comparisons. Perhaps, too, it is another piece of good luck for No. 992, that it is hung so high up as to be likely to escape notice altogether, unless the descriptive title in the catalogue should cause it to be hunted out.

No. 1034, Messrs. Buckler's "Design for the West Front of the Roman Church of St. George, Southwark," is in no danger of being passed by unnoticed, because the intense—and for this climate unnatural blue of the sky, renders it too conspicuous. As to the design itself, his front consists only of a very lofty tower in a style of Early Gothic, and although of good character, did not strike us as particularly novel or tasteful.

Nos. 1037 and 8, show us Mr. S. Smirke's design for the Reform Club House, in an elevation of the side towards Pall Mall, and a perspective view including that and the West end of the building, with its portico. Although merely said to be for "a Club House," there can be no doubt as to the particular one for which it was produced, both because it agrees with the description given of it in our first volume, (page 68), and as the Travellers' and Athenæum Club-houses are seen adjoining it. Most certainly it is not such as to make us regret that it was not preferred to Mr. Barry's, still we do not agree with the 'Art-Union,' which terms it "an ordinary Italian residence, with an ugly Corinthian portico tacked to the front of it." Now whether the epithet ordinary is to be understood as signifying 'usual,' or as expressive of both meanness and common-place character, we do not think it very correctly applied, because, although it may in some respects be in rather questionable taste,—we allude to the mullioned and transomed *croisées*,—it is more than ordinarily ornate, and is stamped by a good deal of picturesque quality. We prefer it greatly to the façade of the Oxford and Cambridge University Club-house, by the same architect, it being treated with more of artist-like feeling, and with greater consistency also. As regards the Corinthian tetrastyle of the West front, we do not pretend to say that it is particularly classical, but its effect in the composition is decidedly better than many of our soi-disant classical things of that kind which are tacked to buildings by no means so good as even "an ordinary Italian residence." Most decidedly too we prefer this to such a piece of architecture as No. 1015. "Design for the Taylor and Randolph building at Oxford," which as far as we can make it out where it hung, seems to us to evince neither originality of any kind, nor even study, both the composition and detail being exceedingly tame and common-place; yet we ought not to speak too peremptorily, because the 'Art-Union' critic tells us it possesses "much merit," further than which, said deponent sayeth nothing, but leaves others to find out, if they can, wherein it consists.

(To be continued.)

ON EXCHANGES.

We present our readers with a brief sketch of a lecture delivered at the the last conversazione of the Architectural Society, by its President, William Tite, Esq., F.R.S., upon the subject of the origin and history of that class of buildings denominated "*Exchanges*;" a subject which has just claims not only to the attention of the public, in an empire of such commercial importance as our own, but more speficically so to the examination of every architectural student, in an age when both at home and abroad, the rapid progress of improvement may be reasonably expected to provide opportunities for the erection of Exchanges as well as palaces and churches.

In introducing his subject by a reference to the state of society in the most remote ages, Mr. Tite observed that the extensive commercial relations of such ancient cities as Tyre, and the vast conflux thereto of mercantile men from all quarters of the known world, render it a matter of little doubt that some place of public assemblage must have been allotted to their especial use. This seems rendered yet more probable, when we observe to what arrangements precisely similar circumstances gave rise, though at a later period, among the Greeks and Romans. It is clear that the αγορα of the former, and the forum of the latter were alike applied indifferently to various public purposes. Sometimes they were used for meetings of a commercial character, as well as for the ordinary purposes of the market place; sometimes for the administration of the laws, or the celebration of games and festivals; and sometimes for places of deliberation upon municipal affairs.

As the number, wealth, and employments of the inhabitants increased, it was found inconvenient to have so many occupations carried on together, and two classes of fora were established, viz. Venalia or market places, properly so called, and Civilia, or places of assembly, of which, however, there was but one until the time of Julius Cæsar. The Venalia were again divided into the Boarium or ox-market, the Piscarium, or fish-market, and the like. Something resembling this separation and improvement is to be traced in the history of the establishment of the English courts of law. The Saxon constitution comprehended but one superior court of justice in the kingdom, viz. the Great Council; but, after the Norman invasion, the ecclesiastical jurisdiction was separated from the civil, and the king subsequently effected another separation between the judicial and the parliamentary power, vested in the remaining members. He then established that very comprehensive court in his own residence, called "the King's Hall," composed of the great officers of state; which became at length divided into the different courts of Chancery, Exchequer, Common Pleas, and the Earl Marshall's court, or Court of Honour. The simple features of a Roman Forum appear at once to convey the image of a modern Exchange, it having been an open area surrounded by a colonnade, about which were subsequently established temples and prisons, courts and record offices, public granaries, offices of money changers, and a variety of trades, the municipal treasuries, and the rostra whence orators addressed the people. Some differences existed between the Greek and Roman Fora, derived from the different uses to which they were to be applied. Those of the Greeks were built square, with the columns near together, to afford as much shelter as possible; above which was an upper ambulatory or gallery for walking. The Roman fora, on the contrary, were oblong in the area, having the columns set at considerable intervals, but still surmounted by the gallery, in which latter feature, also, they somewhat resembled the Bourses of the 16th and 17th centuries. In those places which lay inland, the Forum was erected in the centre of the city, but in marine towns it was situated at the port. Accordingly the Piræus, or maritime town of Athens, was the principal place of commerce connected therewith, and it contained temples and theatres, arsenals, granaries and shops, and also the established place of assembly for merchants.

These circumstances are curiously illustrated by Theophrastus, in a description of the character of an ostentatious Athenian merchant, 'εν τῳ δειγματι 'εσηκως, and vaunting of his enterprise and wealth; in which description it is supposed by Casaubon and others, that the δειγμα expresses the place where samples of merchandize were produced and examined.

Down to this period, and most probably to a much later time, the places of assembly for merchants were to be found in the forum: and they appear to have generally occupied that interior extremity called the Basilica, for the choice of which, perhaps, Vitruvius gives one of the original reasons several centuries after, when he says, "the Basilica should be adjoining to the forum on the warmest side, that the merchants may confer together without being incommoded by the weather." Another cause for the selection might possibly be that they were there completely removed from the noise and confusion of the rest of the market or forum.

Livy also alludes to the formation of a "collegium mercatorum," in the fifth century before the Christian æra; but it may be doubted whether this phrase of itself can fairly be considered as proving any thing more than the existence of a "fraternity of merchants." It will be proper also to observe, before dismissing all notice of that period of remote antiquity, that there were certain secular points of view in which the Temple at Jerusalem may be taken as affording an illustration of this subject. The first Temple, it will be remembered, consisted of several square courts, surrounded by colonnades and chambers; and this building was an extended and greatly improved copy of the tabernacle, to which, therefore, may be referred the remote original of that extremely natural and convenient form for places of public assembly, which were subsequently to be found throughout the whole of the civilized world. When the corrupted traditions of the Hebrews led them to misemploy and profane the second temple, by making it a place of merchandize, the resemblance between the court of the Gentiles and a Roman Forum was very remarkable. After the conclusion of the feast of Purim, in commemoration of the triumph of Esther and Mordecai, the money-changers considered it lawful to seat themselves in the outer court, to exchange foreign coins for such as were current at Jerusalem; for the temple tribute, though collected in heathen money, was required to be paid in the shekels of the sanctuary, and several offerings also required the addition of parts of shekels to make them complete.

In this last circumstance, it will be shown hereafter, that there may be an especial parallel found to the facts that probably gave rise to the disignation of our own edifice of London. The court of the great temple at Mecca, as decribed by Sale, and many of the eastern Khans or Caravanserais will furnish some additional illustration of the forms of buildings applied in later ages and other climes to mixed purposes, not dissimilar to those under consideration.

From precedents such as these it may have been that the Venetians, in more modern times, but during the earlier ages of their republic, obtained a model for their great Exchange on the Island of the Rialto. It will be observed that this place of mercantile concourse was not the celebrated Bridge of the Rialto, as is usually imagined, but a portion of the Island of that name immediately adjacent to the Bridge. This island appears to have been the first inhabited among the many that now constitute the City of Venice; it became the centre of commerce, and the vast depository of the most valuable merchanize of all nations. As described by Sabellico in the year 1492, it appears that nothing was wanting to the completeness of this site, not only for mercantile, but for municipal purposes. The great place of meeting was a spacious quadrangular piazza, almost surrounding the church of St. Jacopo; and in its immediate vicinity were warehouses, banks, shops, markets, public offices, and halls of every description. The greater portion of these buildings was destroyed by fire in 1515, but was rebuilt, in a style of superior magnificence, during the following nine years, under the architectural superintendence of Antonio Scarpagni.

Passing by other Italian structures of inferior note, raised for the same objects, we shall find the example derived from them followed with conspicuous splendour in some of the cities of the Netherlands. To meet the rising commercial importance of Antwerp, at the beginning of the 16th century, a Bourse (according to the name introduced from Bruges), was erected in the year 1531. This structure is 180 feet in length by 140 in breadth, and is supported by 44 stone pillars, which are differently sculptured. It contains numerous subterranean warehouses, over which are the halls occupied by the tribunal and the chamber of commerce. It was not until nearly 40 years after this period that England possessed any similar building, during all which time the merchants were accustomed to assemble twice in each day, in the open air in Lombard-street. The king himself, however, so early as 1535, proposed that they should remove to the old edifice of Leadenhall, which they declined doing: and in 1537 Sir Richard Gresham laid before Thomas Cromwell, then Lord Privy Seal, the plan of a Bourse for London, in the old resort of Lombard-street, to which he had been probably incited by a visit to Antwerp. Before retiring from his Mayoralty in the following year, he made another effort to complete this design in a letter to Lord Cromwell, which is still extant. He states therein that "it will cost £2,000 and more," and at the same time shows the real cause why the work was not then and there carried into effect; since he adds, "there is certain houses in the said street belonging to Sir George Monnocks, and, except we may purchase them, the said Burse cannot be made. Wherefore, may it please your good lordship to move the King's Highness to have his most gracious letters directed to the said Sir George, willing, and also commanding him to cause the said houses to be sold to the Mayor and Commonalty of the City of London, for such prices as he did purchase them for, and that he fault not but to accomplish his gracious commandment. The letter must be sharply made, for he is of no gentle nature; and, that he shall give farther credence to the Mayor, I will deliver the letter, and handle him the best I may: and, if I may obtain to have the said houses, I doubt not but to gather £1,000 toward the building, or I depart out of mine office. There shall lack no good will in me."

The project which thus originated with Sir Richard Gresham, was realized by the liberality and enterprise of his son Sir Thomas, who commenced his edifice in London in the year 1565. The similarity which subsisted between this building and that of Antwerp, was very conspicuous. Like the latter, the Exchange of London had a tall tower placed on the east side of the principal entrance, containing a bell, which twice in the day summoned the merchants to assemble, at noon, and at six in the evening. In the interior of both we observe the same quadrangular arcade, carrying a similar upper story, and surmounted again by a high roof and regular gabled dormers of the same char cter. The Royal Exchange received its name on being opened in person by Queen Elizabeth, on the 23rd January, 1570-71.

There does not appear to have been assigned, either by contemporaneous or modern authority, any reason for the change of the name of this edifice by the Queen; though, from the very time of the proclamation, it seems to have been most effectual and complete. If, however, at this very distant date, a conjecture may be offered, it might have been a design of Elizabeth, which was never brought to maturity, to have re-established, in this building, the ancient exchange of the sovereigns of England, the former situation of which remains commemorated, even at the present day, in the street in Cheapside called *Old 'Change*. It was here that one of those ancient officers known as "the King's Exchangers" was placed, whose duty it was to attend to the supply of the Mints with bullion, to distribute the new coinages and to regulate the exchange of foreign coin. Of these officers there were anciently three, two in London, at the Tower and Old 'Change, and one in the city of Canterbury. Subsequently another was appointed with an establishment in Lombard Street, the ancient rendezvous of the merchants; and it appears not improbable that the Queen's intention was to have removed this functionary to what was now preeminently designated as the Royal Exchange.

As the Bourse of Antwerp had furnished a model for close imitation to the projectors of London, the work of the latter was, in its turn, closely followed by the citizens of Amsterdam. The Bourse, which still subsists there, was commenced in 1608, and opened in 1613. A rectangular area, as in the previous instances, is surrounded by a covered way, formed by forty columns of stone, carrying an upper story and roof exceedingly similar to those before noticed. There are principal entrances on the north and south sides, and the latter has the addition of a lofty bell-tower and clock.

To revert to the Royal Exchange of London, it may be noticed that, the original structure having been destroyed in the great fire of 1666, its successor was erected upon the same site, under the superintendence of Mr. Edward Jerman, one of the surveyors to the city, at an outlay of £58,962. With the facts affecting the recent destruction of this edifice by fire also, we are all too well acquainted; and with respect to the erection of any structure that may supply its place, it may be sufficient just to state, in conclusion, that the instructions under which the various designs for a new Royal Exchange have been prepared, have determined that an open a ea shall be preserved for the use of the merchants, after the manner of the former building, but about one third larger in extent. The Bourse at Paris, the more recently erected Exchange at Glasgow, and the Exchange at St. Petersburg, are all covered buildings. The Exchange at Liverpool, on the other hand, follows the more ancient precedent, retaining the open area and surrounding arcade. As any discussion of the propriety of those instructions that have been issued for the direction of architects on the subject of the new Royal Exchange, would be beside our present purpose, as would any observations in anticipation of a future structure, we may now close our remarks, with a hope that this compressed statement may afford our readers some degree of that interest with which the original lecture was received by the audience of the Architectural Society.

THE ROYAL EXCHANGE.

Sir—Having taken no part whatever in the competition, or in any of the correspondences which have appeared in the various public prints relative to the Royal Exchange, and feeling a general disgust at the intemperate manner in which such correspondences are usually conducted, but understanding that the affair appears as far off from settlement as ever, I now crave through the medium of your widely circulated journal, the promulgation of the following brief remarks.

1st. It appears pretty certain, that the plan which will be adopted will conform, as it should, to the lines of the principal adjoining streets, otherwise the frontages of the building would lie awkwardly with regard to them, and more ground would be given up in making the site rectangular than the required accommodation would well allow. It seems therefore that the plan will be in shape a trapezium.

2nd. In all plans of this shape which I have seen, (that of Mr. Tite included), there are a multitude of irregularities, many rooms out of square, some of the largest of them with whole wings sliced off irregularly, and many doors, windows, and chimneys seemingly placed at random, all which defects would be evident enough to those who might use such apartments.

3rd. Now I would undertake to make such a design (merely by remembering that there is in the world such an art as Geometry, of which Wren, and his kind, made much use, more especially in difficult cases), which design should have every internal apartment, angle, door, window, and chimney regular.

4th. To effect this, I should need only to cut off from the site, the large ranges of apartments in lines exactly parallel to the principal front of the building. This would leave a smaller trapezium in the centre of the ground.

5th. Within this smaller trapezium I should place an elliptical court, and in the four spandrel spaces which would be left, I should place semi-circular staircases, water-closets, and other offices.

6th. The architecture of the elliptical court, I should form something after Inigo Jones's magnificent and universally admired circular Persian court, designed for Whitehall: but instead of having all the columnar statues (say 32 in number) made similar, which by monotony would displease, I would have them each a type of some chief nation trading to London: and if the expense of these Caryatic statues be objected to, I doubt not that the merchants engaged in the several trades, would find the difference between the price of them and of plain piers.

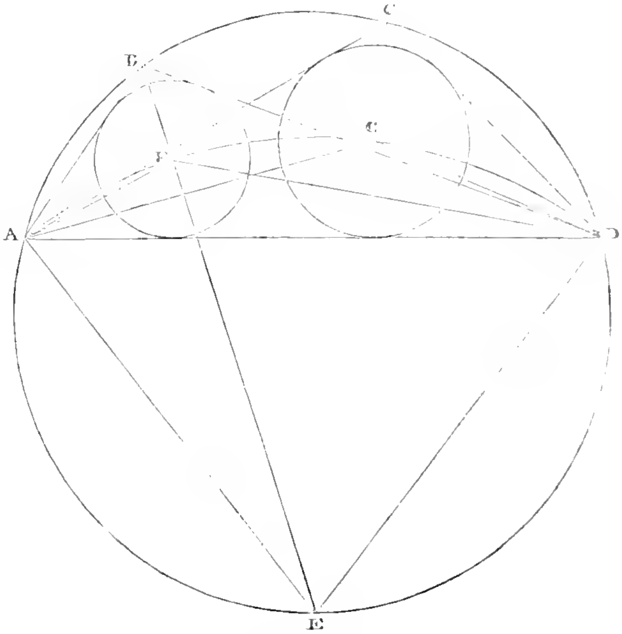
I am, Sir, your very obedient humble servant,

Gray's Inn, June 19, 1840. B.

GEOMETRICAL THEOREM.

Sir—I believe that the following curious property of a circle has not hitherto been noticed; or if it has, I am not aware of its existence in any of our works on Geometry.

Let A B C D E be a circle, of which A C D is any given segment: Let any number of triangles A B D, A C D, &c. be drawn in this segment, and let circles be inscribed in these triangles: their centres F, G, &c. are in the arc of a circle, whose centre is at E, the middle of the arc of the opposite segment A E D.



DEMONSTRATION.

Join A F, F D, A G, G D; then since F is the centre of the circle, inscribed in the triangle A B D, the lines A F, F D, bisect the angles B A D, B D A. (Euc. B. 4, P. 4). For a like reason A G, G D, bisect the angles C A D. C D A; hence the angles F A D, F D A, together, are equal to half the angles, B A D, B D A together, and the angles G A D, G D A together, to half the angles C A D, C D A together. Now the angles A B D, A C D, are equal (being in the same segment), therefore the angles B A D, B D A together, are equal to the angles C A D, C D A together, and as the halves of equals are equal, the angles F A D, F D A together are equal to the angles G A D, G D A together; that is in the two triangles A F D, A G D, two angles of the one, are together equal to two angles of the other, and therefore the third angle A F D, is equal to the third angle A G D. The same reasoning will prove, that all angles similarly circumstanced to A F D, are also equal to A G D: therefore, the points A, F, G, D, are in an arc of a circle.

Join B F, and produce it to cut the opposite circumference in E and join E A, E D; then because the angle A B E, is equal to the angle D B E, the segment A E, is equal to the segment E D, and the chord A E, to the chord E D. Again the angles A B E, E D A, are equal (being in the same segment), and by construction, the angle A D F is equal to the angle F D B, therefore the whole angle E D F, is equal to the two A B F, F D B, that is to the two F B D, F D B, that is to the exterior angle E F D; therefore the angle E F D, is equal to the angle E D F; consequently E F, is equal to E D, that is to E A. The same reasoning would prove E F to be equal to a line drawn from G, to the point E. Wherefore the point E is the centre of a circle, of which F and G, as also the centres of all other circles similarly inscribed, are in the circumference.

H. Spencer.

CANDIDUS'S NOTE-BOOK.
FASCICULUS XVI.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. A friend of mine is in the habit of exclaiming "Damn all Dictionary-makers," and I am tempted to say ditto as regards all illustrators, a set of illuminati who generally display their cleverness by leaving you as much in the dark as possible. Would it be believed that one of these 'picturesque' geniusses, who visited St. Petersburg 'expressly' for the purpose of taking views of the most striking buildings in that capital, actually turned his back upon the portico and dome of the Kazon Church, and brought into his view of that edifice merely an angle of one of the sweeping colonnades! Hogarth's sketch of a serjeant and dog entering an ale-house, which group he exhibited in three strokes of his pencil, might be taken as a satirical quiz upon such shamming illustrations. What then is to be said of Soane who has actually omitted in his 'Designs of Public and Private Buildings,' what is by very far the best piece of exterior architecture he ever produced—namely, the little semicircular loggia at the north-west angle of the Bank!! It is indeed just discernable in a coarse scratch of the general elevation barely an inch in height; but from the peculiarity of its plan, such a piece of design required to be explained by elevations, sections, &c. on as large a scale as the size of the plates would admit, which would have been about half an inch to a foot. That I am not singular in my opinion as to the merits of that piece of architecture is evident, because it was selected as the subject of the medal presented to him by the Institute. Such an extraordinary omission induces me to imagine that Sir John's wits were *knighted* quite as much as himself;—at all events he seems to have been resolved that the purchasers of his work should be left quite in the dark with respect to the subject alluded to. Poor man! he was not deficient in cunning, and had just enough to outwit himself, one notorious instance of which is his singular donation of his house, by which he has bamboozled the public, but damned his own character for munificence, into the bargain.

II. Conversing the other day with ———— (who has a greater reputation for wit than for sanctity) on the subject of the present fashion —style I will not call it, in church building, I remarked that Welby Pugin was after all tolerably right in some respects, and that the practice of enclosing the congregation in separate pews was an insuperable disadvantage in an architectural point of view, besides which it seemed to me objectionable as carrying wordly distinctions and the principle of *meum* and *tuum* into the very House of God. "As regards architectural effect," replied ————, "you are certainly right,—in your other objection as certainly wrong. Do you not perceive the symbolic propriety and expressive meaning of the very things you find fault with."—"I really do not." "Why then, my good friend, you must have grown quite muddy-headed.—What!—do you not at once see the striking propriety—the analogical and practical illustration of Gospel, in putting the pastor into his pulpit, and his *flock* into *sheep-pens?*"

III. "It is most deplorable and paltry," observes Prince Puckler-Muskau, "when, instead of being expunged and corrected, a particular part which is evidently a failure, is allowed to remain a blemish to the whole work, merely because it has cost so much time and money, and the requisite alteration would cost so much more." Although the writer is here speaking of Landscape-gardening, the remark is equally applicable to architecture, many productions of which, might be greatly improved by amendments that are almost self-evident. It is true, there ought never to be any occasion for improvement of such kind, because every part and feature of a building may be, and invariably ought to be, thoroughly studied and foreseen from the designs for it.

IV. Earnestly is it to be wished that architects would endeavour to emulate the other sex in the devoted application of all their faculties, which those exemplary and most truly *con amore* artists bestow upon their handy-works. When I perceive on the one hand with what plodding indifference, hurry, or carelessness, many buildings have been designed; and on the other, what anxious thought, what patience, what contrivance, what ingenuity, what scheming and planning, and how much consultation, are given to devise a ball dress—as if it were a work destined to outlive the eternal pyramids;—when I perceive with what critical study and exactness every part of the fabric is elaborated, and that as much attention is paid to the precise quality and texture of the material, as if all men were men-milliners and able to tell at a glance where a lady's lace and velvet have been manufactured, or what they cost per yard;—when I see and perceive all this, I cannot help drawing a comparison that is greatly to the disadvantage of us 'male creatures,' especially of some of those who call themselves architects. What hurried, slovenly, and slobbered work do they make of it! in what coarse, ill-assorted, and awkwardly put on finery do they attempt to dress up their designs,—to say nothing of the grotesque mixture of arrant shabbiness and such finery which they so frequently parade before our eyes in the most ridiculous manner. We men are dull pedants who judge only by rules, while women are guided by a refined tact, an unerring delicacy of instinct, which preserve them from committing those gross solecisms in taste into which we are perpetually falling: let us therefore cry out *Place aux Dames!* for they deserve to take precedence of all the Old Women in Breeches, who bore us with their Vitruvius, and their Palladio.

V. Lindley Murray would go just as far towards making a poet, as the writings of Vitruvius, Palladio, *et hoc genus omne*, towards forming an architect who should also rank as an artist in his profession. For what are that class of architectural writers more than mere *grammatici*, —useful as furnishing the rudiments and implements of study, and nothing further? But it would seem that in architecture mere grammatical accuracy is held to be everything,—the ideas, the combinations, the conception, the composition—effect, character, expression, comparatively nothing, —what may be left to chance; because, provided no sins be committed against the petty rules of the art, be it as intolerably dull as it may, the work is certain of being recognized as legitimate and orthodox. Such being the case, and negative merit being accepted as possitive—nay as something wonderful, nothing short of a prodigious achievement in art, can we at all wonder at beholding so many sickly insipidities displaying themselves in stone or cement? or such pieces of architectural bathos, as the British Insurance Office, where Agrigentum columns shop windows, crooked balconies, figures of sprawling drunken ladies, &c., are all jumbled and squeezed up together. If the author of that monstrosity be still living, with what a shudder must he be seized every time he passes by it,—unless his nerves should happen to be of iron, and his scull well fortified with lead. However he has certainly given, at his own cost, an excellent lesson *pro bono publico* to the profession, showing them very forcibly what they ought to avoid.

VI. It was the opinion of that exceedingly sensible, but most horrible unsentimental person, Dr. Johnson, that "marriages would in general be as happy and often more so, if they were all made by the Lord Chancellor;"—which, by the bye, would be a complete death blow to the novelists:—and I myself am sometimes inclined to adopt a similar opinion with respect to architectural competitions, and say that in nine cases out of ten, the choice would prove as good were it left to the Lord Chancellor, or the—Lord Mayor. Seldom could their decision prove a worse one than what now frequently occurs: not often would it be so bad, because ignoramus as he might be, a Lord Mayor, would as an individual feel obliged to pay some deference to public opinion; whereas a committee can afford to brave it, since whatever may be the odium that falls upon it as a body, no member of it feels in his own person. As to the Lord Chancellor, however, I should be loth to commit the task of decision to him, because expedition and promptitude are not to be looked for in that quarter. In fact, the Royal Exchange does seem to have been actually put into *Chancery;* for after the lapse of two years and a half the foundations of a new structure are not yet laid, although the space of a single twelvemonth sufficed to rebuild, and refurnish the Winter Palace at St. Petersburg, an edifice three or four times the size of the one intended to be reared in Cornhill. The British Museum also goes on at the true Chancery pace,—*ditto* the Nelson Monument that is to be. Nay, if the truth may be told, Competition itself is a sort of *Chancery*, mere chance having quite as much to do with the decisions, as either judgement or taste.

VII. I incline to the opinion of Mr. Walter Fisher, when he says: "The real truth is, I feel mortified at being kept down by a want of ardour in our patrons. We hear a great deal of Scott and Southey, and Byron, and Wordsworth; and folks talk of Lawrence and Reynolds,—and all the rest of it; but what is poetry of which not one person in ten thousand can judge—to Cookery?" When I say I incline to Walter's opinion,—who, by the bye, if he does not lack conceit has an equal stock of enthusiasm.—I do not mean that I form precisely the same comparative estimate of poetry, painting, and cookery as he does, but merely agree with him that for one who can judge of poetry, there are ten thousand who can judge of and relish cookery; and that there are ten times ten thousand who are most unaffectedly devoted to the latter, for who is passionately addicted to—architecture.

It is invidious to scrutinize motives too narrowly, but I have certain uncomfortable misgivings, that lead me to fancy architecture would have still fewer votaries were it not for the attractions of cookery. If the reader be so obtuse as to ask for further elucidation, I can only pity—not assist him, because it would be impossible for me to explain myself more clearly without becoming libellous, and forfeiting that character for indulgent clemency, and considerate forbearance which I have now established.—*Au reste*, it would be amusing if not edifying to draw a parallel between architecture and cookery, which latter of these two fine arts requires a peculiar genius for combinations, *combinations-geist*, generally dispensed with by the other. At all events it cannot be denied that architects do show themselves less expert than our *chefs-de-cuisine*, for they seldom do more than merely *hash up* afresh the same stale remains of classicality.

FRESCO PAINTING IN ENGLAND.

THE DUKE OF BEAUFORT'S MANSION.

We have several times alluded to the works going on at Beaufort House, but have not until now been able to give our readers any detailed account. We may remark that this mansion is situated in Arlington Street, Piccadilly, having, from the back, a view of the Green Park. It was formerly in the occupation of the Marquis of Camden, but is now being fitted up by the Duke of Beaufort as a town residence. His grace had certainly some difficulties to contend with in the previous state of the house, which, like too many other mansions in London, had been consigned to the tasteful hands of the upholsterer and the whitewasher. It being considered that painting might look as well on the walls as dabbed and spotted paper, a point on which we fear there are some doubts entertained by London residents generally, it was originally suggested, under the idea that Englishmen could not do it so cheaply and so well, that German artists should be employed. While the negociations were going on, Mr. Latilla was mentioned to the Duke as having been engaged in similar works, and having been directed to send in designs, was immediately employed. By this arrangement the work has not only been done much cheaper, and we think many will consider better, but a great service has been rendered to English art. Mr. Latilla's system of fresco painting had already met with much approbation and encouragement, but it wanted this excellent opportunity to display its powers more fully.

Passing on now to the works executed under Mr. Latilla's direction, the first is a vaulted corridor leading from the entrance hall, and which, in the Marquis of Camden's time, remained in all the simplicity of white and unpolluted paint, but is now designed in bigio or chiar' oscuro with trophies and medallions, something in the Roman style. On the side opposite the windows a range of plaster statues of agricultural divinities bear lights in their hands, and serve to break the view. At the end of this corridor is a hall from which a staircase runs to the upper apartments; the walls and ceiling of this staircase have also been decorated with representations of medallions and architectural ornaments.

On the ground floor are the principal apartments, one of which, the banquetting room, we are now about to describe. This apartment may be about thirty feet by twenty, and sixteen feet high, having on one of the long sides three windows, the opposite side an entrance door, another and a chimney at one end of the room, and at the other end folding doors leading out of it. Six large panels are thus left, which are painted with two series of subjects, one representing the seasons, and the other Hebe and Ariadne. As a banquetting room the decorations of course are of a Bacchanalian character, and without departing from the character of the antique, are not repulsive to modern taste. The whole style is a similar happy adaptation of ancient principles, and without being restricted to any one school, has a unity of character which establishes it as a style in itself. The design of the panels is much in the Pompeian taste, but carried out in accordance with the advance of modern art; the pilasters and arabesques have, perhaps, more of the character of Girolamo Romanino, or his model, the baths of Titus, and the tone of colouring shows a nearer approach to the Herculanean than the Pompeian. The ground of the room is of a lavender colour, and upon this a brightness and harmony of effect is produced without spottiness or rawness.

The two panels at each end of the room are devoted to the seasons, the first of which, Spring, is represented by a female figure clothed in white gauze, and floating in true antique style in ambient air. Beneath her is a landscape representing Greek scenery, and under the panel is a mask of a young head in a festoon of spring flowers, daffodils, crocuses, snow-drops, &c.

The next on the same side is Summer, also personated by a young female, crowned with a wreath of roses, and holding a garland in her hand, and floating over scenery representing Egyptian subjects. The festoon underneath is of roses and other summer flowers, and contains a mask of Bacchus.

At the opposite end of the room, the figure next the door, that of an older female, is the emblem of Autumn: she is crowned with poppies, and presides over an autumnal landscape. A mask of a warrior reposes on a festoon of grapes, wheat-ears, and other harvest productions. Part of the drapery of this is, perhaps, a little heavy.

The remaining panel of this series is devoted to Winter, a subject treated in a beautiful and effective method. In a deep blue winter sky floats a young female closely draped, with part of her robe brought round her head as a hood. Above her head is seen the constellation of the Pleiades, and to her breasts she clasps a cinerary urn, the emblem of the closing year. Underneath is a representation of iceclad mountains, forming an appropriate finish to this admirable scene, the character of which is indeed well maintained. A mask of a bearded old man is placed on the festoon beneath, which is twined of the holly and mistletoe and other emblems of Christmas.

The other and smaller series of subjects is on the side opposite the windows. One panel is appropriated to Hebe, who, with her golden vase and cup, and usual attributes, flies over a morning scene. The other panel represents Ariadne with the thyrsus, the scene under being a sacrifice to Bacchus. Under each of these panels is a festoon of flowers with a mask of a female head.

There is nothing much to remark in the smaller doors, they have over them each a small panel, containing a vase and flowers. The ornaments of the folding doors consisting of bluish ribbands and of medallions, have much of the character of the baths of Titus, and over the door is an arabesque on a yellow ground. The treatment of these doors is very skilful, the details made to tell well. The chimney and fire-place is of black marble with ormolu ornaments, and over it is a large glass. This chimney it was very difficult to bring in, but the treatment has been most successful. Over the glass is a deep chocolate ground panel, with boys carrying grapes, accompanying an infant Bacchus riding on a goat. The several compartments of the room are divided by arabesques, consisting of a red staff or thyrsus, with grapes and Bacchanalian emblems. The carving round the room has four corners of a peculiar deep brown used by the ancients, which Mr. Latilla names Etruscan brown. Between these are arabesques on a cream-coloured ground, consisting of boys playing with panthers. The ceiling is of a low cream colour, having in the centre a patera, formed of light festoons and flowers. From this depends a lamp ornamented with vine leaves of ormolu, and grapes of ground glass. The carpet is of a plain pattern, and light in appearance; it is of blue and yellow on a maroon ground, with a white border. The furniture is of the simplest description, a mahogany table and red morocco chairs. These latter accessories are not of the selection of the artist, but it does great credit to the high-minded nobleman who employed him, that he has not, as is too often the case, allowed the furniture to injure the rest of the works. The lamp might have been more in the antique, but it is not offensive. An Elizabethan stove, intended to have been placed in the room, has been removed.

An oval saloon leading from the banquetting room to the drawing room is also painted by Mr. Latilla. It has a white ground with festoons of gold ribband, but we cannot say we like the design of these last. The drawing room is now under the hands of Mr. Jones, (the author, we believe, of the work on the Alhambra.) The design is in a style somewhat of the time of Henry the Fourth, and is of a most gorgeous character, nearly all gold and silver. The panels represent the story of Mary, Queen of Scots, and the walls are of a bright blue, with fleur-de-lis. The effect is admirable, but there are few, we believe, who will not prefer the light elegance of the banquetting room, which both by night and by day is equally effective.

The Duke of Beaufort has reason to congratulate himself on his determination in every respect: his banquetting room has been executed for a tenth part of the German estimate, will remain for centuries, and would be injured by any but the simplest furniture. As a worthy encouragement of English art and an example to other patrons, Beaufort House and its noble owner have done much valuable service, and we shall be greatly deceived if its results are limited to such a sphere, or confined to the employment of one man. We see, in this mansion, the germ of what can be done in our national and civic edifices, and architects and artists will do but half their duty if they do not agitate until in this line, also, we have distanced foreign rivalry. We have enough artists of fame in the country, we have plenty of latent talent, and it wants but scope for exertion to place us in that position which Englishmen, if they have the opportunity, are sure to attain. For three hundred years we fostered foreign art, and the result was that we did not produce even one good artist for every foreigner employed; we got only Hudson, Oliver, and Thornhill, in exchange for Holbein, Rubens, Vandyke and Lely: we began to depend on our own resources, and we have produced men whose names are known to Europe; in all the branches of art for which we have scope, we have made our way, and in despite of want of instruction, want of taste, and want of encouragement, at any rate we have shown that we can produce high art, if it be but called for. The barbarians who could add whitewashed garrets to the British Museum, are but a portion of the great body of Midases in art, who, by indifference or opposition, check its encouragement by the legislature, and although they have begun to find out that whitewash is not the best back-ground for the Elgin marbles, yet they and their brethren must go a step further, if they wish England to make a good figure in the eyes of its neighbours. There is the British Museum, National Gallery, and Royal Exchange to go to work upon, and above all, the new Houses of Parliament; rich as they are in historical associations, they lose half their value without even a mark to tell the scene of so many great events, where the sovereigns of a mighty empire have been created and deposed, tried and executed, where viceroys and ministers have been arraigned, the destiny of the old world and the new determined, kings made tributary, and slaves set free.

We must by this time have made known the high sense which we entertain of the talents and exertions of Mr. Latilla, and we are disposed to look less at his past works, than to dwell upon the hope of those which are to come. Even since his labours at Beaufort House, he has in Italy acquired fresh power and confidence in his art, and his course of instruction has been such as well to fit him for a higher task. For many years he has devoted himself to fresco painting, and the history of his initiation, which we have heard, is a good lesson of the value that may attach to what we too often despise as trifles. John Nash, the architect, brought home from Italy a collection of designs from the Loggie of the Vatican and some Italian artists, whom he employed to paint part of his house in the Raffaelesque style, and Latilla, then a boy, was employed in finishing it after they left, when he was so struck by what he saw, that from that day he devoted himself to fresco, and exerted himself for its introduction.

PUBLIC BUILDINGS IN LONDON.

A Critical Review of the Public Buildings, Statues and Ornaments in and about London and Westminster—1734.

By Ralph.

(Continued from page 201.)

The grand cathedral of St. Paul's is undoubtedly one of the most magnificent modern buildings in Europe; all the parts of which it is composed are superlatively beautiful and noble: the north and south fronts in particular are very perfect pieces of architecture, neither ought the east to go without due applause. The two spires at the west end are in a finished taste, and the portico with the ascent, and the dome that rises in the centre of the whole, afford a very august and surprizing prospect; but still, with all these beauties, it has certainly yet more defects; and the pleasure we receive from the first is so much qualified and tamed by the last, that we rather wonder how we can be pleased so much, than why we are displeased at all. But not to condemn in the gross, I will take the liberty to touch upon a few particulars, and lay myself justly open to censure, in case I mistake, or blame in the wrong place.

In the first place therefore, there is a most notorious deficiency in point of view; such a huge fabric as St. Paul's ought at least to be surveyed at the distance of Temple-bar, and the vista ought to be considerably wider than the front of the building. But this is so far from the case here, that we cannot see it till we are upon it, and this defect is still made worse by turning the edifice from the eye even where it can be viewed, for the sake of that ridiculous superstition of erecting it due east and west. In the next place, the dividing the portico, and indeed the whole structure into two stories on the outside, certainly indicates a like division within: a circumstance abounding with absurdities, and defeating even the very end of erecting it at all. If indeed the architect had been embarrassed to reconcile the distance and height of his columns, I am humbly of opinion that a light and proper attic story had answered all ends both of use and beauty, and left him room to have enlarged his imagination, and have given an air of majesty to the whole: let me add that I apprehend the portico should have been farther projected on the eye, instead of retreating from it, in order to have given a grand contrast to the whole front, and aided the perspective within.

I shall say no more on the outside than this, that according to my best notions of regularity and order, the dome should have been raised exactly in the centre of the whole, and that there should have been two corresponding steeples at the east as well as the west end, with all other suitable decorations: if a view of the whole length of the building, too, could have been opened to the water-side, it would have added greatly to its grandeur and magnificence, and have afforded a most noble prospect from off the river into the bargain. However odd or new the first of these propositions may seem, let any body take a view of St. Paul's from any of the neighbouring hills, and they will instantly discern that the building is defective, and that the form of a cross is more favourable to superstition than beauty; in a word, they will easily see at least, that the dome, in its present circumstance, is abundantly too big for the rest of the pile, and that the west end has no rational pretence to finer and more splendid decorations than the east.

Before we begin our examination of the inside of St. Paul's, it will not be amiss to cast an eye on the statue in the area before it, erected in honour of the late queen. It stands exactly in the front of the building, though it seems, by the odd situation of Ludgate Street, to be on one side, and is, upon the whole, modelled in a tolerable taste, and executed as well; the principal figure, indeed, the queen herself, is an exception to this character; such a formal Gothic habit, and stiff, affected attitude, are neither to be endured or pardoned, and there is not one of those round the base that does not justly deserve the preference.

Whoever understands the nature of public ornamental buildings critically, always lays it down for a rule, that they cannot be too expensive or magnificent; for which reason St. Paul's is so far from being admired for being so grand and august as it is, that nothing is more common than to hear it censured for not being more so. Every body knows that the fund which raised it from its ruins to its present glory, was equal to any design of beauty or majesty; and as those who had it in trust went so far towards this necessary end, it is a thousand pities they did not carry it on much farther, and make this pile not only the ornament of Britain, but the admiration and envy of all Europe. St. Peter's at Rome was already built; a model which the most finished architect need not have been ashamed to imitate, and as all its particular beauties have been long publicly known and admired, I think it was incumbent on us to have equalled it at least; and if we had excelled it too, it would have been no more than might have been reasonably expected from such a nation as ours, and such a genius as Wren.

On these principles it is that men of taste and understanding are surprized, at entering this church, to see so many faults, and miss so many beauties; they discover at once that it wants elevation to give it a proportionable grandeur, and length to assist the perspective; that the columns are heavy and clumsy to a prodigious degree, and rather incumber the prospect than enrich it with symmetry and beauty; half the necessary breaks of light and shadow are hereby wanting, and half the perspective in general cut off; at the same time I do not deny but many parts of the decoration are exceedingly grand and noble, and demand very justly a sincere applause. The dome is, without question, a very stupendous fabric, and strikes the eye with an astonishing pleasure; it is, indeed, one of those happy kinds of building that please all kinds of people alike, from the most ignorant clown up to the most accomplished gentleman; but yet even here the judge cannot help taking notice that it bears no proportion to the rest of the building, and that after you have seen this, you can look at no other part of it; whereas a judicious builder would husband his imagination, and still have something in reserve to delight the mind, though nothing perhaps could be contrived to surprize after it.

For example, the very nature of a choir would not admit of any thing so marvellous as the dome, yet it might have relieved the eye with something equivalently beautiful; the entrance in front might have been more noble and uniform, either composed of wood entirely or marble, for the present mixture of both makes a disagreeable piece of patch-work, that rather disgusts than entertains; the opening on the inside, through the present beautiful range of stalls, might have terminated in a much more magnificent alcove than we see there at present, adorned with all the elegance and profusion of decoration; the altar should have been raised of the richest marble in the most expensive taste, that it might have been of a piece with the rest of the church, and terminated the view of the whole, with all the graces of the most luxuriant imagination. All the intermediate spaces should have been filled up with the noblest historical paintings; all the majesty of frieze-work, cornices, and carving, heightened with the most costly gildings, should have been lavished to adorn it, and one grand flow of magnificent curtain, depended from the windows, to finish and adorn the same.

Thus have I been free enough to give my impartial opinion of St. Paul's; I hope not too presumptuously, and if ignorantly, let every reader's private judgment set me right.

St. Andrew's Holborn, has the advantage of a very good situation, but then it deserves it as little as any modern church in the whole city. The tower is even below criticism, but the inside of the building makes amends for the awkwardness of the out; and is really as neat and well-finished as the manner and taste it is formed in will allow.

Temple Bar is, indeed, the handsomest gate about town, and deserves some degree of applause; if it has any fault, it is this, that the top being round as well as the arch underneath, the whole wants that contrast of figure which is so essential to beauty and taste. The statues on the outside are good, their only disadvantage is the hurry of the place where they are to be viewed, which makes it dangerous to be curious, and prevents the attention to them which they would otherwise command.

The structure of the Temple Gate is in the style of Inigo Jones, and very far from inelegant. I wish I could say the same of the different detachments of building which belong to it, but that is far from being in my power, nor ever can or will: the property is so divided and subdivided, that it is next to impossible that any agreement should ever be made in favour of harmony and decoration. It is certain that nothing can be finer situated than the Temple, along the side of the river, and if we consider the elevation of the ground, and how far it extends, the most barren invention cannot fail of conceiving the uses it might be put to, and the beauties it would admit of. At present there is but one thing which is worth observing in the Temple, and that is the old church which belonged to the Knights Templars of Jerusalem: and the outside even of this is covered from the view, that the whole might be of a piece. The inside indeed is yet visible, and may justly be esteemed one of the best remains of Gothic architecture in this city. The form of it is very singular: you enter first into a large circular tower, which at top terminates in something like a dome, and has a very good effect on the eye; beyond, opposite to the entrance, the church extends itself in three aisles, and is built and finished with as much elegancy and proportion as the taste of those days would allow.

From the Temple it is but a natural step to Lincoln's Inn; but, by the way, it is worth a stranger's curiosity to visit the habitation of the Master of the Rolls, which is certainly built with elegance and convenience, and can be blamed in nothing but its situation, which is undoubtedly as bad as the building itself is good.

Lincoln's Inn may reasonably boast of one of the neatest squares in town; and though it is imperfect on one side, yet that very defect produces a beauty, by giving a prospect to the gardens, which fill the space to abundantly more advantage. I may safely add, that no area any where is kept in better order, either for cleanliness and beauty by day, or illuminations and decorum by night; the fountain in the middle is a very pretty decoration, and if it was still kept playing, as it was some years ago, it would preserve its name with more propriety, and give greater pleasure into the bargain.

The outside of the chapel belonging to this society, is a very good piece of Gothic architecture, and the painting on the windows has a great many admirers within; in my opinion, indeed, it does not deserve quite so much applause as it has received, because the designs are poor, the faces have little expression, and there is little reason, beside a blind regard to antiquity, to extol them at all. The raising this chapel on pillars affords a pleasing, melancholy walk underneath, and by night particularly, when, illuminated by the lamps, it has an effect that may be felt, but not described.

The gardens are far from being admirable, but then they are convenient; and considering their situation, cannot be esteemed too much. There is something hospitable, too, in laying them open to public use; and while we share in their pleasures, we have no title to arraign their taste.

As I find my business increase upon my hands, as I come nearer the polite end of the town, I shall be obliged to divide it into three distinct walks, that it may appear in something like method, and be a better guide to the stranger, or man of taste and curiosity: in the first I propose to go from Lincoln's Inn Fields to the end of Piccadilly; in the second from Temple Bar to Westminster; and in the last from Gray's Inn to Grosvenor Square.

(To be continued.)

CATHOLIC CHAPELS—MR. PUGIN.

SIR—Your correspondent P. S. (as well as some other contributors to your Journal), evinces what appears to me to be a very needless jealousy of the name of "Pugin," and appears to wish to throw discredit upon the statement of the "Argus," that no fewer than seventeen Catholic Chapels are being erected under that architect. Mr. Pugin has certainly done much to excite the jealousy and spleen of Protestant architects, by the severe rubbing up which he has given us; but would it not be better for us to endeavour to learn wisdom from our enemy, (if he is such), than to content ourselves by showing our spleen at every mention of his name? Would it not be more prudent and more creditable for us to eradicate the errors of taste which he has so mercilessly exposed, rather than to bolster ourselves up with the idea that his lampoons are undeserved, or that he is himself equally open to attack? There can be no reasonable doubt of the fallacy of Mr. Pugin's theory that every architectural vice took its rise among the Protestants, and that every merit belongs to the Romanists; there can be no question that though the "Gothic" styles were invented and brought to perfection among the Catholics, they were also first *relinquished* by the Catholics, and (in modern times) first revived by the Protestants. There can be no doubt that Mr. Pugin himself imbibed his taste for these styles while a Protestant, and that he has since been the first to impart this taste to the Catholics, who had previously (in our times) evinced little or no taste for the works of their forefathers—so that this theory of Mr. Pugin's evidently falls to the ground. This, however, so far from vindicating Protestant architects from the charge of bad taste, removes the excuse which even Mr. Pugin made for them. Mr. Pugin's equally severe, and more just criticisms on the modern Catholic Chapels, have been so well received, that we immediately find chapels starting up in every part of the kingdom, in the purest taste, and many of them on a scale of magnificence which would not have disgraced the best ages of Christian architecture. It now remains for Protestant architects to display their zeal and their talents in a similar manner, and to give practical proof that they have been unjustly handled, rather than to attempt a petty revenge by detracting from the merits of a rival, who with all his eccentricities, is beyond comparison the first Ecclesiastical Architect of the day.

I am, Sir, your most obedient servant,

A PROTESTANT ARCHITECT.

London, June 10, 1840.

P.S.—Among the Catholic "Churches" or Chapels I have seen or heard of as being erected, or about to be erected by Mr. Pugin, are those at Derby, Birmingham, Manchester, Keighley, Whitby, Dudley, Reading, at or near Worksop, St. George's Fields, &c., as I have only accidentally seen or heard of these, and have forgotten many more I have heard of, I have no doubt that the number exceeds that named in the "Argus."

ON THE HORIZONTAL AND PERPENDICULAR LINE IN ARCHITECTURE.

BY FREDERICK EAST, M.A.

(Concluded from page 187.)

I had intended with submission to any opinions current amongst professional disquisitors upon the subject of horizontal and perpendicular lines, to have included in the pourtrayal of that matter, a few remarks upon the subject of broken entablatures, so often noticed in a critical way, by the jealous guardian of consistency in classical architecture. Avoiding, however, any further intrusion into the columns of last month's Journal, than the subject *actually* required, I reserved that privilege for the next, and in offering a few opinions upon so interesting a theme, do so with the idea that as this breaking of the cornice is one of the peculiarities of the Palladian school—and of perpendicular Italian; there is a natural link between it and the subject of my last paper, namely, lines.

Some conceive the fashion for breaks, an Italian prejudice discordant with the harmony of correct art, and generally condemn their use as unwarrantable and unmeaning. Others again, in the warmth of their attachment for certain masters, would follow them into every caprice of taste, and find their very eccentricities engaging. I humbly conceive nevertheless, that we cannot employ these breaks, frequently, nor perhaps at all, if the imagination is to be *rigorously* affected,—or if the building, whether in plan or elevation, consists of many parts; since greatness of manner would disappear at once from the superficies, and the eye would compass something of what is little and mean.

Inigo Jones must not lose cast however because he introduces these breaks, and frequently. Popular taste at his time, coveted every thing that was Italian. The king, the court, and nobility, had already conceived these notions, which led them afterwards to vie with each other in the treasures of Italian decoration.

Inigo Jones in the Banquetting House, Whitehall, betrays something more than the ordinary sentiment of his school, by an introduction of these breaks in the façade. That licence so congenial to artist's feelings, seems there betrayed without violence to symmetry; and the effect generally entailed upon their adoption, seems lost in the happiness of his idea.

In the first place the front without them is sparing of details and of breaks. In the second place the building itself was one dedicated to mirth and pleasure: and ideas of strict utility or true support are waved, when the imagination is supposed to be affected by something of the sprightly joys and jovial spirit reigning within. The exterior reveals the interior; you care not as you gaze with your thoughts undisciplined upon the edifice of pleasure, whether you see the column relieving a depending weight, or supporting the various breaks of the entablature. The artist sought to please, and not to affect—to cheer, and not to impose.

With reference to the Persian court, in the design for the Whitehall Palace. There is a freedom, an ease, nay an almost negligent air, in the breaks and the figures that support them—and the object in view here, I conceive was, to please the eye of the king and his favourites. As if stiffness and solemnity were unwelcome to that monarch and his court:—as if the severities of rule, and the sternness of power, were to vanish at once in a building sacred to ease and kingly relaxation.

However much we may dislike their introduction as a custom in architecture—however much we may blame them viewed in the perspective of a street, and confusing to the eye in half profile, there seems something of agreeable pleasure in their aspect when displayed internally.

In his own dwelling, free from the struggles of life and the world, the statesman is half enchanted into playfulness, by the careless assemblage.—The accurate line, the finish of care the student displays, tending to renew thoughts of care and disquietude—vanish in the varied forms of the columns, which ministers to his ease, sooth and tranquilize, the brow of concern.

There is indeed a strange beauty in architecture. Like the composition of the poet and the painter, the design of the architect is at once a tale of interest—a delusive fiction or a startling truth—and the architect most insidiously works upon the gazer, who most studies the secrets of mental impression.

ON SUB-MARINE FOUNDATIONS.

Sir—There is in your last Journal a description of a light house lately erected under the auspices of Commander Denham, R.N., on a sand bank at the entrance of the Wyre Navigation. This structure has been supported upon and secured to the bank with Mitchell's patent screw moorings. The introduction of this principle to the mooring of vessels is good in the opinion of those who have tried them. They are durable, very compact, and take a firm hold of the ground by means of the flanges, which make them exceedingly applicable for that purpose; in rivers and in harbours they can be screwed down without much difficulty, through mud, sand, or shingle to a certain depth. They are, however, an expensive article, if we take into account the providing of barges and the labour of screwing them down, together with the patentee's charge for the mooring itself.

It would therefore have conferred a favour upon the profession if along with the description of the lighthouse we had been also informed of the cost of its erection. I am quite sure that it might have been done at far less expense on the old principle of driving piles into the ground.

The mooring screws are stated in the drawing to be 10 feet below low water mark, which I suppose may allow them to be 8 feet into the sand. Now the expense of a 3 feet mooring with the patentee's charge and the labour in fixing it to this depth would be about £50. On the other hand the cost of driving a pile, say 12 feet into the ground, with the additional length of timber, would not cost one-tenth of the sum, and piles can be driven into as firm a foundation as the screws. Where then is the great advantage of the screw mooring so applied but to increase the expense.

Again, in my opinion the framing ought to have been quite naked from half tide upwards, to prevent as much as possible the shock of heavy seas from injuring the structure, therefore, much dislike "the systematic interlacing of tension rods to render the fabric sufficiently opaque below the platform." I am also much mistaken if this system of bracing will not cause the tide to scour away the sand from the feet of the framing, and expose the screws to its action.

No practical engineer would in my opinion have adopted such a design.

I am Sir, your obedient servant,

One of the Old School.

TIDES OF THE OCEAN.

Sir—The Newtonian theory of the tides having been questioned by many, in which, I confess, I participate, I should esteem it a great favour, if some of your intelligent correspondents would weed my mind of the doubts that have taken deep root on this subject.

If the moon be the influential cause of the rise and the fall of the tides, why is her influence not universal?

Why does she seem to exercise her influence so powerfully on one sea, less in another, and not at all in others, and why is her supposed power entirely subdued by the effects of particular winds on certain coasts?

Why does the tide, ebb and flood, commence at each turn of the tide to run at the bottom of the sea before the water moves on its surface?

What is the cause that, at an island in the South Pacific Ocean, the time of high water is always the same?

I am aware that the moon and the tides retrograde coextensively, but this does not prove a coincidence.

I am aware, too, that it is said, by way of establishing a theory, that the Baltic and Mediterranean seas are not of sufficient expance to admit of the moon's influence—although the seas are much more extensive than the English or Irish channels—but the real cause why there is no ebb and flow tides in those seas is, that the seas do not rise or fall at either of the points connecting them with the ocean; for the flow and fall of the tides, and the velocity with which the current passes out and in of a tidal harbour or arm of the sea, is governed by the velocity and rise of the tides at the entrances thereto, and therefore, without looking for any other cause, here is the real *cause*.

The great difference of flow in the same sea, has, hitherto, not been satisfactorily accounted for.

Thus, for example, the flow on the eastern shores of America opposite the Straits of Gibraltar, is 30 to 40 feet—*none* on the latter.

A flow on the Pentland Ferbs and along the north coast of Scotland, of 20 or 30 feet; on the coast of Norway opposite, and at the Cattegat, the entrance to the Baltic, no rise in the water.

In the Irish Channel, on the coasts of England and Wales, the flow of the tide is great; on the Irish coast opposite, a small rise of the tides.

In the English Channel, on the French coast the flow is great; on the English coast but comparatively small.

If an allowance is made for the particular formation of parts of the coast, and other local circumstances, they are not sufficient to establish the accuracy of the Newtonian hypothesis on the tides.

I remain, your's, &c.,

14*th June*, 1840. Nauticus.

WATER OF THE VISTULA.

Sir—In your Journal of last month there appears an account of the casualty in Prussia,—the water of the Vistula having been diverted from its former course, and forced for itself a passage into the Baltic Sea in a new direction, at some distance from its former disemboguing point, *i.e.* via the Old Fairwater. As the current had previously, from times immemorial, passed into the ocean at the latter point, with great sluicing and scouring velocity, produced an impassable bar, so will the water, which now runs out at the new point, produce the like effects, by forming a bar at its new disemboguing point.

The bar at the Old Fairwater having some years back blocked up its entrance, and prevented ships entering to go up to Dantzig to discharge and load their cargoes. A new lateral cut was made, and so formed a passage to sea via the New Fairwater; and at the connecting part of the New Cut with the Vistula, a gate was fixed to prevent the current passage running to sea through the New Fairwater, and although this work has been completed for many years, no bank or bar has been formed at the new entrance, so that the egress or sluicing water constantly in its egress action, has blocked up the old entrance, but as there is no water or current passing to sea by the new Fairwater, no bar accumulates.

The division of the current, before alluded to, cannot in any way affect the entrance to Dantzig by the New Fairwater, but if the current of the Vistula should continue its new course, and not again return to its old channel, a material alteration will soon be discovered in the bar or bank at the entrance of the Old Fairwater.

Nauticus.

ON OBLIQUE ARCHES.

(In Reply to Mr. Buck, C.E., &c. &c.)

Sir—In consequence of what has already appeared in your Journal, I trust to your candour to insert my answer. I consider, Sir, that the insertion of it is not only due to me, individually, but to all who are interested in practical attainments. The facts which I state in reply are plain, and whilst they expose undue pretension, they have the merit of being in themselves irrefutable.

I am, Sir, very truly your's,

Peter Nicholson.

My attention was accidentally called, about the first instant, to an article in the *Railway Magazine*, of the 25th of January, 1840, written by Mr. G. W. Buck, of Ardwich, Manchester, in reply to some remarks which appear in my Treatise on the Oblique Arch, respecting some inconsistencies in certain formulæ, &c., in his "Essay" on the same subject. Mr. Buck says in his reply,—"At page 8 of his preface, in speaking of the forms of his templets which are necessary for working the stones, Mr. Nicholson says—'they are not shown by any other author who has wrote upon the subject.' Now, if Mr. Nicholson will refer to the 3rd chapter of my "Essay," he will find that chapter to be exclusively devoted to an explanation of the method of making the templets and working the voussoirs; moreover the fifth plate contains eight diagrams exhibiting the forms of these templets." Now, Sir, I *have* examined the third chapter of Mr. Buck's "Essay," and I can find *no* method explaining the making of the curved edges of the templets, Nos. 1 and 2, plate 26, in my work, to which I refer when I say "they are not shown by any other author who has written upon the subject;" and I have also examined the fifth plate in his "Essay," which, Mr. Buck says, contains eight diagrams exhibiting the forms of these templets, and I have been equally disappointed, for I can find *no such templets exhibited*. Mr. Buck does not even show how the radius of curvature of these templets may be found; neither does he give a hint that they are necessary. The arch squares, Nos. 3 and 4, entirely depend upon the curved edges of No. 2, and No. 1. Now, Sir, that Mr. Buck should have made these assertions is, to me, a matter of the utmost surprise, seeing that he must have known, when he made them, that he was deliberately stating that which was incorrect. The only method which Mr. Buck gives for working the arch stones is a very complicated and a very clumsy one, the principle of which he has taken from the 55th page of my work on Stone Cutting, published 12 years ago, and which method is much more difficult, even for a person possessed of considerable mathematical knowledge, to work by, and at the same time much more liable to error, than the method which I give, and which, in order to guard against error, I have adapted to the understanding of the most ordinary mason. In fact, it requires very little more attention than a common square segmental or semicircular arch, and the rules, or squares by which the stones are wrought are exceedingly simple in their construction. On this point it may not be amiss to add that although every mason is naturally inclined to work the bed of a stone first, yet, the first conception which I had of forming the stones of an oblique arch was certainly the most rational: first to form the soffit, then one of the beds, and lastly the other bed. And I did this because it was easier to conceive how the spiral surface might be obtained from the cylindric, than the cylindric surface from the spiral surface. This method of working the arch stones was, I believe, adopted from the year 1828, when my book on Stone Cutting was published, and continued until the year 1836, when Mr. Fox published a small Tract, as an original work on Oblique Arches, supposing himself to be the inventor of all that was known upon that subject. He says:—"But I am not aware that any rule has been published that would enable the stones to be wrought at the quarry into the desired form." The templets which Mr. Fox uses are shown in my Treatise on Masonry and Stone Cutting, plate 17, where the two equal circular-edged rules, Z, Z, the straight edge Y, and the arch square γ are those which he employs. Mr. Fox, after some trials in working arch stones, preferred to form the bed to the spiral surface of each arch stone first; and he was certainly the first to apply the winding straight edges for working the spiral surface of the beds, and to show the angle of the twist.

Mr. Buck next goes on to reply to the inconsistency which I noticed in certain formulæ, in his "Essay," and in one part of his Letter he says:—"Here I take the opportunity of saying that, after making the discovery of the mutual convergence of the chords of the curves of the joints of the face of the arch, and after obtaining the formulæ applicable thereto, I long sought in vain for a *demonstration* of the generality of this property. On applying to my mathematical friends, both in London and in Cambridge, I was equally unsuccessful. Under these circumstances, being experimentally quite certain of the existence of this property, I assume it as a postulate in the "Essay," and the whole of the investigation contained in the 7th, a concluding chapter (*the only part of the work which I consider theoretical*) is based upon it. The publisher, Mr. Weale, well knows how anxious I was to have given a demonstration in the work, and that I was finally under the necessity of publishing it without, although no one appears to have noticed this deficiency." This, Sir, I consider to be a sufficient admission of the justness of my remarks, and one which renders it perfectly unnecessary for me to allude further to those remarks at this time. Mr. Buck also says: "It is not my wish or intention to be drawn into a review of Mr. Nicholson's book, but I think it right to make the following few remarks. In problem 9, referring to plates 28 and 29, he gives directions for radiating the joints of the face of the arch in two different ways. By his first method the joints are to be at right angles to a tangent to the elliptic curve: by the second method they will radiate to the point of convergence, which I have denominated the focus; this latter method is that given by me, and which Mr. Nicholson has here adopted. Now, if the voussoirs be worked in spiral beds, *according to his rules*, they must necessarily radiate in this way; and consequently they cannot be made to radiate as described in his first method, *unless the beds are worked in some other way, the directions for which he has not given.* This dilemma leads me to infer that Mr. Nicholson is not practically familiar with the subject on which he has written. I have confined myself to the points referred to by Mr. Nicholson's strictures, or I might have added more on the subject."

Now, Sir, I will reply to these "remarks" in their order, premising that I never have objected to any one reviewing my works *provided that they are competent to the task*, and provided also that they come to the performance of that task in a fair and manly spirit! Now, Sir, first, as to the radiation of the joints. The lines $b\,h$, $c\,i$, $d\,j$, &c., (plate 28 in my book) are not the joints, neither are they intended to be representations of the joint lines; they are merely to direct the construction of fig. 2, in the same plate, in order to find the angles made by lines approximating nearly to the joint lines of the face of the arch, and tangents to the bed lines, or the angles made by these approximating lines to the joints on the face of the arch and tangents to the bed lines at the points in which they meet the plane of the face of the arch; and, in speaking of these lines in my work, at page 16, I say that the method is a near approximation, and that its simplicity is ample compensation for its introduction. Plate 29 of my "Guide to Railway Masonry," was engraved at the same time as plate 20, and is the same in every respect, as regards the construction of the two developements. Plate 20, and its explanation in page 6, was published in Part 2, May 11, 1839, and is referred to at page 27, as being necessary in the construction of plate 29. From the difficulty of getting the proofs from the printer, the third part was divided into two half parts; the first of which was published in August, and the second in November, at Newcastle-upon-Tyne, Mr. Buck's work being published in July, and the 29th plate in my "Guide," shewing the method of drawing the joints, and which Mr. Buck says I have "adopted" from his work, being published in August, there was not time for me to have "adopted" his plan, even if I had been driven to such a strait as to think of, or to stoop to, such a thing; and, moreover, I can prove by my engraver *that all the plates in my book were finished* four months *before the letter-press could be got from the printer, and a very considerable period before the publication of Mr. Buck's "Essay."* The joints in the elevation of the arch, plate 29, are drawn by an entirely different method from that used by Mr. Buck, although it may, perhaps, amount to the same thing, and are found by making the developements of the intrados and extrados of the arch, and transferring the points made in each developement by the joints to its corresponding curve in the elevation. These points being joined form the chords of the curves which form the joints in the elevation. We all know, Sir, that "facts are stubborn things," and I leave Mr. Buck to reconcile these facts with his somewhat fugacious assumption that I have "adopted" *his* plan in *my* book.

I now proceed to the second part in which Mr. Buck says—"this dilemma leads me to infer that Mr. Nicholson is not practically familiar with the subject upon which he has written," &c., and upon this point I will refer Mr. Buck to the 10th page of the History of Oblique Arches, in my work, which will, I think, convince him, if he be capable of conviction, that I was perfectly aware, when I wrote my work, of the nature of the joints in the elevation of an oblique arch; in addition to this, I may say that I have seen *nine* oblique bridges on "the Newcastle and North Shields Railway," and *five* on "the Brandling Junction Railway," all executed in stone, on the principle laid down by me, making, upon the two Railways *fourteen* bridges within a distance of about *eight* miles from Newcastle, and built, as it were, under my own immediate inspection. To this I may add, that one oblique bridge was built on "the Hartlepool Railway" in 1834, precisely on my principle, and that I have had the satisfaction of seeing all the stones which were formed by my templets unite closely without requiring the slightest alteration. By this bridge on "the Hartlepool Railway," I clearly show that a bridge was executed from the principles laid down in my Treatise on Masonry and Stone Cutting BEFORE ANY OTHER WORK WAS PUBLISHED ON THE SUBJECT, and that the templets shown in my "Guide to Railway Masonry," plate 26, No. 1, No. 2, No. 3, and No. 4, are decidedly my own discovery or invention The finding of the angle of the twist is due to Mr. Fox, and I have already said the discovery of the point of convergence in which the chords of the curve of the joints of the arch stones in the face of the arch meet each other is due to Mr. Buck; but I here tell him that although the finding of this point is very useful in drawing an elevation, it is not absolutely necessary in the construction of the oblique arch: and I again maintain that, from the want of proper definitions of the terms used by him, he has written very obscurely of the principles on which he professes to treat, even in describing the common-place things contained in chapter 3. As a farther proof of the correctness of my principles, I insert the following letter which was spontaneously addressed to me by Mr. Welch, C.E., and Bridge Surveyor for the County of Northumberland:—

"Elswick Villas, Newcastle, April 18, 1840.

"To PETER NICHOLSON, ESQ.

"Sir,—Having now seen my design of the Oblique Bridge over the River Tees, on the line of the Great North of England Railway, successfully carried into effect, I am enabled to speak with certainty upon the correctness of your published principles for the construction of Oblique Arches. My bridge consists of four arches, built at an angle of 50°, the chord of the right section of each arch is 45·96 feet, and that of the oblique section is 60 feet. I may also state that I consider your work on the oblique arch the most practically useful of any that I have seen: and as the structure which is near to Croft fully warrants the highest opinion of it, I beg, as a member of the profession, for which you have done much, to thank you for the great pains you have taken in working out so clearly the principle of the Oblique Arch.

"I am, Sir, your most obedient servant,

"HENRY WELCH, Civil Engineer."

I think, Sir, I may safely place this testimony of a *practical man*, against Mr. Buck's assertion that I was not familiar with the subject upon which I had written!

I will now notice one very distinguishing feature between Mr. Buck's work and mine, although based upon the same principles:—Mr. Buck's work is only intended for the use of those who may happen to have been trained in a proper course of mathematical study, and which, I believe, is not the case with a tithe of the young men for whose use, chiefly, Mr. B. has written his book. On the other hand, mine is intended as a purely practical work, and as such, I have shown in it, how every useful length, distance, or angle of an oblique arch may be found, principally by common arithmetic, from the doctrine of similar triangles.

Since the above was written, I have seen an article signed "W. H. B." in the "Civil Engineer and Architect's Journal" for May, 1840, purporting to be "a few remarks on the construction of oblique arches, and some recent works on that subject, but which is, in fact, a mere echo of Mr. Buck's letter, and an ill-natured review of my book, written by some tyro, who understands lamentably little of the subject upon which he professes to write. W. H. B. says, in speaking of my book, "there is a problem 'to find the curved bevels for cutting the quoin heads of an oblique arch,' the reader being unable to learn, from the heading of the problem, whether it relates to square or spiral joints, naturally proceeds to wade through it, with the hope that it may afford some means of ascertaining this fact, but here he soon becomes lost in a labyrinth." Now, sir, I assert that W. H. B must either have been very inattentive, or very stupid, not to have observed to what species of joints the problem referred, since every page in which I treat of the oblique arch has the words "*On the Oblique Arch with Spiral Joints*," placed in capitals over it. W. H. B. next says, "you are told to divide the arc ABC into as many equal parts as the ring-stones are in number, and through the points of division draw *bk*, *ci*, *dj*, &c., perpendicular to the curve ADE." Again, he says, "you are told to join *am*, *bm*, *cm*, &c., but where the point *m* is to be placed Mr. Nicholson has quite forgotten to say." Here I acknowledge an error in point of reference; where I say divide the arc ABC, it should have been divide the arc ADE, which every *impartial* reader would have seen was a mere error in the type, as I immediately mention the arc ADE again, and I have also omitted to say, "draw GM perpendicular to GL." To show W. H. B. how difficult it is to keep clear of errors in printing, I will point out, in the two last sentences which I have quoted from him, no fewer than five blunders—*bk* is an error, there is not a *k* in the page in my book to which he refers; it ought to have been *bh*. Neither is there an *m* in the page, which he has mentioned four times. W. H. B. should at all events transcribe correctly from a work which he professes to criticise so profoundly, or he will assuredly lead both himself and others into "a labyrinth!"

I now state again to Mr. Buck, that neither himself, nor any other writer upon the oblique arch, has shown the templets by which the arch-stones are wrought by my method, and that I am the inventor of all those templets; and I further distinctly tell him, that *had he not pirated his principles from my work on stone cutting, his "Essay," in all probability, would never have been in existence.* I will also tell him that, however fine the theory of the principles of any scientific work may be, those principles will be literally useless, if not *properly adapted to the capacity of the person who has to execute the work!* That I have always considered as the grand object to be attained, and I think I may say, without vanity, after having received testimonials both *publicly and privately*, that I have not been altogether unsuccessful. The draughtsman will find my work on the oblique arch to be as useful and as simple in the delineation of his plans as any work on the subject in existence.

Now, Sir, in conclusion, let me state to Mr. Buck, that this may be the last time that I may have an opportunity of addressing him: for I am now an old man, and, in the ordinary course of nature, may be considered as standing upon the brink of the grave, and am, therefore, unable to undertake the exertion of further controversy with him. What I have done for the working man will be a theme for posterity, when neither Mr. Buck nor myself will have the power of hearing it. I pray that this may not be deemed the boast of an old man—as such it is not intended—but I have thought it my duty to say so much in justice to my own character, with which Mr. Buck has taken such unwarrantable liberties. I could not have rested satisfied without giving vent to my feelings at the ingratitude which Mr. Buck has shown. But, Sir, I have now done with him, and

"PALMAM QUI MERUIT, FERAT!"

PETER NICHOLSON.

Newcastle-on-Tyne, May 23, 1840.

SIR—In my paper on Oblique Bridges in reply to B. H. B., which is published in your Journal for this month, I have inadvertently inserted a few words which are incorrect, and ought to be expunged. At the second line from the bottom of the first column of the 198th page, the following sentence commences:—"this triangle must be supposed to exist in the thickness of the arch, *and to be parallel to a tangent plane at the point sought*, and therefore," &c. The words in italics I ought not to have inserted, and I shall be obliged by your giving notice to this effect in your next number.

Your most obedient servant,

Manchester, June 8, 1840. GEO. W. BUCK.

Antiquarian Discoveries in France.—"A discovery has recently been made at Bougon, near Mothe-Saint-Heray, in the Two Sevres, of a tumulus, which promises to throw great light on the civilization of the ancient Celts. A gallery and vast grotto has been opened. It is formed of nine stones in erect positions, covered by a slab twenty-six feet three inches in length. The interior is completely filled with bones. The head of each skeleton touches the walls of the grotto, and by the sides of each vases of baked earth, containing provisions for the use of the deceased in the other world, the wahala or paradise promised to the brave. Nuts and acorns are found in these vases in perfect preservation. There have also been found two hatchets and two knives made of flint, several smaller sharp instruments, the use of which is not known, two collars, or necklaces, one of shells and the other of baked earth, several bears' tusks, the bones of a dog, and a plate, upon which there are fragments of a rude design. Four of these vases are perfect: two of them very much resemble flower-pots: a third has the form of a soup-tureen; and the fourth, though much the smallest, is the most curious, as it is the cup of a Druid. The tumulus is two hundred paces in circumference, and between eighteen and twenty feet high. Its formation may be placed at 2,000 years ago. The vases and utensils attest the infancy of the arts, and the nascent civilization of a barbarous people."—*Quotidienne.*

Ancient Monuments.—A discovery has been made in a cellar in Paris, at the corner of the Rue Mauconseil, in the Rue Saint-Denis, of nine figures in stone, the size of life, having the heads and garments coloured and gilt. They are the figures of saints and kings, and one of them wears a helmet. They apparently belong to the earliest times of the revival of art; and have, in all probability, been buried where they were found, to escape the ravages of some outbreak of Iconoclasm. It is probable that they belonged to the ancient church of the *Pelerins de Saint-Jacques*, which stood near the site of their discovery.

AN ESSAY ON THE CONSTRUCTION OF OBLIQUE ARCHES.*

By Edward Sang, M.S.A., Civil Engineer, Edinburgh.

(Abridged from the Edinburgh New Philosophical Journal for April.)

Scarcely any branch of civil engineering bears so closely on the advancement of civilization as the art of road-making. The immense sums that are annually expended on them evince the importance of our roads. Our object is not merely to find a path from one town to another, we must be transported in the most expeditious manner possible. Is there a declivity; thousands are spent to remove it: is a road suspected of being a few yards longer than is needed? a new line is immediately chalked out. One might almost imagine that a monomania had seized us, and that the tulip, the dog, the pigeon, and all the other fanciers had deserted their peculiar departments to concentrate their energies on this one grand matter of roads. The madness is a very reasonable one; for if there be a hill, multitudes daily climb and descend it: or if a road be circuitous, the quantity of unnecessary travelling might soon be sufficient to carry one comfortably round the globe.

While journeying, we are often annoyed by bridges. Sometimes, for cheapness, they have been erected far out of the line of road, and we enjoy, on one side of a river, the delightful prospect of doubling along the other. At other times, after skirting the banks as if on a journey to the source, we are all at once wheeled right across the water, and ere we are certain that our necks are yet safe, an equally sudden turn restores us to our original direction. And occasionally our vexation is crowned by an altercation between the drivers as to which of two vehicles is bound to back down the steep slope of some antiquated erection. That time has now gone by when a bridge of any kind was hailed with satisfaction; we have scarcely such a thing as a ford wherewith to contrast it, and having only bridges to compare with bridges, we have become somewhat nice in our taste. Many of the old high-backed bridges have been replaced by others with level road-ways; these again by bridges with road-ways inclined to suit the elevation of the opposite banks, and now another improvement is beginning to be called for, that of crossing the river obliquely, so as to make the bridge harmonize with the general line. This we may consider as the *ne plus ultra* in bridge building, for then the road-way over the bridge coincides both in plan and in section with the rest of the road, and therefore conducts us in the easiest manner possible from the one bank to the other. The skewed arch is inseparable from the railway, as by its introduction alone the engineer is able to free the line from awkward and injurious turnings.

Having been consulted concerning the construction of an oblique bridge of considerable magnitude, and never having met with any regular investigation into the theory of such structures, I was induced to undertake the analysis. The results of that analysis I proceed to lay before the Society of Arts, in the hope that, though I may be wrong in supposing them new, their publication may serve to disseminate correct notions on this intricate subject. It is a common idea that the oblique is weaker than the right arch, and that the twist of the stones causes a great waste of material. The truth is, that if both bridges be skilfully constructed, there is no difference in point of strength between them, while the twist on the arch-stone of the oblique bridge causes a most trifling loss of matter, and therefore our road trustees should never hesitate to adopt that which agrees best with the rest of the line. There is no limit to the obliquity, nor need even the several abutments run parallel with each other.

The general question of the construction of an arch resolves itself into two parts; the first relating to the connexion which ought to exist between the curvature of the vault and the weight piled on each portion of it, is absolutely identical in the two cases of right and oblique bridges, and is therefore left out in the present inquiry; the second, however, relating to the forms of the arch-stones, bears directly on the oblique arch, and will therefore engross almost our whole attention. The outline of the bridge and the form of the vault having been determined on, the problem becomes this: *To cover the surface of the centering with blocks of such sizes and forms as may insure the stability of the structure.* Now, if it be premised that the curved surface of the vault must never be vertical, the solution of the problem can always be attained.

It is clear, from the general form of a bridge, that the lines of pressure ought to run from one abutment to the other, and should be contained in vertical planes parallel to the walls of the parapet. Imagine, then, that the vault is intersected by a multitude of such planes, the lines of intersection will indicate the directions in which the pressures ought to be transmitted from block to block. Now the stability of a structure is obtained by making the surfaces at which the pressures are communicated perpendicular to the directions of those pressures, and therefore all that is required is to trace on the surface of the centering a line which may cross all the lines of pressure at right angles. In the case of the right arch, that line is a parallel to the abutment; but in the oblique arch it becomes bent in a peculiar manner.

At the crown of the cylindrical oblique arch, the joint-line is perpendicular to the parapet; of course, it begins to descend on the surface of the vault, and as it descends it gradually bends away from that direction to become more and more nearly parallel to the abutment. If the crown line be regarded as the absciss, and the line of pressure as the corresponding ordinate of the joint, the differential co-efficient of the line of pressure is in all cases proportional to the cosine of the inclination which its extremity has to the horizon. If there be, then, two closely contiguous joints, the portions of the lines of pressure intercepted between them will be proportional to the cosines of the obliquities, and hence it follows that the breadth (measured on a line of pressure) of the stones in a given course diminish in the ratio just mentioned. It is a well known principle, that the strain upon any arch stone is proportional to the secant of the same obliquity; and thus, if the depth of the stones be augmented to meet this increased strain, it would follow that each voussoir in any given course ought to exhibit the same extent of section by a plane parallel to the parapet. The arch stones, both for convenience of workmanship and for appearance, must be uniformly disposed from side to side; and hence throughout the whole structure they ought to be of uniform volume, with the exception of the half stones left at the end of each alternate course for the purpose of *breaking the joint*. The deepening of the arch-stones toward the spring of the arch is often, though very improperly, omitted ; in such case the above statement does not hold true.

Even although the arch-stones were all equally broad upon the centering, those nearer the abutments would appear narrower on the Ground Plan, the breadths of their projections being proportional to the cosines of their obliquity: hence the ground plan of an oblique arch must present a very rapid diminution of breadths toward the spring of the arch, the breadths of the projections being, indeed, proportional to the squares of the cosines of the obliquities.

The Side Elevation of a vault with uniform voussoirs would exhibit narrower intervals toward the crown, the breadths being proportional to the sines of the obliquities; hence the side elevation of a skewed arch must present narrow intervals both at the crown and at the abutment, and wider intervals upon the shoulders. The breadths are proportional to the products of the sines by the cosines of the obliquities; that is, to the sines of twice the obliquities; and thus the side elevations of those arch-stones which are inclined at 45° will be the broadest.

The End Elevation, or the projection of a joint upon the plane of the parapet, possesses the very singular property of being entirely independent of the angle of the skew, and of depending alone on the form of the longitudinal section of the vault. This curious fact can very readily be demonstrated. The projection of a right angle upon a plane parallel to one of its sides is always a right angle, and therefore the projection of the joint upon the plane of the parapet must cross the projection of every line of pressure upon the same plane perpendicularly. But the projections of all the lines of pressure are equal to, and placed side by side with, each other, and are so whatever may be the angle of the skew, so that the delineation of the end elevation of a joint, which requires only the tracing of a line that may cross all these at right angles, will be performed exactly in the same manner whether the bridge be more or less oblique. When the angle of obliquity diminishes to zero, that is, when the bridge becomes *right*, the end projections of the joints contract into mere points, which points are the commencements, so to speak, of the permanent curves above mentioned.

The end elevations of the *beds* of the voussoirs, or rather of the lines formed by the intersection of these beds with the planes containing the lines of pressure, are also normals to the lines of pressure, and must therefore be tangents to the end projections of the joints. From this it follows, that a short portion of a course, or a single arch-stone, is very nearly contained between two planes slightly inclined to each other; and that, therefore, the loss of material arising from the *twist of the stone* must always be insignificant. Those engineers who have experienced a loss on this account, have done so because their bridges

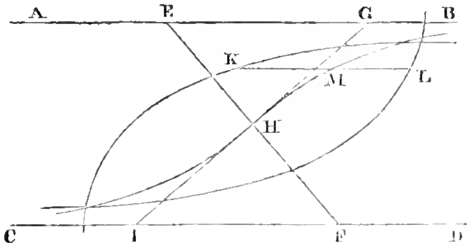
* Read before the Society for the Encouragement of the Useful Arts in Scotland, on 18th November and 2nd December, 1835; 27th January, 1836, and 16th May, 1838

were not properly designed. If the stones be obtained in *squared blocks* from the quarry, there will be a loss on the ends of the stones; but this, as every builder knows, can be avoided by proper management in the quarry. And thus, on the whole, the loss of material for the skewed bridge need not exceed to any extent worth naming that for the right one.

The above statements are true of cylindroid oblique arches, *whatever may be the forms of their principal sections*; they are at variance with the statements and so-called experience of engineers of established reputation: complete demonstrations of them are given in the appendix. They are equivalent to differential equations, and require to be integrated in order to give practical results; these results vary according to the particular form assumed for the longitudinal section of the vault. I proceed to give a few of these results, commencing, on account of its more frequent occurrence, with the circular arch.

On investigating the form of the projection of a joint of a circular oblique arch upon a horizontal plane, I arrived at a new curve, to which the name *Double Logarithmic* has been given.

Fig. 1.



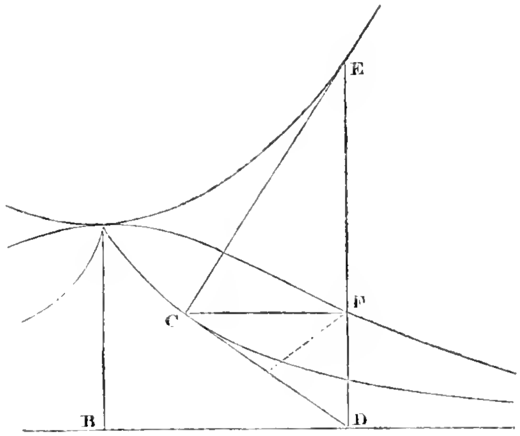
Having projected the entire semicylinder, of which only a portion can be used with propriety, let AB, CD, be the sides of the projection, and EF, parallel to the parapet, the plan of one of the lines of pressure. Bisect EF at right angles by GHI, and form two logarithmic curves of which AB, CD, may be the asymptotes, EG the common subtangent, their ordinates being parallel to EF. Then draw lines KL parallel to AB, and intercepted between the logarithmics, the middles M of these lines trace out the horizontal projection of one of the joints. The lines AB, CD, are thus asymptotes to the horizontal projection, and this geometrical property illustrates the mechanical impossibility of constructing a semicylindric arch, without trusting to the cohesion of the mortar. The introduction of the logarithmic curve into investigations concerning bridges, has been of great utility, and the analogy between this curve and the common catenary is striking. The catenary is also formed by bisecting the interval between two logarithmics; but these have a common asymptote with rectangular co-ordinates, while the bisected line is parallel to the ordinate. The computations needed for the delineation of such projections, are by no means tedious: they may be performed rapidly by help of Napierian logarithms; but a better method, capable of giving all the projections, will be explained shortly.

It may be expected, from what has been said of such elevations in general, that the end elevation of a circular oblique arch shall present some interesting peculiarity. The end elevation of a joint ought, in fact, to cross at right angles the circumferences of circles described with equal radius from points lying in a straight line; now, this is the distinguishing characteristic of the tractory, and that curve must therefore be exhibited on the end projections of all circular oblique arches.

On examining the projection of one of the joints upon a vertical plane perpendicular to the parapets, I obtained the genesis of a peculiar curve still logarithmic in its nature, and somewhat resembling in its form the superior branch of the conchoid. If we conceive the side elevation of the semicylinder to be traversed by horizontal lines, the distances intercepted on these lines bear to the corresponding distances intercepted by a certain normal curve, the ratio of cotangent of obliquity to radius. This normal curve, which belongs to an arch with its obliquity 45°, I have named the COMPANION TO THE TRACTORY; it admits of a very neat mechanical delineation.

Let a rod AB, equal in length to the radius of the arch, be made to rest upon a smooth board only at the point A, while the extremity B is guided along the line BD; A will, as is well known, describe the equitangential curve or tractory. Suppose that the guide to which the point B (or in an oblique position D), is attached, carries a vertical rule DFE, and that, on that rule, there slides a right angle DFC, one side of which is constrained to pass through C:* then will the point

Fig. 2.



F trace the *Companion to the Tractory*. A very simple addition will convert this instrument into that described by Leslie in his Geometry of Curve Lines, for forming the catenary. A grooved rule has only to be attached, making the right angle DCE, while the groove DF is continued to meet it: E then traces out the catenary. Since, *from the nature of the figure*, ED DF = AB², it follows, that the companion to the tractory has its ordinates inversely proportional to those of the catenary, and that, therefore, it might, with propriety, have been named the *inverted catenary*.

All these projections of the joints, and the forms too of the individual arch-stones, can be much more readily obtained from the delineation of the surface of the centering. Regarding the crown line as the absciss, and the actual lines of pressure as the ordinates (on the curve surface), half the ordinate plus 45°, has its logarithmic tangent proportional to the absciss. Having once obtained the log-tangent corresponding to a given distance along the crown line, a simple proportion will give that corresponding to any other absciss; the log-tangent corresponding to half the length of an arch-stone having been found, the repeated addition of that quantity to itself will lead to a knowledge of the position of the corner of each stone in the whole structure, the simplest operations of trigonometry only being needed. Indeed, the labour of the whole calculation is but a minute fraction of that expended in the drawing of the plans. By these means, the accompanying model of the surface of the centering, its development, and various orthographic projections, were completed.* The simple inspection of these, and their comparison with most of the skewed bridges already constructed, will shew in what respects this branch of architecture has hitherto been defective.

I cannot leave the subject of the circular arch without indicating the extensive and indispensable use of logarithms in the calculations. Napier, when he founded first the rudiments of the fluxional calculus, and thence the logarithmic method, sanguine though he may have been as to the immense value of his discoveries, could never have imagined the prodigious impulse which they have since given to every branch of exact science. Each new mathematical research piles another stone on the monument of Napier.

Neither can I avoid remarking, that the ingenious speculations of the earlier geometers concerning the various mechanical curves, speculations which have been by many regarded as fanciful and useless, are one by one turning to account in the progress of modern philosophy.

The elliptic arch, being much recommended by the gracefulness of its form, is frequently used. If we view the circular oblique arch from a distant point in the continuation of its axis, it does indeed appear elliptical; but then the ellipse has its major axis directed vertically, so that a circular skewed bridge can hardly have a fine appearance unless the segment be extremely flat. Let us then inquire into the phases of an elliptic skew.

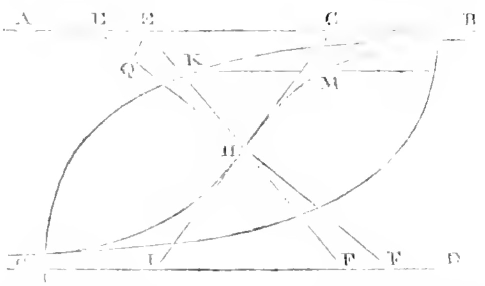
The horizontal plan of the joint is still a double logarithmic curve; and its delineation, including, of course, that for the circular arch, is as follows.

EF being as before, the plan of one of the lines of pressure, find HQ a third proportional to the horizontal and the vertical semi-axis; through Q draw Q'E parallel to HG. Describe then logarithmics having E'G for their common subtangent, and having their ordinates

* In practice, it would be more convenient to lay a jointed rod equal to half AB from the middle of AB to the rule DFE as indicated by the dotted lines.

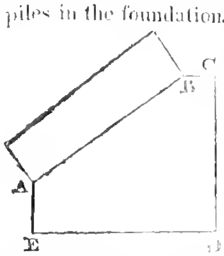
* These are deposited in the Museum of the Society of Arts of Scotland

Fig. 3.



parallel to EH, the bisection of the interval between these will give the horizontal projection of the joint. Similarly, the side and end projections are modifications of those belonging to the circular arch:—they are fully investigated in the appendix.

Having obtained a tolerable approximation to the forms of the arch stones, it is not uncommon for bridge-builders to throw the remaining responsibility on the abutments, which, besides transmitting the pressure, have to continue its distribution among the parts of the pier. In truth, the principles of equilibrium seem never, even in the case of the right arch, to have penetrated beyond the facing stones of the piers; and the effect of the arrangement *in every bridge which I have seen, or the drawings for which I have inspected,* is to throw the whole weight of the arch on the outside stones of the pier and on the outer row of piles in the foundation. To see this clearly, let us draw one of the abutment stones of a right bridge. The oblique face AB receives the pressure of the lowest voussoir; and it ought to receive that pressure perpendicularly. But the stone is prevented from yielding by resistances against the surfaces CD, DE: the pressure of the voussoir is thus decomposed into two pressures, one against CD, well known to be the horizontal thrust of the bridge, and the other against DE, equal to the weight of all the mason-work between the crown of the arch and the vertical line through B. Now, since all the stones of the piers are squared, no change (except by improper straining) can take place in the directions in which these pressures are propagated. The pressure against CD is communicated along the abutment course to the spring of the next arch, or to the corresponding breadth of the final abutment; while the pressure against CD is transmitted through the facing stones of the pier to the outer row of piles. It will, indeed, be said, that the cohesion of the mortar, and the alternate jointing of the courses, render the pier one mass, and that, therefore, such niceties are not worthy of attention. But, indeed! is the final disposal of the entire strain of a bridge such a trifle? Then let us fit our arch-stones by guess, and sweep the span in any fancy. It is at this very corner that all the care of the engineer is required; and I do maintain, that the method in common use outrages the doctrines of equilibrium, and renders our arches less secure than they ought to be. It is a piece of bad engineering to throw the whole weight of a bridge upon one row of its supports, and to give the others scarcely any strain; especially when it is considered that that row is most liable to decay. The alternate jointing of the stones calls into action that species of resistance which ordinary building-material is least capable of exhibiting; one end of a stone is pressed downwards, while its other end is engaged between two blocks; the consequence is a tendency to break the stone over, to *distend* its upper surface; and it is notorious that the strength of stones in this way is much inferior to their power of resisting a simple crush. The alternate jointing and the mortar are useful enough in correcting the bad effects of unavoidable inaccuracy; there is no need for deliberate error to put them to a severer use.



The best possible arrangement is to give to each square foot of the foundation its fair share of the whole burden. In order to do this, it becomes necessary to lay a counter arch, of a parabolic form (its convexity downwards), upon the pier-head. Such an abutment course would carry the horizontal thrust to the spring of the next arch, precisely as a flat course would; but it would distribute a uniform downward pressure on each horizontal foot; and, in this way, the foundation would be pressed on exactly as if the whole weight of mason-work, from the crown of the one arch to the crown of the other, were piled upon it in squared courses.

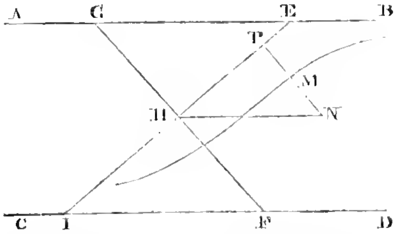
On investigating the forms of the joint on a parabolic skew, I found its plan to be a line of the third order, the double parabola; that its end elevation is a semi-cubic parabola; and that its side elevation is another line of the same order. Students of the higher mathematics will at once recognise the equations of these curves as the results of other inquiries. For the computations of the parts, on account of the regular progression of the different examples, the method explained in my treatise *On the Solution of Equations of All Orders*, will be found to afford peculiar facilities.

Appendix.

In the preceding part of this paper, I have stated the general principles which ought to regulate the construction of oblique arches. In this, the second part, I propose to enter more into detail, and to give the demonstrations of the theorems above laid down.

The general investigation into the stability of a vault would necessarily be complicated by the peculiarities of the ultimate abutments, and by the assumed directions of the lines of pressure; for these directions are, within certain limits, arbitrary. For the present purpose, it is enough to consider the case of a vault resting on parallel abutments, cylindroid, and having the lines of pressure contained in vertical planes parallel to each other.

Fig. 5.



Let AB, CD, represent the two abutments, HN the crown line, GF and PN the horizontal projections of two of the lines of pressure.

Of rectangular co-ordinates, let the x be in the direction HG, the y in PM, and the z vertically. For convenience, also assume oblique co-ordinates v along HN, u along NM, and z as before; put also GHN the angle of the skew $= s$. The formulæ of conversion will be

$$\left.\begin{array}{l} x = v\cos s,\ \ y = v\sin s - u;\ z = z \\ v = x\sec s,\ \ u = x\tan s - y,\ \ z = z \end{array}\right\}\quad . \ . \ \text{A}$$

If the equation of the generating curve of the vault, of which EF is the projection, be taken

$$u - \phi\, z = 0 = \text{B}$$

the same equation will serve as that of the vault itself; or in rectangular co-ordinates

$$x\tan s - y - \phi\, z = 0 = \text{B, whence}$$

$$\frac{d\,\text{B}}{d\,x} = \tan s;\ \frac{d\,\text{B}}{d\,y} = -1;\ \frac{d\,\text{B}}{d\,z} = \phi'\, z.$$

The equation of the plane containing one of the lines of pressure is,

$$x - \text{X} = 0 = c;\ \text{whence}$$

$$\frac{d\,c}{d\,x} = 1, \frac{d\,c}{d\,y} = 0;\ \frac{d\,c}{d\,z} = 0;$$

so that the equations of the straight line touching B =, 0 $c = 0$ are

$$\frac{\text{X} - x}{0} = \frac{\text{Y} - y}{-\phi'\, z} = \frac{\text{Z} - z}{-1}\quad . \ . \ \text{(D)}$$

where X, Y, Z belong to any point in the tangent; x, y, z to the point of contact.

Again, let $u - \theta\, v = 0 = \text{E}$ be the equation of the horizontal projection of a joint, or in rectangular co-ordinates,

$$x\tan s - y - \theta\,(x\sec s) = 0 = \text{E; then}$$

$$\frac{d\,\text{E}}{d\,x} = \tan s - \sec s.\,\theta'\, v;\ \frac{d\,\text{E}}{d\,y} = -1;\ \frac{d\,\text{E}}{d\,z} = 0.$$

The equations of the joint are $\text{B} = 0$, $c = 0$, therefore, those of a line tangent to it are

$$\frac{\text{X} - x}{\phi'\, z} = \frac{\text{Y} - y}{\phi'\, z\,(\tan s - \sec s.\,\theta'\, v)} = \frac{\text{Z} - z}{\sec s.\,\theta'\, v}\quad . \ . \ \text{(F)}$$

The stability of the structure demands, that the line whose equations are (F) be perpendicular to that whose equations are (D), therefore the condition of stability is contained in this equation,

$$(\phi'\, z)^2\,(\sin s - \theta'\, v) = \theta'\, v$$

$$\left.\begin{array}{ll}\text{or} & \phi' z = \sqrt{\left\{\dfrac{\theta' v}{\sin s - \theta' v}\right\}} \\ \text{or} & \theta' v = \sin s \dfrac{(\phi' z)^2}{1 + (\phi' z)^2}\end{array}\right\} \quad . \quad . \quad . \quad (G)$$

The last formula may also be put thus:

$$\frac{\delta u}{\delta v} = \sin s \frac{d u^2}{d u^2 + d z^2}$$

in which the characteristic δ refers to the joint, d to the line of pressure. But $\frac{d u^2}{d u^2 + d z^2}$ is the square of the cosine of the inclination of the line of pressure to the horizon; whence, if we denote that inclination by i,

$$\frac{\delta u}{\delta v} = \sin s. \cos i^2 \quad . \quad . \quad . \quad (H)$$

When, then, as is the case at the crown of the arch, i is zero $\frac{\delta u}{\delta v} = \sin s$; but $\frac{\delta u}{\delta v} = -\frac{\delta y}{\delta v} + \sin s$ so that, at the crown, $\frac{\delta y}{\delta v} = o$, that is, the horizontal projection of the joint, is there perpendicular to the parapet, as might easily have been anticipated; but when i increases, its cosine decreases, and therefore $\frac{\delta y}{\delta v} = \sin s. \sin i^2$ (I) must increase: that is, the line must bend away, from being perpendicular to the parapet, until, if i could reach 90°, it would be parallel to the abutment.

Since $\frac{\delta v}{\delta x} = \sec s$, the above quotation put in rectangular co-ordinates becomes,

$$\frac{\delta y}{\delta x} = \tan s. \sin i^2 \quad . \quad . \quad . \quad (K)$$

If a be taken to represent the arc of which u is the projection, $\cos i = \frac{du}{da}$ and equation H becomes,

$$\frac{\delta a}{\delta v} = \sin s. \cos i \quad . \quad . \quad . \quad (L)$$

and thus, if we imagine two joints running quite close to each other, cutting the crown-line at the minute distance δv, the distance δa, intercepted between them on the arc, or the breadth of the course, is proportional to cosine i.

The above equation can also be put under the form

$$\frac{\delta a}{\delta x} = \tan s. \cos i \quad . \quad . \quad . \quad (M)$$

Again, we have $\frac{\delta u}{\delta z} = \cot i$; whence equation H becomes,

$$\frac{\delta z}{\delta v} = \sin s. \sin i. \cos i = \tfrac{1}{2} \sin s. \sin 2 i. \quad . \quad . \quad . \quad (N)$$

$$\frac{\delta z}{\delta x} = \tan s. \sin i. \cos i = \tfrac{1}{2} \tan s. \sin 2 i. \quad . \quad . \quad . \quad (O)$$

From which it will be seen, that the general statement made as to the side elevation of the joint is true.

Lastly, we have

$$\frac{\delta y}{\delta z} = \sin s \frac{\delta v}{\delta z} - \frac{\delta u}{\delta z} = \tan i = \frac{\delta z}{\delta u} \quad . \quad . \quad . \quad (P)$$

whence it is, that the end elevation of the joint crosses that of the line of pressure at right angles.

Before proceeding to apply the above differential equations to particular cases, the following recapitulation may be made:

Equation H gives the Horizontal Projection.
.. L .. Development.
.. O .. Side Elevation.
.. P .. End Elevation of the Joint.

And it is to be remarked, that these equations are absolutely general, applying to every skewed cylindroid arch.

Having now completed the general investigation, I proceed to apply the principles to specific cases; in the first case to the circular arch.

Denoting by r the radius of the circle, we have

$$i = \frac{a}{r}, \; z = r \cos \frac{a}{r}, \; u = r \sin \frac{a}{r}; \; z^2 + u^2 = r^2;$$

equations which take the place of (B) in the general analysis.

For the horizontal projection of a joint we have

$$\frac{\delta u}{\delta v} = \sin s \left(\cos \frac{a}{r}\right)^2 = \sin s \frac{r^2 - u^2}{r^2}$$

and thus

$$\frac{\delta v}{\delta u} = \text{cse } s. \frac{r^2}{r^2 - u^2};$$

whence integrating

$$v = r. \text{cse } s \text{ nep. log } \sqrt{\left(\frac{r + u}{r + u}\right)}$$

Now $v' = r.$ cse $s.$ nep. log $(r + u)$ is the equation of a logarithmic curve to oblique co-ordinates having one side of the semicylinder for its axis, and r cse $s.$ for its subtangent: while $- v'' = r.$ cse $s.$ nep. log $(r - u)$ is that of a similar curve having the other side of the semi-cylinder for its asymptote, and thus the v of the joint which is the arithmetical mean of these is obtained by bisecting the interval between the two logarithmics.

Passing to common logarithms, and putting M for the modulus, ·43429418, &c. we have

$$v = \frac{r. \text{cse } s}{2 \text{ M}} \log \frac{r + u}{r - u}$$

$$u = r \frac{10^{\frac{2 \text{ M } v}{r \text{ cse } s}} - 1}{10^{\frac{2 \text{ M } v}{r \text{ cse } s}} + 1}.$$

The horizontal projection of the joint of a circular skewed arch is thus a new curve, to which I have given the name of Double Logarithmic: the analogy between this curve and the common catenary has already been pointed out.

In order to trace the side elevation, we must resume equation (O) which, when adapted to the circular arch, is

$$\frac{\delta z}{\delta x} = \tan s. \frac{z}{r} \sqrt{\left(\frac{r^2 - z^2}{r^2}\right)} \qquad \text{whence}$$

$$k = \frac{r. \cot s}{z} \text{ nep. log } \frac{r + \sqrt{r^2 - s^2}}{r - \sqrt{r^2 - z^2}}$$

$$= \text{nep log } 10. \, r. \cot s \log \tan \left(45° + \frac{a}{2 r}\right)$$

But the equation

$$x' = \frac{r}{z} \text{ nep. log} \frac{r + \sqrt{r^2 - z^2}}{r - \sqrt{r^2 - z^2}} - \sqrt{r^2 - z^2}$$

is just the equation of the tractory, whence

$$x'' = \frac{r}{z} \text{ nep. log } \frac{r + \sqrt{r^2 - z^2}}{r - \sqrt{r^2 - z^2}}$$

is the equation of a curve having its ordinates greater than those of the tractory by the quantity $\sqrt{r^2 - z^2}$, this curve I have named the *companion to the tractory*, or, on account of the connection which is explained in the paper, and which at once flows from the above, the *inverted catenary*.

The equation for the end elevation of a joint adapted to the circular arch is

$$\frac{\delta y}{\delta z} = \sqrt{\left(\frac{r^2 - z^2}{r^2}\right)} \qquad \text{whence}$$

$$-y = \text{nep. log } \sqrt{\left\{\frac{r + \sqrt{r^2 - z^2}}{r - \sqrt{r^2 - z^2}}\right\}} - \sqrt{r^2 - z^2}$$

which is the well known equation of the tractory. This is the characteristic curve of the circular oblique arch: as all tractories are similar to each other, it is easy to make a table of its co-ordinates.

The preceding equations enable us to obtain any one of the projections of the joint, and are essential to a knowledge of the nature of the different curves. They are, however, inconvenient when we wish to ascertain the dimensions of the individual arch-stones, and need, for that purpose, to know the intersection of the joint with any one of the lines of pressure. The equation of the development furnishes us with the means of obtaining these points, as well as all the projections, by processes remarkable for their simplicity. To find this equation I resume (L) which, adapted to the circular arch, becomes

$$\frac{\delta v}{\delta u} = \csc s . \sec \frac{a}{r} \qquad \text{whence}$$

$$v = r . \csc s . \text{nep. log tan} \left(\frac{\pi}{4} + \frac{a}{2r}\right)$$

or, observing that $\frac{u}{r} = i$, and passing to common logarithmic tables,

$$v = \text{nep. log } 10 . r \csc s . \log \tan \left(45° + \frac{i}{2}\right)$$

whence by inversion

$$\log \tan \left(45° + \frac{i}{2}\right) = \frac{\text{M.} \sin s}{r} . v.$$

from which the values of i can be very easily found; especially when they correspond to equi-different values of v.

The expert computer will now perceive at a glance, that all the operations needed to determine the co-ordinates of the various points may now be arranged in a simple tabular form so as to require scarcely any figuring.

I now proceed to the Elliptic Oblique Arch. Put r for the horizontal and ρ for the vertical radius; the equation of the curve then becomes

$$\frac{u^2}{r^2} + \frac{z^2}{\rho^2} = 1$$

which takes the place of (B).

This equation may also be put under the form

$$u = r \sin \alpha, \; z = \rho \cos \alpha.$$

where α is the inclination of the trammel bar that would trace out the ellipse; from this we find

$$\frac{\delta v}{\delta \alpha} = \frac{\csc s}{r} \left\{ (r^2 - \rho^2) \cos \alpha + \rho^2 \sec \alpha \right\} \qquad \text{whence}$$

$$v = \frac{\csc s}{r} \left\{ (r^2 - \rho^2) \sin \alpha + \rho^2 \text{ nep log tan} \left(45 + \frac{\alpha}{2}\right) \right\}$$

Otherwise we obtain

$$\frac{\delta v}{\delta u} = \frac{\csc s}{r} \left\{ (r^2 - \rho^2) + \rho^2 \frac{r}{r^2 - u^2} \right\}$$

$$v = \csc s \left\{ \frac{r^2 - \rho^2}{r^2} u + \frac{\rho^2}{r} \text{ nep log} \sqrt{\left(\frac{r + u}{r - u}\right)} \right\}$$

At first glance it might be thought that this equation gives a new curve; it is, however, still a double logarithmic, having its parts determined in the manner already described.

To find the side elevation we have

$$\frac{\delta z}{\delta x} = \tan s \frac{- r \rho z \sqrt{\rho^2 - z^2}}{\rho^4 + (r^2 - \rho^2) z^2} \qquad \text{whence}$$

$$x = \cot s \left\{ \frac{r^2 - \rho^2}{r \rho} \sqrt{\rho^2 - z^2} + \frac{\rho^2}{r} \log \sqrt{\left(\frac{\rho + \sqrt{\rho^2 - z^2}}{\rho - \sqrt{\rho^2 - z^2}}\right)} \right\};$$

it is, however, more easily determined thus

$$\frac{\delta x}{\delta z} = \cot s \frac{r^2 + \rho^2 \tan \alpha}{r \rho \tan \alpha}$$

$$= \cot s \left\{ \frac{r}{\rho} \cot \alpha + \frac{\rho}{r} \tan \alpha \right\}$$

$$\text{But } \delta z = - \rho \sin \alpha . \delta \alpha. \qquad \text{whence}$$

$$x = - \cot s \left\{ \frac{r^2 - \rho^2}{r} \sin \alpha + \frac{\rho^2}{r} \text{ nep. l. tan} \left(45 + \frac{\alpha}{2}\right) \right\}$$

For the end elevation we have recourse to equation (P) which gives

$$\frac{\delta y}{\delta \alpha} = \frac{\rho^2}{r} \left\{ \sec \alpha - \cos \alpha \right\} \qquad \text{and thus}$$

$$y = \frac{\rho^2}{r} \left\{ \text{nep. log tan} \left(45 + \tfrac{1}{2} \alpha\right) - \sin \alpha \right\}$$

which is the equation of the tractory modified by the existence of the factor $\frac{\rho}{r}$. From this equation the determination of the individual point is most easily obtained.

I now proceed to consider the Parabolic Arch. f being the focal distance, the equation of the parabola is

$$u^2 = 4 f z, \text{ whence } u \, d u = 2 f d z$$

whence again the equation

$$v = \csc s \left\{ u + \frac{u^3}{12 f^2} \right\}$$

which belongs to the horizontal projection; also

$$x = \cot s \left\{ 2 u + \frac{u^3}{6 f^2} \right\} \qquad \text{or}$$

$$x = \cot s . \frac{2}{3} \sqrt{f z} \left\{ 3 + \frac{z}{f} \right\};$$

and also

$$y^2 = \frac{4 z^3}{9 f}$$

which are the equations of the three projections.

I have now run over the equations which serve to determine the different parts of oblique, circular, elliptic, and parabolic arches, and had intended to supply examples of the requisite calculations; but after proceeding to some length in this, it occurred to me that those who have followed the preceding investigations stand in no need of such illustrations, and that these, therefore, would merely occupy room without being productive of any benefit.

HARBOURS (SOUTH EASTERN COAST.)

A Copy of the Report of the Commissioners appointed to Survey the Harbours of the South-Eastern Coast, to the Lords Commissioners of the Admiralty.

WITH AN ENGRAVING, PLATE XII.

HAVING completed the inquiry on the subject of the Harbours on the South-Eastern coast of England, we request you will lay before the Lords Commissioners of the Admiralty the result of our investigation.

Mr. Wood's letter of the 25th of July last conveyed to us the directions of their Lordships "to visit the coast between the mouth of the Thames and Selsea Bill, and to examine and report on the state of the existing harbours between those points, with reference to their being available as places of shelter for vessels passing through the channel, in case of distress from weather, and also as places of refuge for merchant vessels from enemy's cruizers in time of war, and more especially as to their being made stations for armed steam-vessels employed for the protection of our trade in the narrow part of the channel;" for which purpose, the harbours being accessible at all times of tide, and their capability of defence, were stated to be most important considerations.

Their Lordships further desired us "to report as to what situations we would recommend as best calculated for these various purposes; whether in any of the existing harbours, or at any other places within the assigned limits; and also what works would be necessary to render them available; and what the probable expense of the undertaking would be."

Before entering into the details of the subject, it will be proper to state that a question arose whether it fell within the province of the Committee to offer any remarks on those harbours which were found on inspection to be incapable of access at all times of tide.

A perfect harbour of refuge, we understand to mean, such as is capable of receiving any class of vessels, under all circumstances of wind and tide.

Now there is no such harbour along the whole range of coast from the Nore to Selsea Bill; nor are any of the existing harbours capable, by any improvements or alterations to their present entrances, of being made accessible at low water even to the extent of six feet, with floating berthage inside.

Most of the harbours on this part of the coast are formed by piers carried out from the main land, and are tidal harbours, dry or nearly so at low water, with bars at their entrances: these harbours would therefore be excluded from our consideration, if their capability of being made available at all times of tide was to be considered a necessary condition.

There can be no doubt, however, that the existing harbours are of importance to merchant vessels of the smaller classes at various times of tide, according to their draught of water; and though they may not be capable of receiving a large ship, may afford shelter to a smaller one; and thereby become a harbour of refuge to a class of vessels the most numerous and least prepared for heavy weather, or to escape an enemy in time of war.

The value of such imperfect harbours is also increased by the diminution of late years in the size of trading vessels. The large class of ships which were employed in the West India, and the still larger in the East India trades, have been succeeded by vessels of much smaller tonnage. The coasting and coal trades are carried on in vessels of comparatively light draught of water; and steam-vessels, whose draught is easy compared with sailing-vessels of equal tonnage, are rapidly increasing in number, and often supply the places of the larger class of vessels which were formerly employed in the merchant service.

To these vessels, therefore, some of the harbours at the present moment are open for several hours of each tide, and a few of them may be capable of being rendered more accessible by the removal of obstructions at their entrances, or by additional works.

This part of the coast possesses the advantage of a good rise of tide; and though the harbours are only available under special conditions, the numerous instances of shelter and protection afforded by each to ships in distress, serve to show their value in a national point of view, and the importance of not allowing them to fall to decay.

Although, therefore, we are convinced that none of them can be made perfect harbours of refuge, we still have considered them as falling within the scope of our inquiry; not as requiring from us specific details of the works which may be deemed desirable, but to explain briefly their present extent and capabilities, and to note generally what may have presented itself to us in the way of improvement; and we therefore propose to consider the objects of the inquiry under two heads, viz.: 1st, The state and capabilities of the existing harbours, &c., (in the order in which we visited them); and 2ndly, The situations best calculated for harbours of refuge, and as stations for armed steam-vessels in the event of war; confining to harbours for these latter objects, the necessary condition of being accessible at all times of tide.

The river Thames is usually considered to terminate at the Nore. From the Isle of Sheppey to Westgate Bay, the numerous sands and shoals which extend in all directions along the coast, prevent the approach of vessels of any size; and the cliffs, which consist of sand and clay, are gradually yielding to the action of the sea, and supply a constant source of materials for fresh accumulations.

We did not, therefore, consider it necessary to visit this part of the coast, where no harbours at present exist.

Margate.

Margate was the first place at which we landed after leaving the river.

The harbour is situated in a small bay between two extensive flats of chalk rocks, the Nayland on the west, and the Fulsam on the east, both of which are covered before high water. The artificial harbour is formed by a stone pier, which commences on the eastern side of the bay (around which the town is situated), and extends 800 feet to the westward, in an irregular curve, leaving the entrance open to the north-west.

The rise of average spring tides at the pier-head, is about 13 feet, and that of neap tides eight feet; but spring tides ebb outside of the pier-head, and leave the harbour dry at low water. A wooden jetty has been run out from the root of the pier, over the Fulsam rocks, to the distance of 1,100 feet, for the convenience of passengers, &c., landing from or embarking in the steam-packets at low water.

The pier and jetty belong to a joint-stock company, the chairman, surveyor, and harbour-master of which attended us, and gave us the information we required.

It is evident that the harbour in its present state possesses none of the requisites of a harbour of refuge, and can only be considered valuable, in a national point of view, as affording the means of supplying pilots, anchors, and cables, &c., to vessels driven into the roads in distress.

The surveyor, by order of the directors of the pier and harbour company, prepared and submitted to us a design for constructing a harbour of refuge at this place, by extending curved piers upon the Nayland and Fulsam rocks; enclosing an area of considerable extent on and around the site of the present harbour, and leaving an entrance of 300 or 400 feet in width towards the north-east, with 16 feet depth of water at the mouth.

The expense of such a work is estimated by the surveyor at 275,000*l.*; but the cost of deepening the harbour is not included in this sum; and as the bottom rises gradually to the beach, the area possessing even 8 feet water would be very limited, and considerable excavations would be necessary to render it available to any extent.

A second design was submitted to us, said to be formed on a plan suggested by the late Mr. Rennie, who is quoted as having thought highly of the situation for a harbour of refuge. It consisted of an outer harbour of less dimensions than the one proposed by the directors of the pier and harbour company, enclosed by walls; and an inner basin with gates to shut in the water at flood-tide, for the purpose of clearing the entrance at low water.

The power of sluicing at so great a distance as that proposed in this plan, could only be applied with advantage to a surface dry, or nearly so, at low water; and the idea of keeping a deep-water harbour of any useful width, clear by means of such sluicing, appears to us to be impracticable.

Several other plans were brought before us for the construction of a harbour at this place; but as we shall have occasion to show in the sequel that other situations possess greater advantages for the attainment of the objects pointed out by their Lordships' instructions, we do not consider it necessary to enter into any details of these suggestions.

Broadstairs.

From Margate we proceeded to Broadstairs. The harbour at this place is formed by a wooden pier, about 100 yards in length, extending from the northern side of a small bay.

The entrance faces south-west, but the harbour is much exposed to the sea, which is driven in by winds from the eastward.

At spring tides there is about 16 feet water at the pier-head, and 10 at neaps, but the whole harbour is dry at low water; and, during spring tides, nearly 100 yards outside the pier is left uncovered.

A plan was submitted to us by the harbour commissioners for constructing a larger harbour, by extending piers from the opposite extremities of the bay, 320 yards into the sea, by which eight feet in the entrance at low water might be obtained. But we do not consider it necessary to enter into further particulars of this project, as it does not appear to us that a work of such magnitude is required in this situation, or that the advantages anticipated would be commensurate with the expense.

The harbour is managed by commissioners, under an Act of Parliament passed in 1792.

Ramsgate.

Ramsgate harbour, which was the next place we visited, consists of an inner and outer basins, formed by substantial stone piers, extending 1,310 feet into the sea, and encloses an area of 42 acres.

The inner basin is used as a wet dock for vessels to load or unload their cargoes, &c., and contains a dry dock where vessels of 300 to 400 tons burthen can be repaired, &c.

The entrance of the outer harbour is 200 feet in width, and opens to the south-west.

The rise of average spring tides is from 13 to 14 feet at the pier-heads, and of neap tides nine feet, giving in the entrance 19 feet at high water of spring tides, and 16 of neaps.

For the purpose of scouring the outer harbour at low water, powerful sluices have been constructed through the cross wall of the inner basin, the discharge of water from which serves to keep open the channel to the inner basin and the gullies which extend round the harbour at the foot of the piers, in certain portions of which, near the entrance of the harbour, the depth increases to about six feet at low water.

The mud which remains in the middle of the harbour serves as grounding banks, and affords a soft bed on which vessels entering with loss of anchors and cables can take the ground in safety; and these banks are considered essential for the purpose.

A new communication between the outer and inner basins has lately been completed, the gates of which are 42 feet in width.

One of Morton's patent slips has also been laid down in the outer harbour, on which steam-vessels, &c. of too great beam to enter the graving dock in the inner basin can be hauled up and repaired.

The situation of this harbour appears to have been selected more from its position with reference to the Downs than from any local advantages afforded by the formation of the coast. There is no natural backwater, so essential in tidal harbours for the purpose of scouring, nor does the line of cliff offer shelter against any winds but those which blow from off the land; and yet in this situation, without one natural facility but that of a chalk foundation, a harbour has been constructed which, notwithstanding its imperfections, is undoubtedly the best on the south-eastern coast of England.

During gales from the southward and westward, which throw a heavy sea into the Downs, and render the anchorage insecure for heavily-laden coasters, and merchant vessels of the smaller classes frequently unprepared for riding in open roadsteads during heavy weather,—this harbour affords a place of shelter where vessels of considerable draught of water may run for protection at tide time.

By the accounts we received from the harbour-master of the number of vessels which have annually sought shelter from weather, &c. since the completion of the harbour, it may be inferred that the object for which it was constructed, viz. an asylum for ships in distress in the Downs, &c., has been to a certain extent attained.

No plans for the improvement of this harbour have been submitted to us; and from the nature of the bottom outside, which consists of chalk rock, with not above six feet water at some distance from the harbour's mouth, at low water spring tides, it is obviously incapable of being rendered accessible for vessels drawing more than that depth of water. It cannot, therefore, be considered a perfect harbour of refuge, nor is the situation eligible for the purposes pointed out in their Lordships' instructions.

The care and management of the harbour is placed, by Act of Parliament, in the hands of trustees.

Deal and Sandwich.

From Ramsgate we proceeded to Deal, where a deputation from that town and the borough of Sandwich waited upon us, and submitted to our inspection plans for the construction of a harbour on the beach, with docks, &c., to communicate with the latter town. The River Stour, which enters the sea through the Sandwich flats, being proposed to be converted into a backwater, for the purpose of scouring the entrance.

The scheme has been under contemplation for many years, but nothing has been undertaken towards carrying it into execution.

We thought it right, however, to inspect the coast in the neighbourhood of the site of the proposed harbour, to ascertain the feasibility or otherwise, by an extension of the plan, of rendering it subservient to the objects of our inquiry.

The shingle, which first makes its appearance about a mile to the northward of Sandown Castle, extends in a vast bank along the shore towards the South Foreland, and is continually moving by the action of the waves in the direction of the prevailing winds, and forming accumulations to the northward. This is an objection to the construction of a harbour on this part of the coast, and it is very doubtful whether vessels in distress in the Downs could make use of one in this situation. These reasons appear to us to render the plan ineligible.

The situation to which we next directed our attention was the space within the breaksand, and the expediency of enclosing the "Small Downs" and the area within, by extending a breakwater along the sand, and a pier from the shore. The magnitude and extent, however, of such a work, which would require a breakwater and pier of upwards of five miles in length, the small depth of water at the northern entrance, and the uncertain nature of the foundation, induce us to abandon the idea of a harbour of refuge at this place.

Dover.

We next visited Dover. This harbour, from its proximity to the French coast, and as the principal port of communication between Great Britain and the Continent, has been regarded at all times as a place of the greatest importance.

We shall have occasion to refer to the situation in the latter part of this Report; and it will only be necessary in this place to give a brief description of the harbour in its present state.

It consists of an outer and an inner basin, with a backwater which opens into the latter, called the Pent.

The outer harbour contains an area of seven acres and a half, the inner basin six acres and a quarter, and the pent 11 acres and a half. A wet dock, of an acre and a half, opens into the western side of the outer harbour, which again communicates with a graving or repairing dock.

The entrance between the pier-heads (which are partly formed of stone and brickwork faced with wooden piles) is 110 feet in width, and opens to the south-south-east.

The rise of average spring tides is from 18 to 19 feet, and of neap tides from 12 to 13 feet; but the depth at high water in the harbour at spring tides is only 17 to 18 feet, and in the basin 16 to 17 feet, and about three feet less during the neaps.

The harbour is therefore left dry at low water.

The bottom consists of chalk, on which a deposit of mud in certain places has accumulated, but not of sufficient depth to enable heavily-laden vessels to take the ground with safety, especially during easterly winds, when, from the confined area of the outer harbour, and the rebound from the upright walls, there is a considerable agitation in the water.

During south-westerly gales, vessels experience difficulty in entering, from the heavy sea to which the harbour's mouth is exposed; and another formidable obstacle arises from the shingle bar, which winds from this quarter throw up across the entrance, and which at times has rendered the harbour inaccessible for several weeks together. Numerous plans and suggestions have been devised, and large sums of money expended for remedying this evil.

Formerly there were only three sluices or culverts, communicating by means of a pipe with the inner basin; but since 1837, a new and expensive work has been completed, consisting of a brick reservoir in the western pier, communicating, by means of a tunnel 30 feet in width and 16 in height, with the inner basin and pent. From this reservoir, five new sluices, seven feet in diameter, lead to the extremity of the pier-head; and from the powerful volume of water thus discharged, and the impetus acquired by the proximity of the reservoir, it has generally been found sufficient, with the assistance of the sluices in the cross wall, between the basin and outer harbour, to remove the shingle from the pier-head, and keep the channel clear to a level below that of the harbour's bottom.

We have been informed that since the construction of this work until January last, no instance occurred of Her Majesty's steam-packets being prevented from entering the harbour at tide-time, in consequence of the bar. But during the violent gales which took place in the latter end of the month of January and beginning of February in this year (1840), the Government packets were ordered to proceed to the Downs, to avoid the liability of being shut into the harbour by an accumulation of shingle and the heavy sea at the entrance. There were, however, but three days during which vessels were actually excluded.

It should be observed that these sluices, though efficacious to a certain extent, are not capable of removing the obstruction altogether. The force of the water, which at its exit from the culverts is very great, loses its impetus as it spreads over a larger surface, and forces the shingle to a comparatively small distance, where it is liable to form banks beyond the power of the sluices.

With regard to the improvements which might be made to this harbour, it appears to us that the general enlargement of the harbour, the inner basin and pent, and the widening of the internal communications, would be most desirable, as well as the extension of the stone groin, called Cheeseman's Head, on the western side of the harbour's entrance. But these suggestions, so far as regards the entrances, will be much modified in the event of a harbour of refuge being constructed at this place.

Various plans and suggestions for the improvement of the present, as well as for the formation of a new harbour, were submitted to us by Colonel Williams, Lieutenant Worthington, Mr. Jeffery, Mr. Stuart, Mr. Tait, Captain Meriton, and several other gentlemen; but as we shall have occasion to recommend a plan for the attainment of the objects of our inquiry, in the subsequent part of this report, we do not consider it necessary to enter into the details of these propositions.

The harbour-master and other officers of Dover, and pilots belonging to this, as well as to the other Cinque Ports, waited upon us by order of his Grace the Lord Warden, and gave us any information we required.

The habour is managed by commissioners, of whom the Lord Warden is chairman, *ex officio.*

Folkstone.

From Dover we proceeded to Folkstone. This harbour was constructed under an Act of Parliament in 1809, by a joint-stock company, to whom the property belongs, but at present it is in the hands of the Exchequer Bills Loan Commissioners.

The harbour, which is entirely artificial, is formed by rubble-stone piers, and encloses an area of 14 acres. The western arm extends in a south-south-west direction 140 yards across the beach, and is united with the main pier, which is carried in a straight line east and by south about 317 yards. A projecting pier has since been run out from the shore, on the eastern side, towards the south-west, 236 yards, leaving an entrance of 123 feet in width, open to the east and by south.

A groin has been constructed near the eastern extremity of the main pier, which extends at right angles 130 feet seaward, for the purpose of preventing the shingle from obstructing the harbour's mouth. This, however, has not overcome the evil; for the shingle having accumulated along the southern side of the main pier to the line of extension of the horn, finds its way round the extremity, and creates a bar nearly across the entrance.

The rise of spring tides averages about 18 to 20 feet, and neap tides from 12 to 14 feet, but the harbour is left dry at low water; and the greater part of the interior is blocked up by a bank of shingle rising to the height of several feet above high water, and leaving only a channel of inconsiderable width along the side of the main pier.

A small stream is pent up at the north-western side of the harbour, for the purpose of scouring at low water; and with the assistance of manual labour, in addition to this very inadequate backwater, the channel is kept open so as to allow vessels of 10 to 12 feet draught to come alongside of the main pier at the top of high water.

This harbour, in its present form, is not capable by any improvements of being made available for the purposes of our inquiry, and we do not consider the situation eligible for the construction of a deep-water harbour.

From Folkstone we proceeded to Hythe, and inspected the coast to Dungeness. No harbours at present exist between these places, and from the nature of the coast, the situation is inapplicable for their formation; but several plans having been submitted to us for the construction of a harbour at Dungeness, we landed for the purpose of examining the beach, and ascertaining the practicability or otherwise of the propositions.

Vice-Admiral Sir Edward Owen, in a communication which he subsequently addressed to the Committee, stated, that "during the late war, when the presence of the flotilla and the encampment of troops on the opposite coast demanded unceasing vigilance, and the employment of many armed cruisers of the smallest description, the inconvenience of sending these vessels to Sheerness for the purposes of trivial repairs, and payment of the men, &c., was greatly felt, both in the loss of their immediate services, and from the interruption to the more regular and important arrangements of defence; and Dungeness being then considered the rendezvous of greatest moment, he contemplated the formation of a basin within the shingle, in a position between No. 2 battery on the east, and No. 4 battery on the west, with an outlet on either side, by which vessels might enter or put to sea when their services were required."

The propositions submitted to us by Mr. Potter and Mr. Douglass were of a similar nature; and there can be little doubt, from the prominent position of this extensive point of land, and the anchorage it affords to vessels on either side, according to the direction of the wind, that the situation is desirable for a harbour.

The shore at the southern extremity is extremely steep, and descends at once into deep water; but the whole promontory consists of vast accumulation of shingle, constantly increasing and extending seaward; and were a basin to be constructed in the centre, the entrances on either side would speedily be choked up, and, in our opinion, no scouring power would be able to keep the channels clear below the level of low water. However desirable, therefore, the construction of a deep-water harbour may be in this situation, the physical obstacles to its formation and maintenance appear to us to render the scheme impracticable.

In corroboration of this opinion, and the constant motion and increase of shingle, it is worthy of remark, that the site of the present lighthouse, when first erected in 1792, was only 100 yards from the sea, and now, in the lapse of 47 years, the beach has extended 118 yards to the southward, leaving the lighthouse 218 yards inland.

The former lighthouse, which was pulled down when the present one was completed, was at that time upwards of 640 yards from the extremity of the Ness.

Rye.

Rye, which was the next harbour we visited in our progress round the coast, is situated in the bight of the bay formed by Fairlight Head, on the western side, and Dungeness on the eastern. The harbour is formed in the channel of the river Rother, at the point where it enters the sea, after receiving the waters of the Tillingham and the Bride, two small rivers which unite with it near the town of Rye. A wooden pier of piles has been constructed on the eastern side, and embankments have been thrown up on the western side, leaving an entrance between of 160 feet in width.

The average rise of spring tides is about 17 feet, and during neap tides from 9 to 12 feet at the pier-head, whilst the lift in the bay is 22 feet. At low water the harbour is left dry.

The depth of the channel up the river decreases gradually to the town, where there is 14 feet water at the top of spring tides, but during neaps seldom above nine feet.

The approach from the bay to the entrance of the harbour is very intricate and difficult, especially to sailing vessels, arising from the sandbanks and the tortuous course of the channel.

The shingle, which extends on both sides of the harbour's mouth, is accumulated at the entrance with winds either from the westward or eastward of south, and forms banks on either side (according to the prevalence of the wind), which, in combination with sand, serve to block out the sea, and render the channel crooked and uncertain.

There can be no doubt that these natural causes have mainly contributed to the deterioration of this port, formerly of greater capacity, and a place of importance; but at the same time it should be observed, that the encroachments which have been made from time to time on the original extent of the river, have proved a powerful cause of injury. Individuals interested in the maintenance and improvement of the harbour are fully aware of this fact, and the contests which arise on the subject of drainage, between the landowners and those concerned in the navigation of the river, have become a fruitful source of litigation. Extensive low lands over which the river formerly flowed at high water, have been reclaimed for the purposes of agriculture, and the powerful backwater which was thereby acquired, and operated as a scour during the ebb to clear the channel and keep the entrance open, has been diminished, and at the present moment is almost destroyed, by the erection of sluice-gates across the river, a little distance above the town, for the purposes of draining the lands at low water, and of preventing the flow of water up its natural channel, which, if not thus obstructed, would again inundate the lands below the level of high water.

No cause has operated more extensively to injure the entrances of harbours of this country, than excluding the tidal waters from lands below the level of high water, which served as natural reservoirs at flood tide, and were the means of affording a powerful discharge during the ebb. The portion of the river between the embankments formed for the purpose of excluding the high water, is often benefited by the contraction of the channel, and the consequent acceleration of the current, but the communication with the sea below such embankments is injured, and nothing more deserves the vigilant attention of Government, or of the parties entrusted with the conservancy of harbours, than the subject of encroachments, which are usually made gradually and silently, as dictated by private interest, and are difficult afterwards to remove.

At the present moment a stone wall is in progress of erection from the eastern pier-head, and is intended to be carried out as far as low water, across the extensive flats which form the bar at the entrance, in a south-half-east direction. By this means the water, which on its exit from the harbour spreads over the sandbanks and forms a crooked passage as it meets with obstructions, and is deflected from side to side, will be directed in a straight line; and there can be no doubt that the continuation and completion of this stone groin will render the navigation of the entrance less difficult, and at the same time enable vessels of greater draught of water than at present to enter at tide-time.

By straightening and deepening the channel up to the wharfs or quays at the town, a considerable improvement may also be effected; but from the limited means at the disposal of the commissioners, it will necessarily take a long time to complete these works.

Hastings.

No harbour at present exists between Rye and Newhaven; but the construction of one at Hastings having been frequently contemplated, we visited that town. The mayor and other gentlemen of the place attended, and laid before us several plans which had been prepared for the purpose; and Colonel Williams, late of the Royal Engineers, afforded us much information, together with his suggestions on the subject.

We do not, however, consider it necessary to enter into the particulars of these plans, as a few remarks will show the unfavourable nature of the situation for the objects of our inquiry.

The coast runs, with little deviation, in a straight line, nearly east and by south, and west and by north, and is entirely exposed to the prevailing southerly and westerly winds. There is no natural backwater, nor the facility of making an artificial one to any useful extent; the shore composed of shingle, and not above four fathoms water at a distance of three quarters of a mile from the beach, which would give but a limited area of 12 feet water (at low water), in proportion to the size of the harbour, were piers to be carried out to such an extent.

A small tidal harbour for the use of trading vessels, &c. would, no doubt, be a valuable adjunct to the town and neighbourhood, but we do not consider the situation adapted for any national work.

Cuxmere Haven.

At Cuxmere Haven, which is situated on the western side of Beachy Head, there is no artificial harbour. The shingle beach crosses the entrance and rises several feet above low water, and the interior of the haven is left dry at three-quarters ebb. We did not consider it necessary to land at this place, but proceeded round the coast to Newhaven.

Newhaven.

The harbour of Newhaven is formed in the channel of the river Ouse, at its entrance into the sea, by wooden piers carried out in a southerly direction across the beach. The river is navigable as far as the town of Lewes, and open to the flow and ebb of the tide for four miles further up the stream, or twelve miles altogether, and affords a powerful backwater for scouring the entrance.

The average rise of spring tide at the harbour's mouth is from 19 to 20 feet, and of neap tides about 14 to 15 feet. The bar, however, is left dry at low water spring tides, but within the piers there is about two feet water at such times, and this depth continues uniform for a mile up the channel.

The distance between the pier-heads is only 106 feet. On the western side of the harbour, the wooden pier, which extends about 250 yards, has been continued inwards by a stone embankment nearly three-quarters of a mile in a straight line; and the bar, which formerly extended from the western side nearly across the mouth of the harbour, has been considerably reduced since the completion of this work, the extension of the eastern pier, and other improvements which have of late been made in straightening and deepening the river above the town.

During the flood-tide and fine weather the harbour is easy of access, from the indraught and eddy-tide which set towards the mouth; but from the rapidity of the stream during the ebb, it is not considered safe for a sailing vessel to enter, and the flag at the pier-head is in consequence lowered at high water.

This harbour appears to be one of considerable value, and to possess facilities for further improvements; and there can be little doubt that an additional depth of water might be obtained by the adoption of judicious measures.

The observations we had occasion to make on the subject of encroachments, when treating of Rye, are equally applicable to this harbour; but great care should be observed, in straightening the river, to exclude the waters only from such places as afford a loose soil and serve to slit up the channel.

The piers at present only extend to the line of low water on the beach; and to render the harbour more available, it would be advisable to continue them some distance into the sea, and at the same time, by deepening and enlarging the river above the harbour, a larger body of water would flow up at tide-time, and give a commensurate discharge on the ebb. A dock or pent might be constructed on the low ground on the western side, between the entrance and the town, called Sleeper's Hole; and a groin extended from Borrow Head into the sea, would facilitate the ingress and egress of vessels, by protecting the harbour's mouth from the swell occasioned by south-westerly winds, and serve to keep off the approach of shingle to the entrance. The expense, however, of these works cannot be stated without previous minute surveys, &c.

The harbour is managed by trustees.

Shoreham.

Shoreham, at the mouth of the river Adur, was the next harbour we visited.

The river, which formerly entered the sea nearly at right angles with the line of coast, has been gradually diverted from its original exit by the shingle, which constantly travels from the westward, and until a few years ago flowed along the shore in an easterly direction for three or four miles, before it at length found its way through the shingle bank into the sea.

This accumulation of shingle, consolidated by the alluvial deposit from the river, now forms an embankment between the river and the sea, varying from 200 to upwards of 300 yards in width; and an area of considerable extent is left within, into which the sea flows.

The entrance which existed at the eastern extremity of this estuary, once the river's mouth, has been blocked up, and an artificial channel has been cut through the shingle embankment about a mile from the town of Shoreham. This opening is preserved by wooden piers (formed of piles), 218 feet apart, which run in a south-south-west direction across the shingle into the sea. Within this entrance a third pier has been built out from the shore nearly across the harbour, for the purpose of directing the waters on the ebb, from the eastern and western sides of the inlet, directly to the mouth. The great body of water which thus ebbs and flows through the entrance serves to keep the channel open; and though the width is so considerable, the stream runs between the pier-heads at the rate of five or six miles an hour. The harbour's mouth is nevertheless subject to a bar, which rises occasionally above the low water level, and shifts its position from 60 to 160 feet from the pier-heads.

The lift of spring tides is about 15 feet, and neaps about nine feet. The depth of water over the bar at high water is from 14 to 17 feet, according to the tides and state of the bar.

From its proximity to Brighton, this harbour is of importance to the local trade. We were informed that upwards of a thousand vessels enter annually. It is capable of improvements; the most obvious of which are, the extension of the present piers and the filling in of their centres with rubble, which are now partly open, and admit the shingle into the entrance.

The interior of the harbour might, at the same time, be deepened and generally improved, but we do not consider it capable of being converted into a deep-water harbour for the purposes pointed out by their Lordships.

The harbour is the property of a joint-stock company, established by Act of Parliament.

Littlehampton.

Littlehampton, which is the next harbour on the coast, is formed by the channel of the river Arun, which is led in a southerly direction into the sea, between two piers, composed of piles, with an extension of dicker-work.

The depth of water in the entrance between the piers is two to three feet below the level of low water, but a bar extends outside the dicker-work, across the mouth, which rises about two feet above the general surface, and is left dry at low water.

The lift of average spring tides about 16 feet, and of neaps 11 feet.

The larger vessels which enter usually remain near the river's mouth, at Littlehampton; but a vessel of 13 feet draught, when she has passed the bar, can proceed to Arundel Bridge, a distance of six miles, the bottom continuing of an uniform level throughout that extent.

The tide flows nearly 25 miles up the river, but the backwater thereby afforded proves of little value, in consequence of the narrowness of the channel and the sluggishness of the stream. It is scarcely necessary to add, that the harbour is not available for the objects of our inquiry, and the shoalness of the water on this part of the coast renders the situation inapplicable for any national undertaking.

The harbour is under the management of trustees.

Pagham.

Pagham was the last place we examined; it consists of low ground of very considerable extent, over which the tide flows at high water, and is entered by a crooked channel which continues some distance inland; vessels of 40 tons and under, with coals or manure, are the only traders to the place.

There is no artificial harbour, and the situation is not deserving of attention.

General Remarks.

Having now completed our remarks on the state and capabilities of the existing harbours, &c., it is evident that there is no port at the present moment between Sheerness and Selsea Bill which can be considered an available harbour of refuge at all times of tide, or that possesses the capability of being rendered efficient for such a purpose, by any improvements or alterations which could be made.

We proceed, therefore, in conformity with their Lordships' instructions, to point out the situations which, in our opinion, are best calculated for stations for armed steam-vessels during war; and the works necessary to render them available for such a purpose, and at the same time to combine all the objects for which refuge harbours are so much required for the security of shipping navigating this part of the Channel.

We are decidedly of opinion that deep-water harbours on this part of the coast must be formed in the sea by means of breakwaters detached from the main land, on the same principle as that in Plymouth Sound, or connected with the shore by piers similar to the harbour at Kingstown, near Dublin.

The situation which appears to us to be of the greatest importance, and at the same time offers the most eligible position for a deep-water harbour, is Dover Bay. Independently of its proximity to the Continent, this bay possesses considerable advantages: the depth of water at 400 yards from the shore, is two fathoms at low water of spring tides, and but six fathoms at 1,100 yards; which therefore affords a sufficient width for the construction of a capacious deep-water harbour, without getting into such a depth for the site of the piers or breakwater as would add greatly to the expense of the works. The principal feature of the proposed plan is a breakwater, at the average distance of 1,000 yards from the shore, with piers projected from the land towards its eastern and western ends, leaving one or more entrances, as shown on the plan, Fig. 1, at A, B, and C.

These piers and breakwaters to consist of large blocks of the hardest chalk rock, with a thick covering of stone, either granite or hard limestone.

The space between the piers, or length of the harbour, as shown upon the plan, is 2,300 yards, and the area enclosed would comprise 450 acres,* of which 320 would have from six to two fathoms at low water, and 130 acres under two fathoms. The breakwater may be connected with the east and west piers, and have but one entrance in the middle (C), 600 or 700 feet in width; or it may be detached from the piers, so as to leave an entrance (A) nearly opposite the present harbour, and another opening (B) at the eastern end.

The advantages of two entrances, one at the eastern and the other at the western end, instead of one only in the centre, would be that vessels might enter or leave the harbour with the wind from any quarter, and a ready access be afforded to the mouth of the present harbour from the western entrance, without passing through the centre of the new harbour.

On the other hand, one entrance in the middle would have the advantage of rendering the interior of the harbour in some degree quieter than with two entrances.

On consideration of the subject, our opinion is in favour of the two entrances at the east and west ends; but the decision of the question need not delay or interfere with the execution of the work, as it might be proceeded with along its whole extent (with the exception of the entrances), and the result of the advantages, or otherwise, be tested by actual observation.

As a second place for a harbour of refuge, we recommend the bight to the eastward of Beachy Head and westward of Langley Point, and the formation there of a detached breakwater curved or in kants, the main body running nearly parallel with the shore, leaving entrances to the eastward and westward, to enable vessels to sail out or in with any wind (Fig. 2).

There is a sufficient depth of water near the shore, and but a small increase of depth for a considerable way out; affording a large harbour space, and facility for the formation of the necessary works. Looking at the locality as nearly equidistant from the South Foreland on the east, and the harbours and anchorages within the Isle of Wight on the west, and to its relative position with many harbours on the opposite shore; also to its proximity to the elevated promontory of Beachy Head; we think it offers important advantages, both as an asylum harbour and station for armed steam-vessels.

The breakwater, if built in five fathoms water, and one mile from the shore, would give a width of about half a mile, having in no part less than two fathoms depth at low water; the area of course depending on the length.

One and a half mile of breakwater, including the arms, would give shelter over 450 acres of surface.

The third and last situation we recommend for a harbour of refuge, is under the chalk cliffs to the eastward of Margate. The Chalk Bank and Longnose Spit stretch out to the north-east from Foreness Point: upon this site we propose a pier to commence at the shore, and to be extended 1,000 yards clear in a north-north-east direction; thence to turn west-north-west for a length of 2,000 yards; terminating in a round end, to form the northern head of the entrance. The western pier to be carried out from the shore in nearly a north-east direction, and be the same length as the east pier.

This would enclose a harbour of 460 acres, of which 352 acres would be not less than two fathoms, increasing to six fathoms, and 108 acres would be under two fathoms at low water.

The entrance opening in a north-westerly direction would receive the protection of Margate Sand, and an opening in a west-north-west bearing would also permit vessels to sail in with winds from the south round westward to north-east, and out with winds from the north round eastward and southward to south-west. And in extreme cases, when the harbour could not be entered by sailing vessels, shelter would be given them under, or to the eastward or westward of it.

The construction would be, as at Dover, a core of chalk blocks from the adjoining rocks, faced with stone.

The advantages of this situation will be apparent when it is remembered that our eastern coast is literally without shelter from easterly winds for vessels of any magnitude.

A harbour off Foreness must, therefore, be regarded as one of refuge for vessels stationed in the North Sea, and would more particularly have reference to every thing connected with the opposite ports eastward of Calais.

For the mercantile marine, especially, navigating the northern part of the English Channel, the situation would be most desirable; inasmuch as vessels bound to the westward from the river Thames or the North Sea, arriving off the North Foreland, and then finding the wind strong from the southward and westward, would, in order to avoid anchoring in the Downs, and the liability to accidents which so frequently occur there in south-westerly gales, gladly avail themselves of the shelter which this harbour would afford.

To vessels, also, caught in the Downs by tempestuous weather, or having received damage, a harbour off Foreness, accessible at all times of tide, would prove an invaluable asylum, where heavily-laden ships would escape the danger of grounding; and a considerable fleet of such vessels would lie in perfect security from storms or an enemy, until a change of wind would enable them to proceed down Channel.

Similar advantages would be experienced during easterly winds, by vessels from the westward, bound to ports upon the east coast; whilst to steam-vessels the harbour would be accessible in all winds and weather.

The cost of each of the three harbours of refuge we have recommended, may be taken as nearly equal; none of them less than £2,000,000 sterling, nor much exceeding that sum. An addition of a quarter of a mile to the length, would give an increased area of 100 acres, and would add about £300,000 to the estimated expense of each harbour.

We have not considered it necessary to enter into any details as to the defences which might be required to these places of refuge, but there can be no doubt of the practicability of rendering them secure.

The introduction of steam navigation will render a rapid communication along the coast an object of far greater importance than heretofore; and we consider that railways along the coast, on each side of Dover, may be made extremely useful in sending support in the shortest possible time to any point where the presence of troops may be required.

We have, &c.

RAILWAY COMMUNICATION WITH SCOTLAND.

Second Report of Lieut.-Colonel Sir Frederic Smith, of the Royal Engineers, and Professor Barlow, to the Lords of the Treasury, in pursuance of the Addresses of the House of Commons, of the 11th and 20th August, 1839.

Railway Committee Office,
5, Committee Room, House of Commons,
May 16, 1840.

Sir—The instructions of the Lords Commissioners of the Treasury, communicated to us in your letter of the 26th November, 1839, having directed that we should examine and report upon the surveyed and projected lines for a railway communication between London and the cities of Edinburgh and Glasgow, in conformity with the address of the House of Commons, dated the 11th of August, 1839, we entered upon this inquiry immediately on receiving from the promoters of these lines the documents which had been prepared for the investigation.

The address to which we have referred prays "that her Majesty will be pleased to give directions that an engineer, or engineers, may be appointed to to inquire and report upon the relative merits, and the preference which ought to be given to the respective already surveyed and projected railways between London and the cities of Edinburgh and Glasgow, following, namely, viâ York, Newcastle-upon-Tyne, and Berwick; viâ York, Newcastle-upon-Tyne, and Hexham; viâ Lancaster, Whitehaven, and Carlisle; and viâ Lancaster, Penrith, and Carlisle; and said inquiry and report to include the relative merits of the two lines, from London to York, by Derby and Rotherham, and by Cambridge and Lincoln."

The investigation entrusted to us divides itself into two branches; the one being the relative merits of the competing lines between London and Edinburgh, and the other, of those projected between London and Glasgow.

Their lordships having granted an extension of time to the promoters of certain lines north of the Carlisle and Newcastle Railway, for the purpose of enabling these parties to render their surveys more complete, and some of the documents necessary for testing the relative merits of the proposed lines of communication from London to Newcastle not being ready for our examination, we have devoted our attention principally to the subject of the communication between London and Carlisle, and to the merits of the Cumberland railways, as regards their connexion with the western parts of Scotland, and the north of Ireland, to which our attention is called by the address of the House of Commons, dated the 20th August last, and we have now the honour to report the result of our inquiries.

It appears that by the London and Birmingham, the Grand Junction, and the North Union lines, the communication by railway is complete as far as Preston, being a distance of 218 miles 51 chains, and we find that the Preston and Lancaster Railway is in a state of great forwardness. When this last-mentioned line shall be finished, the distance by railway from London to Lancaster will be 238 miles 69 chains.*

Description of the competing Projects.—Three projects were laid before us for the extension of this great trunk line to Scotland.

One from Lancaster, along the west coast of Cumberland, through Whitehaven to Maryport, in order to join the railway now in progress between the latter place and Carlisle.

Another from Lancaster by Kirkby Lonsdale, and the valley of the Lune to Penrith, and from thence to Carlisle; and a third from Lancaster to Kendal, and thence up the valley of Long Sleddale, and by Hawes Water to Penrith, to form a junction with the proposed railway from the last-mentioned place to Carlisle.

West Cumberland Coast line.—The documents respecting the Cumberland coast line, delivered to us by the solicitors, Messrs. Haslam and Bischoff, and the engineers, Messrs. Rastrick and Hague, are copies of their parliamentary plan and section; drawings descriptive of the proposed mode of forming the embankments across Morecambe Bay, and the Dudden Sands, and a general plan of the country through which the line would pass. We were also furnished with a printed copy of a report on this project, by the engineers, and with a detailed estimate, formed by Mr. Hague, of the cost of the embankments.

The whole of the drawings illustrative of this project have been prepared in a very perfect and creditable manner, and have much facilitated our examination of the country.

Penrith and Carlisle line.—Mr. Larmer, the engineer, and Mr. Dixon, the secretary to the provisional committee of a Company for forming a railway from Carlisle to Penrith, supplied us with a section of this line, and a map of the county, on which the proposed route is traced.

Lune line.—We may here observe, that if this railway should be formed, it would be connected, at its southern terminus, with either of the inland lines that may be established from Lancaster. Mr. Larmer not only surveyed and projected the line from Carlisle to Penrith, but also that from Penrith to Kirkby Lonsdale. The line from the last-named place to Lancaster, we were informed, was laid down by persons under the direction of Mr. Locke, but the sections of the whole extent between Penrith and Lancaster, and tracing of it on maps of Cumberland, Westmoreland, and Lancaster were placed before us by Mr. Larmer, by whom we were also furnished with an estimate of the cost of the entire distance from Lancaster to Carlisle, and a report descriptive of this project.

Kendal line.—From Mr. Cornelius Nicholson, secretary to the provisional committee for the Kendal line, we received a section of this proposed railway, and a map of Westmoreland and a part of Lancashire, on which the direction of the line is traced. The survey, as well as a gross estimate of the cost of the line, were prepared by Mr. Bintley, of Kendal, by whom a report respecting it was drawn up, which will be found in the appendix.*

In the course of our examination of the documents submitted to us, we found that, with the exception of the drawings and report of the coast line, they were insufficient for the purpose of fairly testing the relative merits of the several projects now under consideration, and we therefore called for further information, not only as to their mechanical, but also as to their statistical properties. This information having been in part supplied on the 18th February, we commenced on that day an examination of the country through which these projected railways would pass, and we shall now give a general description of their principal features, beginning with the Cumberland coast line.

Cumberland Coast line.—It is proposed that this railway should commence at the terminus of the Lancaster and Preston Railway, and that, curving round towards Skirton, it should first cross the Kendal Canal, and then the River Lune; the latter on a bridge, the arching of which is represented by Mr. Rastrick to be 660 yards in length, and of the extreme height of 67 feet above the bed of the river. From Skirton the line is to proceed by Torrisholme to the village of Poulton; from hence it would be carried, in the direction of Leonard's Point, in the peninsula of Low Furness, on a lofty embankment of 10 miles and 51 chains in length, to be constructed across the estuary of Morecambe Bay, into which the Kent, the Crake, and the Leven empty themselves. Through the peninsula the railway would have to be formed in a line of double curvature, and in some deep cuttings in sandstone rock. It is also proposed to form an embankment across the Dudden Sands, from Bonhead Crag to Hodbarrow Point, a distance of one mile and 65 chains. These embankments are understood to be the suggestions of Mr. Hague, whose plan provides locks and flood-gates for the rivers, the channels of which he proposes to straighten and embank. It is here proper to state that the promoters of this line calculate upon reclaiming by the two embankments 52,000 acres of land, which they value at 23*l.* per acre, and they have therefore taken credit for £1,196,000 in the estimate of this part of their project.

From Hodbarrow the line would pass near Bootle to Ravenglass, through a country presenting no engineering work of difficulty or great expense until arriving at the River Esk, where a viaduct will be necessary of upwards of a quarter of a mile in length, and of 23 feet in the extreme height, approached by an embankment of about a mile in length, and of the average height of 15 feet.

The line is to curve at Ravenglass, passing the rivers Esk and Mite, and to take a direction towards the coast, crossing the river Calder at its mouth. It is also to be carried over the river Ehen, and thence to keep along the shore, requiring the occasional formation of embankments, between high and low water mark, to the valley of St. Bees. Here a curve is proposed towards the north-east to unite with one bending towards the north-west, which would bring the line, with tolerably easy work, to Whitehaven. It is proposed to carry the railway through the whole length of this town, on a series of arches, which Mr. Rastrick's section shows to be of the extreme height of 27 feet, and of the length of half a mile. On leaving Whitehaven a tunnel of 1,320 yards in length would have to be cut through sandstone. The line is from hence to pass towards Harrington, along the coast, through some short, but rather deep cuttings, and over four embankments, measuring altogether two miles in length, and of the respective heights of 18, 23, 27, and 34 feet.

Mr. Rastrick's plan is to cross the upper end of the harbour of Harrington by a bridge, which his section shows to be 120 yards long, and 27 feet high.

From hence the line is intended to take the direction of Workington, and to cross the harbour, as well as the Derwent river, on bridges and embankments.

From the Derwent to the terminus of the Maryport Railway, with which Mr. Rastrick's line is proposed to be joined, the work will be easy.

Expensive, or objectionable parts of the Cumberland Coast line.—The operations of an expensive, difficult, or objectionable character on the coast line, which we have thus briefly described, are as follows:—

1. The bridge over the river Lune.
2. The embankments across Morecambe Bay and the Dudden Sands, with the embankments to confine the courses of the rivers which empty themselves into these estuaries.
3. The cuttings in rock through Low Furness.
4. The viaducts and embankment across the rivers Esk and Mite, and over the sands at Ravenglass.

* If a line should be formed from Rugby to Stafford, or from Rugby to Stone, the distance would be shortened by about eight miles.

* We must observe, that the report omits to mention some of the expensive operations on this line, and but slightly notices other important works involved in Mr. Bintley's project: and we cannot help expressing our surprise that he should have stated that the proposed tunnel through the Gate Scarth, which the highest geological authorities represent to be composed of green slate and porphyry, could be formed at the rate of £50,000 per mile, a sum which is totally inadequate to cover the cost of so formidable an undertaking, particularly as the summit is nearly 1,200 feet above the tunnel.

5. The very extensive demolition of houses at Whitehaven, and the formation of viaduct of half a mile in length through that town.

6. The tunnel to the north of Whitehaven.

7. The crossing of Harrington Harbour, and the injury which would thereby be caused to that port, and

8. The crossing of Workington harbour, and the Derwent river.

To these may be added, the stoppage of the Ulverstone trade during the formation of the river channels, and a part of the Morecambe Bay embankment.

Although each of these operations would be attended with considerable expense, none of them presents what may be termed, great engineering difficulties, excepting the embankments of Morecambe Bay, and the Dudden Sands; but these are works of an extraordinary character and magnitude, and therefore require our particular notice.

Morecambe Bay Embankment.—The formation of an embankment of upwards of ten miles in length, across an estuary where the sea has been known to rise 30 feet, and where in gales from the north-west to the south-west, it rolls in with tremendous force, and with a rate of tide during the springs, of more than four knots an hour, may justly be termed a project of a gigantic character, and will, if executed, reflect much credit on the engineer.

The mode in which Mr. Hague would form the embankment is both novel and ingenious. (Vide *Journal*, Vol. I., p. 409).

The mode proposed for forming the embankment across the Dudden is the same as that for Morecambe Bay.

In Mr. Hague's report, (which will be found in the *Journal*, Vol. I. p. 410), he states that the total cost of forming the embankments and railway across Morecambe Bay and the Dudden Sands, would amount to £345,230 3s. 4d., and of forming the new channels for the rivers which flow into these estuaries to £88,901 6s., making a gross sum of £434,131 9s. 4d.

Not being satisfied with this statement, we called for a detailed estimate, which Mr. Hague accordingly prepared for us.

In this document the sum allowed for the embankments across the Bay is stated as £395,453 1s. 4d., and for the river channels £71,758 0s. 7d., making a general total of £467,211 1s. 11d., which exceeds by £33,679 12s. 7d., the sum specified in Mr. Hague's first report.

On a careful examination of these documents it appeared to us that a further detail was necessary, and we therefore requested additional information in respect to the alteration of the river channels.

From Mr. Hague's reply, which we received on the 23rd March, we find that he estimates the cost of raising the soil from the proposed river courses at only one-third of a penny per cubic yard; and of raising, depositing, and forming it into the embankments at 2*d.* per cubic yard. Conceiving this allowance to be inadequate to defray the cost of the work, we considered it proper to obtain the best information within our reach on this important item of expense; and, on application, we were supplied by the secretary* of the Trinity Board with a statement of the average cost of working the dredging engine used by them in the Thames. These are of the same power as the engines which Mr. Hague proposes to use; and it appears that, independently of the first outlay for the purchase of the vessel and machinery, the average expense of raising the mud from the river and shooting it into the barges, amounts to not less than 3*d.* per ton. Estimating the weight of a cubic yard to be 1 1-5th ton, the cost of removing the soil from the River Thames to the barges only, according to the above statement, amounts to 3 3-5ths of a penny per cubic yard.

We have also been in communication with the engineer† under whose direction the improvements in the River Dart have recently been made, and this gentleman has favoured us with a statement, from which it appears that the actual expenditure incurred in that work for dredging and depositing amounted to 4*d.* per ton, or nearly 5*d.* per cubic yard. We therefore feel warranted coming to the conclusion that Mr. Hague's allowance of 2*d.* per cubic yard, for dredging and depositing soil, in the formation of the river courses within his proposed embankment, is much too low, and that the smallest estimate that can be admitted for this work is 3½*d.* per cubic yard.

This increase of 1½*d.* per cubic yard would make the cost of the channels amount to £85,999 1s. 1*d.*: a sum which we are convinced would be found barely sufficient for the purpose, the more especially as there are other items in the estimate for the channels inserted at inadequate prices.

It is unnecessary for us, under all the circumstances of this inquiry, to go into any great detail of the result of our examination of the estimates of the embankment; but we must observe that an insufficient allowance has been made for the cost of some of the items, and especially in respect to the mass of stones proposed to be placed under the railway, in the centre of the embankment.

Mr. Hague allows £50,089 17*s.* 6*d.* for this item; but he has so much under-rated the quantity of stones that would be used, that without adding anything to the price which he has allowed for this material, and which we also think too low, we feel bound to add one-fourth to the above stated gross sum, increasing it to £62,612 6*s.* 10½*d.*

We should also observe, that in Mr. Hague's estimate of the embankments, he has not only inserted very low, and, on some occasions, inadequate prices for the proposed works, but he has also given the mere net quantities of materials and labour, allowing nothing for those contingencies which, in all great works, invariably arise. In an operation of the peculiar and difficult character now under consideration, contending, as the engineer would have to do, with the rapid tide we have described as pouring into the bay, contingencies beyond the ordinary proportion would be inevitable, and the least allowance that could prudently be made for them would be 10 per cent.

It is stated by Mr. Hague that the operations of the tide would supply 6,149,379 out of the 10,153,785 of cubic yards of sand and silt required for his embankments, and that when formed as proposed, they will be watertight, without having recourse to the expensive operation of puddling.

We do not believe that these expectations would be realized; but even admitting that this would be the case, the minimum cost of the embankment and channels, according to our opinion, would amount to £493,975 11*s.* 9½*d.*, and, with the addition of 10 per cent, for contingencies, the estimate should not be stated at less than £543,373 2*s.* 11½*d.*, being £109,241 13*s.* 7½*d.* more than the sum specified in Mr. Hague's original report.

The projectors and promoters of the Morecambe Bay line appear, however, to entertain a confident expectation of effecting their object at a cost which would render the work highly advantageous in a pecuniary point of view, and, at the same time, most beneficial to this part of the country.

A very intelligent gentleman,* who is a land-owner at the upper part of the bay, has made several experiments, with various kinds of grain, to test the quality of the soil proposed to be enclosed; and based upon the results he has thus obtained, he gives it as his decided opinion that it will be highly productive.

It is now necessary to say a few words respecting the proposed operations at Whitehaven and Harrington.

Proposed operations at Whitehaven.—We annex two sketches, showing the line selected for the railway through those places. It will be seen, that the intention is to take down houses in Whitehaven to the extent of half a mile in length, and to construct the proposed viaduct on the sites which these buildings occupy. It is true that, for the most part, they are of little value; but, nevertheless, the compensation that would be claimed for them would, in all probability, be considerable; and, should they become the subject of litigation, the amount that would be awarded to the proprietors, and the law expences connected with this part of the work, would be found no inconsiderable items in the cost of the railway.

As we have already stated, it is intended to cross Harrington Harbour by a viaduct.

The crossing of the Harbour at Harrington.—The whole extent of the harbour is only 762 feet in length, and 220 in breadth; and, as it is used as well for a port of refuge as of lading, and there is an insufficiency of space for vessels to anchor and swing in, an artificial beach has been formed at the eastern or upper end, on which they are enabled to bring up.

The proposed viaduct would cut off about a third of the harbour. This would not only be objectionable on account of its diminishing the capacity of the port, but also by its depriving the shipping of the artificial beach to which we have just alluded. The objection to curtailing the size of the harbour will be apparent, when we state that the harbour-master supplied us with a return (verified by the custom-house officer), by which we find that, in the course of the last year, no fewer than 510 vessels used this port, and that, during gales of wind, it was frequently so full that they were in actual contact from side to side. After well considering this part of the subject, we are of opinion, that whatever expense or other inconvenience it might cause, it would be necessary to adopt some other mode of carrying the railway past Harrington than that proposed.

From the table of gradients it will be seen that the gradients of this line are very favourable.

EXAMINATION OF THE INLAND LINES.

Examination of the Line from Penrith to Carlisle.—We shall now describe the two inland lines, commencing with the proposed railway from Penrith to Carlisle, which is common to both projects.

In this line, which is about 17½ miles in length, no engineering difficulty presents itself.

It would pass through or near the following places: Calthwaite, Southwaite, Barrock, Wreay, Brisco, and Upperby, to form a junction with the Newcastle and Carlisle Railway at St. Nicholas.

The greatest embankment in this distance would be about two miles in length, and of an average height of about 16 feet, between Penrith and the Peteril stream.

At Southwaite, a cutting would be necessary of about three quarters of a mile in length, averaging 20 feet in depth, in sand and clay.

Near Wreay, a heavy cutting is proposed, in sand and gravel. Its length is about a mile, and its extreme depth 50 feet, the average being 30.

Examination of the Line of the Lune, from Lancaster to Penrith.—We shall proceed to point out the course of the lines which are proposed to form a junction with the Penrith Railway, and we shall begin with the project of the valley of the Lune, starting from Lancaster.

It is intended that the terminus should be that of the Lancaster and Preston Railway, and that the line should be carried in the direction of Kirkby Lonsdale; a few miles to the westward of Sedbergh; thence by Borrow Bridge and Orton, and through Crosby, Ravensworth, Newby, Melkenthorp, and Clifton, to Penrith.

Between Lancaster and Kirkby Lonsdale the prominent features of this

* Jacob Herbert, Esq.
† Mr. William Kingston.

* Mr. James Stockdale, of Carke.

line are, first, the crossing of the River Lune at the Crook, on a bridge of 60 feet in height, and consisting of three arches of 50 feet span; then short cuttings in gravel of 65 feet, and 50 feet in depth; and near Kirkby Lonsdale a cutting of a quarter of a mile in length, and of the extreme depth of 67 feet, in limestone.

From this spot to nearly opposite to Sedburgh, the only engineering work requiring notice is the crossing of the Lune twice in the short distance of 15 chains.

At Borrow Bridge the Lune would have to be crossed on a bridge of about 48 feet in height, consisting of one arch of 60 feet span; and here an embankment of nearly half a mile in length, and of the mean height of 20 feet, would also be necessary. From hence to Orton the points deserving of remark are the formation at Tebay of an embankment of half a mile in length, and about 35 feet in height; and the crossing of the Lune on a bridge of 54 feet in height, and about 200 feet in length.

From Tebay the line rises at the rate of 1 in 132, for upwards of three miles to Orton Scar, the proposed summit, which is 650 feet above the Lancaster terminus.

In approaching this summit, where a tunnel of about 1 mile and 30 chains would be requisite, there would be a cutting in rock of rather more than a mile and a half in length, and averaging 48 feet in depth; the extreme depth being 84 feet. On the northern side of the tunnel, another cutting in the same material would occur, of about half a mile in length, averaging 36 feet, and of the extreme depth of 75 feet.

These two cuttings, and the tunnel, which are in red sand-stone and limestone, would be the heaviest and most expensive operations on this line.

The extreme height of the hill above the tunnel is shown in Mr. Larmer's section as being 322 feet, and this we have found to be correct, by a survey made under our directions, and to which we shall hereafter more particularly allude.

Between the northern end of the tunnel and Crosby Ravensworth, the railway would keep in the valley, in which Mr. Larmer proposes to cross a mountain stream two or three times; for this purpose bridges would be necessary; but we are of opinion that it would be better to change the course of the stream, and to form a proper embankment for the railway, to keep it clear of the water during floods.

At Crosby Ravensworth a bridge 44 feet high, and at Mauls Meaburn another, 50 feet high, would be necessary, over two streams; an embankment would likewise be required at the latter place. At Morland Bank there would be an embankment of half a mile in length, and of the extreme height of 55 feet.

Between Newby and Melkenthorp a cutting in limestone, of a mile in length, and of the extreme depth of 28 feet, would be requisite. At the last-named place the Leathe would have to be passed, on a bridge of 66 feet in height, with an arch of 50 feet span, approached by considerable embankments.

At Clifton there must be a cutting in sand, of about a quarter of a mile in length, and averaging 30 feet in depth.

Between Clifton and Penrith, the Rivers Lowther and Eamont would have to be crossed on bridges of 52 feet in height, and 200 yards in length.

Examination of the Kendal Line, from Lancaster to Penrith.—It remains for us to describe the Kendal line.

It is proposed that this line should form a junction with the Lancaster and Preston Railway, at about 2 miles 54 chains from the terminus at the former place; that it should pass in a tunnel under the town of Lancaster, and then by a stone bridge across the river Lune, near the ruins of the old bridge.

From this point it would pass the villages of Sline, Bolton, Carnforth, and Warton; and thence crossing the Rivers Betha and Viver and the canal, it would be carried to within about a mile of the town of Kendal.

The line would then be continued by a rather indirect course to the entrance of the valley of Long Sleddale, where it would cross the river Sprint. It is intended that it should be carried to the upper end of this valley, where a tunnel becomes necessary to pass through Gate Scarth. Issuing on the north side of the hill, the railway would open on the valley of Mardale-green, and after passing by another tunnel through Chapel Hill, be continued along the western side of the lake of Hawes Water, surrounded by scenery of the most beautiful and romantic character, as far as the village of Brampton. From hence it would run for several miles nearly parallel to the course of the River Lowther, as far as the village of Askham, where it would skirt the park of Lowther Castle; it would then have to cross the River Eamont, and proceed direct to the proposed southern terminus of the Carlisle and Penrith Railway.

The chief details of this line are as follow:—

The length of the tunnel proposed to be formed under the town of Lancaster is 13 chains; the length of the bridge over the Lune is represented by Mr. Bintley to be 400 feet, and its height 26 feet. Near Hestbank a tunnel of eight chains in length is shown in Mr. Bintley's section, but it is believed that this may be avoided.

No severe work would occur until nearly opposite to Carnforth Lodge, where there would be a cutting of half a mile in length, averaging 20 feet in depth, followed by an embankment of about a mile and a quarter in length, and 20 feet in mean height, having, about mid-way, a bridge over the River Keer.

From hence towards Burton there would be two cuttings through alluvial soil and limestone; the average depth being about 30 feet, and the total length something more than a mile.

Between the towns of Burton and Kendal the rivers Betha and Viver, as well as the Lancaster and Kendal Canal, would have to be crossed on bridges, and a tunnel of 13 chains in length, and nearly half a mile of deep cutting in schistose rock, would be necessary.

From Kendal to the entrance of the proposed summit tunnel, Mr. Bintley's section shows the necessity of the following works; and although an inspection of the country led us to believe that the line might, in some few instances, be improved, we do not think that the alterations we suggested on the spot are of sufficient importance to be adverted to in this report.

There are two rock cuttings of the average depth of 30 feet, and measuring together seven eighths of a mile in length; then there is a viaduct of the extreme height of 125 feet, and 16 chains in length; and in the following order, a tunnel of 11 chains, another of $14\frac{1}{2}$ chains, then a cutting of three quarters of a mile in length, and averaging 48 feet in height; a viaduct 114 feet in extreme height, and 9 chains long, a cutting a quarter of a mile in length, of the average depth of 30 feet; an embankment also of a quarter of a mile in length, and 45 feet in height; again a cutting of the same length, and 38 feet in depth, an embankment half a mile in length, and 40 feet in height, crossing the Sprint on a bridge; and, finally, another embankment of 25 chains in length, and 50 feet in height.

These cuttings are chiefly in schistose rock. The River Sprint, which runs through the valley of Long Sleddale, has a rather tortuous course; and, as it frequently crosses the line of the railway, some difficulties would necessarily arise in diverting the course of this river, as well as of the mountain streams which flow into it.

In connexion with the summit tunnel there is a cutting, the longitudinal section of which is nearly of a triangular form, being three quarters of a mile in length, and 63 feet in extreme depth.

The length of the tunnel is shown on the section prepared by Mr. Bintley as 2 miles and 20 chains, and as being 1200 feet under the summit of the hill through which it would have to be pierced. On issuing from the tunnel, on the north side of the hill, there would be a cutting of rather less than a quarter of a mile in length, and about 40 feet in depth, and then a short tunnel of 20 chains, through Chapel Hill. It is stated by Mr. Bintley, that these cuttings and tunnels would be in rock of the clay slate formation.

The Rev. A. Sedgwick, who has very minutely examined this district, represents it as being composed of green slate and porphyry, which he conceived to have been elevated by the protrusion of mountain granite and syenite.*

Beyond the short tunnel there would be an embankment of about a mile in length, and about 28 feet in height. From hence, passing by Brampton and Hilton, there is nothing of importance to notice until arriving at Askham, where a cutting would be requisite, in rock of the grawacke formation, of $1\frac{1}{4}$ mile in length, and averaging 25 feet in depth.

Between Askham and Penrith there is no work of consequence, excepting the bridge across the Eamont, which would require to be 85 feet in height, and 200 feet in length.

Operations of an expensive or difficult character on the Kendal Line.—The engineering difficulties, or works of a very expensive character on the Kendal line, are as follows:—

1st. The tunnel under the town of Lancaster.

2nd. The bridge over the Lune.

3rd. The works in the valley of Long Sleddale; and,

4th. The summit tunnel.

The tunnel under the town, although only 13 chains in length, would be expensive, and might give rise to some opposition on the part of the inhabitants.

It is proposed to build the bridge for the railway over the Lune at the point where the old bridge formerly stood, and where the river makes an elbow towards the southern shore. In order to diminish the cost of the work, by avoiding the necessity of using coffer-dams, Mr. Bintley proposes to construct the bridge on the shore, opposite to Lancaster, and afterwards to divert the course of the river, so that it may flow through the arches of the proposed bridge, and he would then fill up the present bed of the river, and form an embankment across it.

The operations in the valley of Long Sleddale would require to be managed with much care and dexterity, for owing to its narrowness, and the space required for the railway embankments, the present courses of the River Sprint, and of its tributary streams, would be much interrupted.

However, all these matters are of but little moment in comparison with the great work of this line, the summit tunnel.

Summit Tunnel on the Kendal Line.—We have before remarked that this tunnel is proposed to be $2\frac{1}{4}$ miles in length, and to be approached on the south through a cutting of three quarters of a mile in length, and on the north by a tunnel of one quarter of a mile in length, and a cutting of nearly the same extent, making a total length of nearly $3\frac{1}{2}$ miles of very severe work.

Comparison of the Lines.—Having now described, in sufficient detail, the principal features, as far as regards construction, of the three competing lines, we shall proceed to consider their defects and advantages, in order to decide upon their relative merits.

In the two inland lines, which we shall first compare together, the most striking defects are, obviously, their summit tunnels. * *

* Trans. Geological Society. 2nd Series, vol. 4. p. 67.

Observations on the mechanical properties of the three competing Lines.—Coast Line.—Referring now to the mechanical properties of these lines, it appears that the length of railroad to be executed on the coast line, between the terminus of the Preston and Lancaster railway at Lancaster, and the Maryport railway, amounts to 66 miles 42 chains, and that the length of the Maryport and Carlisle Railway, which is now in progress, is 28 miles 3 chains, making the whole distance between Lancaster and Carlisle 94 miles 45 chains; the gradients being of a favourable description.

Lune Line.—By the inland line of the valley of the Lune, Orton, and Penrith, the whole distance between Lancaster and Carlisle is 68 miles 48 chains; but the gradients are less favourable than those of the coast line.

Kendal Line.—By the other inland line viâ Kendal, the distance between the termini at Lancaster and Carlisle is only 64 miles 34 chains; but as this line enters Lancaster on a different level from the terminus of the Preston and Lancaster railway, it does not form a junction with that line till it has passed 2 miles 54 chains farther on, towards Preston; so that the whole length* of new line to be executed on this route will amount to 67 miles 8 chains, the gradients being somewhat less favourable than on the line of the Lune.

In order to make a comparison of the mechanical advantages and disadvantages of these lines, we have reduced several gradients to equivalent horizontal distances.

The principle of this reduction may be briefly stated as follows.

Explanation of the term equivalent horizontal distance.—There is always an increased tractive power required to ascend a plane beyond that which is requisite on a level, and therefore (the engine being the same) a certain amount of additional time is required in the ascent. This additional time would allow the engine to pass over a certain extent of horizontal distance with the same load, and this increase of distance may be taken as a measure of the retarding effect of the ascending plane.

In descending the same plane, the tractive force and time requisite are less than on a horizontal plane, and this effect may therefore be indicated by a horizontal line shorter than the plane; but as there is always more time lost in ascending than is gained in descending any given plane, a loss is sustained on the aggregate, and this whole effect may be expressed by an increased length of line, greater or less according to the steepness of the plane and the amount of the load, and this increased line is what has been denominated the equivalent horizontal distance.*

This mode of reduction has been carefully applied to the several gradients on each of the three lines now under consideration. We find that the locomotive power requisite to work the coast line of 94 miles 54 chains, with a gross load of 50 tons, is equivalent to that which would work a horizontal line of 98 miles 31 chains; while the mean equivalent distance, for the inland line of the valley of the Lune, is 78 miles 1 chain; and for the Kendal line, between Lancaster and Carlisle, 75 miles 9 chains. As far, therefore, as regards the expense of locomotive power, the advantage is much in favour of either of the inland lines, as compared with the coast line, while all the other expenses are still more in their favour, these latter expenses being generally proportional to the actual distance, such as police, stations, water stations, road repairs, government taxes, &c.

In order to ascertain the effect that this increased locomotive expense would have on the general working expenses of the several lines, we have examined with great care and attention the official returns of the principal working railways, separating, as far as possible, the charges for locomotive power from the other charges; and although we have found considerable differences in the proportions, according to the prices of fuel and other circumstances; yet, upon the whole, it appears to be a fair average to assume the locomotive expenses as amounting to one-third (or about 33 per cent.) of the total working expenses of a line of railway of moderate traffic; and since the equivalent distance on the inland lines is about one-sixth greater than the actual distance, the additional locomotive charge due to the gradients will amount to about 1-18th, or six per cent. on the general expenses of the line; or estimating, as is usually done, the total expenses at half the income, to about three per cent. on the latter; which, if borne by the traveller, would have the effect of increasing his fare *4d.*, on either the Kendal or Lune line, assuming the fare under ordinary circumstances at *2d.* per mile. At this rate of charge, and making the addition of *4d.* on the inland lines, the fare for the journey between Lancaster and Carlisle would be—

By the Coast line	15*s.* 9*d.*
By the Lune line	11 7
By the Kendal line..........................	10 11

In respect of time; estimating the speed, including stoppages, at 22½ miles per hour on the equivalent distances on the three lines, we find it to amount—

By the Coast line to..........................	4h. 22m.
By the Lune line	3 28
By the Kendal line	3 20

It appears therefore, notwithstanding the mechanical disadvantages of the gradients on the inland lines, as compared with those on the coast line, that the expense to the traveller, as well as the time of performing his journey, would be considerably greater on the latter line than on either of the former.

We have next examined the claims of the three lines as regards the amount of population, and present coach and mail traffic.

* See appendix to Barlow's treatise on the strength of Iron, &c., and also part 3. vol. iii. of the Transactions of the Institute of Civil Engineers.

The amount of population per mile has been found by dividing the total population within 10 miles on each side of the respective lines by the number of miles, employing in each case the census of 1831, and the amount of coach traffic has been determined in the usual way, from returns supplied to us from the stamp office.

We thus find—

	Population per mile.	Passengers per annum.
By the Coast line....................	1,923	8,040
By the Lune line	2,240	21,528
By the Kendal line	2,460	21,528

To bring these several results more immediately into one point of view, we have collected and arranged them as in the following table:—

Table showing the Relative Properties of the projected Lines between Lancaster and Carlisle.

Data.	Kendal Line.	Lune Line.	Coast Line.
	M. C.	M. C.	M. C.
Length of line already made, or in progress ..	—	—	28 3
Length of new line to be made	67 8	68 48	66 42
Length of line to be worked between Lancaster and Carlisle..............................	64 34	68 48	94 45
Locomotive power requisite to work each line, expressed in equivalent horizontal distances	75 9	78 1	98 31
Expenses of journey, per passenger, at 2d. per mile of actual distance, including 4d. extra on the inland lines	s. d. 10 11	s. d. 11 7	s. d. 15 9
Time on each line between Lancaster and Carlisle, at 20 miles per hour, of equivalent distance..................................	H. M. 3 20	H. M. 3 28	H. M. 4 22
Population per mile in length, within a distance of ten miles of each line	2,460	2,240	1,923
Average number of passengers licensed to be carried per annum, by mails and stage-coaches, the whole distance	21,528†	21,528†	8,040

It will be clear from an inspection of this table, that it would cost each passenger between Lancaster and Carlisle about 4*s.* more on every journey by the coast route than by either of the inland lines, besides the loss of nearly one hour in time.

For these reasons, as far as regards the communication between England and Scotland, which is the great object of our inquiry, we consider it to be our duty to give the preference to one of the inland lines.

As regards the communication between London and Manchester, viâ Carlisle, with Glasgow, there can be no question, from what has been stated, that the preference ought to be given to one of the inland lines; but it must also be admitted, that the coast line would offer greater facilities for communicating with Belfast and the north of Ireland.

We have, however, to observe, that the harbour now forming at Fleetwood, which, by the Preston and Wyre Railway, will be put in communication with London, and the manufacturing districts of Lancashire, appears to us likely to form a good point of departure for the north of Ireland and west of Scotland.

But the great question for consideration is, whether every passenger between Lancaster and Glasgow shall be compelled to spend 4*s.* or 5*s.* and lose one hour each journey by being taken round by Maryport, or whether the Irish passenger shall incur the same increased expense, and about the same loss of time, by being taken round by Carlisle to Maryport, to embark in the Belfast steamer, supposing him to select this route in preference to that by the Preston and Wyre Railway to the Harbour of Fleetwood. Now, as such steamer can only be supposed to make one or two passages per week, while the trains between Lancaster and Csrlisle would probably run several times per day, it would be exceedingly prejudicial to the general public interest that the whole of the Scotch traffic should be compelled to pass along the coast line. With regard to the statistical claims of the coast line, it appears from returns with which we have been furnished, of the assessed taxes along this line, as well as of the exports and imports of the several harbours, the steam-boat traffic, and population, that these, although considerable between Carlisle and Whitehaven, are not so for the remaining 54 miles, viz., between Whitehaven and Lancaster, so that when divided upon the whole distance, they are generally less per mile than on the inland lines.

Opinion as to the preference which should be given.—From a full and careful consideration of all the bearings of the case, we therefore feel it our duty to reject the coast line, so far as regards its being made a link in the chain of connexion between England and Scotland.

The next question is, the preference which ought to be given to one of the two projected inland lines.

Referring again to our table, it appears that the mechanical superiority, although inconsiderable, is with the Kendal line, its equivalent distance being 75 miles 9 chains, while that of the Lune line is 78 miles 1 chain.

* The Kendal line passes the Lancaster station to a junction with the Preston and Lancaster, 2 miles 54 chains nearer to Preston than Lancaster, making the distance from Carlisle to Lancaster only 64 miles 34 chains.

† Each of these numbers include the whole present mail and stage traffic between Carlisle and Lancaster, viâ Penrith.

The statistical properties are nearly the same on both lines, with the exception that the Lune line would not take in its route the important and thriving town of Kendal. The advantages this town would derive from the near approach of a railway from the north would be considerable, particularly from the facility it would afford for obtaining coal, of which the consumption is there represented to be large; and reciprocally the railway would derive an increase of its revenue by its connexion with this town.

It was evident to us in the course of our inspection of the country, that the engineering difficulties of that part of Mr. Bintley's line which extends from Kendal to Mardale Green, would entitle the Lune line to a preference, and we therefore inquired whether it might not be practicable to connect the two lines together by adopting Mr. Bintley's route from Lancaster to Kendal, and Mr. Larmer's from Penrith down to Borrow Bridge, and by finding a practicable line from the last named place to Kendal; but Mr. Larmer stated that such a line would be of too expensive a character to admit of this proposition being entertained. However, since our return to London, and indeed since this report has been drawn up, the provisional committee of the Kendal line have requested us to receive and report upon a survey, recently made by Mr. Larmer, to connect the lines of the Lune and Kent, nearly in the manner above described. Our instructions preclude us from acceding to this request, but we have no hesitation in saying, that if a line has been found which would afford the advantage of a direct railway communication to Kendal, without either materially increasing the cost of construction, or the length of the line between Lancaster and Carlisle, and which would be free from other defects, it might be more beneficial to the public than the Lune line. This, however, is a subject for future consideration, and in the meanwhile, keeping in view the general tenor of our instructions, the main feature of which, in the present part of our inquiry, is that we should determine what, under all circumstances, would be the best means of establishing a railway communication between London and the city of Glasgow, having reference, also, to the interests of the manufacturing districts of Lancashire, the western parts of Scotland, and the north of Ireland, we feel bound, after a careful and deliberate review of the advantages and disadvantages of the three competing lines, to state that we give the preference to the line of the valley of the Lune and Penrith over the Kendal line, on account of the greater engineering difficulties on the latter; and that we also give the Lune line a preference over the coast line, in consequence of its shortening the time and diminishing the cost of travelling to the greater proportion of passengers who would require to avail themselves of railway communication north of Lancaster.

We have to remark that the line to which we have thus given a preference, will require a smaller capital than either of the other lines; for the cost of its construction will be less than that of either the Kendal or the coast line; and it must be borne in mind that as respects the last, although its promoters calculate upon a great return for their outlay, by the land to be reclaimed in Morecambe Bay, still the capital for the embankments must be raised in the first instance.

It may not be irrelevant to observe, that if the statement of Mr. Hague, as revised by us in a former part of this report, should be nearly accurate, viz., that the cost of forming water-tight embankments across Morecambe Bay and the Dudden Sands, with the works dependent thereon, would only amount to £543,372 2*s.* 11½*d.*, and if there should appear a probability of the land to be reclaimed realizing so large a sum as £1,196,000, this project might stand on its own merits, apart from any connexion with a railway.

In conclusion, we have only to state that in our inspection of the coast line, we were accompanied throughout the whole distance by Mr. Briscoe, an assistant to Mr. Rastrick, and in our examination of Morecambe Bay by Mr. Hague, the engineer, and by Mr. Yarker, the solicitor, besides other gentlemen interested in this project. Mr. Larmer pointed out the Lune line, and Mr. Bintley the Kendal line, and we were also accompanied by the secretary and several members of the Kendal committee, all of whom evinced every desire to facilitate our inquiry; but it is to be regretted that more time and means had not been at the disposal of the surveyors of the inland lines, to have enabled them to prepare their plans and other drawings in an equally perfect and satisfactory manner with those of the coast line.

We have, &c.,

Frederic Smith, Lieut.-col. R. E.
Peter Barlow, F. R. S.

To Robert Gordon, Esq., M. P.

Hull and Selby Railway.—We are glad to be able to state that a deputation of the Directors of this Company went over the line from the passenger station at Hull to the junction with the Leeds and Selby Railway at Selby, on Saturday, May 30. The carriage was drawn by one of the engines made for the Company, by Messrs. Fenton, Murray, and Jackson, of Leeds. The line being laid upwards of one-half of its entire length upon longitudinal bearings of Riga timber, is particularly easy and smooth; the remaining portion of the line is laid upon cross sleepers, and the whole will be completed in a satisfactory manner. As a considerable portion of the second line is finished, and a great number of men are employed upon the remaining part, there is no doubt that both lines will be completed for opening to the public on the 1st July, the time proposed by the Directors. The buildings at the Hull terminus, and also those at the Selby terminus, are nearly finished, as are the various station-houses on the line, and the Directors have in the past week appointed the clerks and other officers of their establishments.—*Hull Observer.*

REPORT ON THE PLANS FOR PREVENTING ACCIDENTS ON BOARD STEAM VESSELS.

In consequence of the accident of the "Earl Grey" steam boat in 1835, the Trustees of the river Clyde, with a laudable desire to avert similar accidents, very shortly after the disaster issued the following advertisement.

"The Parliamentary Trustees on the River Clyde hereby offer a premium of One Hundred Guineas to any person who shall, in the opinion of the Trustees, or of a Committee of their number, within one month of this date, essay or furnish the best practical mode of effectually preventing accidents, from the imperfect construction or use of the steam engine, or gearing of steam vessels, in their navigation upon navigable rivers, and of carrying the same into permanent effect or execution, independent of the control or discretion of the master or crew of the vessel.

The Trustees have also placed at the disposal of a Committee of their number, One Hundred Pounds, to be distributed among such scientific or other persons as may be unsuccessful competitors for the above premium, but who may, nevertheless, suggest such improvements upon the plan of the successful competitors, as, in the opinion of the Committee, may be beneficially adopted or ingrafted upon the said plan."

In compliance with this advertisement there were no less than 65 designs of apparatus and essays sent in. For the purpose of guiding the judgment of the Committee, they determined upon referring the whole to parties fully competent to investigate the merits of each apparatus and essay, and selected the following gentlemen: Mr. Robert Napier, Mr. James Smith, and Mr. D. Mackain, who undertook the task referred to them.

In consequence of the advertisement not limiting the premium to the actual inventor, numerous schemes were sent in which were the inventions of others, and many in daily use in all parts of the world. For the purpose of assisting the referees in their examinations, they divided the several designs and essays into classes, and again subdivided the classes into sections, and after a careful examination the referees sent in their report to the Committee, accompanied with drawings of the apparatus submitted to them. As this report is of considerable length, it is not our intention to give the whole, but shall content ourselves by giving the most material parts of it, accompanied with engravings of the apparatus for which the premiums were allotted.

REPORT.

To the Trustees of the River Clyde, Glasgow, by Robert Napier, Esq., of Glasgow, James Smith, Esq., of Deanstone, and D. Mackain, Esq., of Glasgow.

In compliance with the request conveyed to us severally by Mr. Turner, we have carefully considered the various plans, models and essays, lodged in the Council Chambers, numbered from 1 to 65.

As the terms of the advertisement neither restrict the competitors to the production of plans of their own invention, nor preclude from competition any apparatus already in use, it involves the possibility of the Trustees awarding the premium to one person, for the invention of another; or to the exhibitor of apparatus, which, though in general use, may still be considered the best adapted to attain the end in view.

Though we mention this to show that, unintentionally, private wrong might be done, or that a reward might be paid for an exhibition of that with which every maker of steam engines is acquainted, yet the open nature of the competition may have had the effect of obtaining, and we doubt not it was the object of the Trustees to obtain, a general view of the opinions entertained by persons whose attention has been directed to the important subject of preventing dangerous accidents on board of steam vessels.

The competitors differ in opinion as to the causes by which explosion is produced, and in consequence, the apparatus they submit vary in their construction and proposed use, according to the idea which each entertains on this subject.

A number of the plans very closely resemble each other, differing only in unimportant details—this we consider to be the natural result of so many persons applying themselves to the attainment of one object. It is also remarkable, that a great number have adopted the common safety-valve, as the principal part of their several designs; which may be regarded as a tacit acknowledgment of its general efficiency and extreme simplicity.

From these causes we have found it convenient, in preparing our Report, to divide the plans into classes, according to the causes of explosion which they are designed to modify or prevent, and to form these classes into sections, according to the means by which these objects are expected to be attained.

FIRST CLASS.

The first class contains the designs submitted by the competitors who are of opinion, that explosion proceeds from a gradual accumulation of steam in the boiler, increasing in elastic force by the continued action of fire in the furnaces, until it exceeds the strength of the boiler.

This class is divided into eight sections.

First Section.—The first section embraces those designs by which the competitors propose to discharge a quantity of water into the furnace, or into the flues leading from them, whenever the force of the steam is sufficient to raise the water from the boiler to a certain height in a pipe, so that thereby the intensity of the fire may be diminished.

Second Section.—The principle on which the designs in this section are constructed, is, that when the pressure of the steam is sufficient to raise water from the boiler to a certain height, it rises round a hollow vessel or float, suspended at that height from one end of a lever, the other end being connected with a safety-valve of the common form. In some of the plans, the hollow vessel or float is designed to act as the load on the safety-valve, so that, to whatever extent it may be immersed in the water, so raised by the strength of the steam, to that extent is the safety-valve lightened of its load. In others, the weight of water displaced by the float, is a force, in addition to the steam, to raise a valve loaded in the ordinary way.

Third Section.—This section embraces the greatest number of plans, which contain, in general, the common safety-valve enclosed in a case, so as to prevent all access to it. The design of some of the plans is, however, worthy of attention, from their ingenious complexity.

Fourth Section.—These designs have the common safety-valve cased in, to prevent it from being overloaded, but have attachments to the valve, by which it can be opened by the engine-man whenever he finds it necessary to permit the steam to escape.

Fifth Section.—The distinguishing feature of the plans in this section, is the introduction of a piston in connexion with the safety-valve, with the design that the gradual increase in the force of the steam shall, by acting on the under side of the piston, become a proportionally increasing power to open the safety-valve.

Sixth Section.—The arrangement of the apparatus in this division is designed with the view of loading the safety-valve when the engine is at work, and of taking off the load when it is at rest.

Seventh Section.—In this section the exhibitors propose to substitute mercury for the loaded valve, which is usually employed to confine the steam until it has acquired a certain amount of force.

Eighth Section.—The competitors included in this section propose a connexion to be made between the throttle and safety-valves, by which, when the speed of the engine is required to be reduced, the safety-valve is opened, and the steam allowed to escape.

SECOND CLASS.

The second class of competitors are those who are of opinion that the explosion of boilers is the effect of the instantaneous production of steam, or the evolution and ignition of inflammable gases in the boiler, in consequence of a deficiency of water; by which the flues (or passages through the boilers for the flame from the furnaces) being uncovered, they become red hot, and on water being brought in contact with them, explosion is produced.

This class is divided into two sections.

First Section.—The first section proposes self-acting apparatus for feeding the boilers while the engine is in operation, so as to prevent the water from falling below a certain level.

Second Section.—The second section proposes means of giving information when the water shall have fallen below a certain point in the boiler, by means of a pipe open at both ends and approaching to within a short distance from the flues, so that, when the water shall have been sunk below this pipe, the steam will be allowed to escape.

THIRD CLASS.

The third class are those competitors who consider explosions to be the result of weakness in the boiler, and propose that they shall be frequently proved.

This class might be divided into two sections, viz., those who recommend that periodical attempts be made to explode the boilers with a great pressure of steam, and those who suggest that they shall be frequently proved by a forcing pump; but it is unnecessary to make this distinction.

We shall close this summary by stating that there are several ingenious designs which cannot be classed with any of those mentioned, nor with each other; and, consequently, for an explanation of the principles of their construction and intended mode of operating, it would be necessary to transcribe the several essays in which they are contained; but this we consider unnecessary, from their being nothing of sufficient merit in them to recommend them to the notice of the Trustees. It will be remarked that, almost all the competitors propose their several designs to be adopted only as additions to the existing means of preventing explosion; that they almost unanimously recommended the continued use of the existing safety-valve; that several recommend the frequent proof of boilers: while a few only propose the appointment of inspectors.

In recommending to your favourable consideration some of the designs, we beg to lay before you the circumstances which guided our selection.

The theory advanced in the Essay No. 1, of explosions proceeding from the formation of gas in the boiler, by the flues becoming red-hot, thereby decomposing t e water, and then inflaming these gases, has been, in our opinion, most conclusively set aside by the eminent philosopher, Mons. Arago, in a memoir on the subject of the present report. "Some persons," he writes, "struck with the prodigious and instantaneous effects which often result from the explosion of boilers, are persuaded that steam alone is incapable of producing them, and they call to their aid some gases susceptible of explosion." On this he remarks, "Hydrogen alone, or mixed with vapour, cannot explode—a mixture in the suitable proportions of oxygen and hydrogen is susceptible of explosion; but how are these gases to be collected in the boiler? Hydrogen is the product of the oxidation of metal—from whence, therefore, proceeds the oxygen? Can it be from the air contained in the feed water? It is warm, which prevents it from containing much air. I shall add, in fine, that the oxygen of the air would combine itself much more readily with the incandescent sides of the boiler, than with hydrogen; and that the product of the decomposition of water would be—not hydrogen and oxygen, but hydrogen and azote,"—a non-explosion mixture. And further, in a Report by the Committee of the Franklin Institute, on the explosions of steam boilers, made at the request of the Treasury department of the United States, they state, as the result of direct experiment, that the gas obtained by injecting water into a red-hot boiler, was a "non-supporter of combustion, and non-combustible."

The other theory advanced by the Essayists Nos. 1, 4, 7, 8, 9, and 20, is, that if the flues become red hot, and water be poured into the boiler, a volume of steam, of dangerous elasticity, is instantaneously formed, to which the safety-valves cannot give vent with sufficient rapidity, and, in consequence, the boiler explodes. In regard to this supposed cause of explosion,—the American Commissioners succeeded in exploding an experimental boiler, by injecting water into it while not only the flues, but the top, bottom, and sides, were assiduously kept red hot. This was done to ascertain the greatest effect that could be produced by steam generated under such circumstances. Their other experiments prove that water does not evaporate so rapidly when brought in contact with red-hot iron, as when the iron has been cooled down to a much lower temperature, and at this reduced temperature iron does not contain any considerable quantity of heat. In all experiments made by them and others, *time* has been a necessary constituent in the circumstances which permit a certain volume of water to be evaporated, and *confinement* to give it force; and the opening of a safety-valve has always been found to diminish the pressure, and lower the temperature of the steam. We are inclined, under a peculiar and merely possible combination of circumstances, to view this as a cause of danger; but we have not been able to discover any authentic instances in which explosion has been clearly traced to it. The general practical result of the flues being allowed to get red hot, is, that the plates composing them crack on admission of water, and from the copious discharge of boiling water and steam which ensues, many serious accidents have happened to the engine-men and fire-men, through whose negligence they have been occasioned.

Notwithstanding of the above theories advanced by the competitors, and also of several others promulgated by persons of high standing in the scientific world, we cannot, after a careful comparison between their reasoning and our own experience, arrive at any other conclusion than—that the explosions of steam boilers proceed from a gradual accumulation of steam, which, being deprived of sufficient means of escape, is, by the continued action of the fire in the furnaces, raised to a dangerous, and often destructive degree of density; and we conceive that all danger can be avoided by the regular action of the common safety-valve, if properly constructed and made of *sufficient capacity*. It sometimes happens that these valves, from neglect, become fixed; and we are of opinion, that the apparatus designed by the Essayists Nos. 2 and 41, which are drawn as figures 1 and 2,* are well calculated to apply a force, in addition to the strength of the steam, to overcome this adherence; and they have the advantage of being so designed, that after the overplus of steam shall have escaped, the safety-valve is allowed to resume its useful position.

We have remarked, that the greater number of explosions of steam boilers have occurred at the instant of starting the engine. Without taking on ourselves to assign any reason for this, or our being able to trace the immediate circumstance which precedes, and may have caused the explosion, we are of opinion, that the risk of accident may be lessened by the weight on the safety-valve being diminished until the engine is in motion, and the steam flowing away by a regular current. We are not satisfied with the efficiency of the various plans which are designed to attain this object; but we recommend to your notice, for its novelty, the design in Essay No. 18.

We conceive it to be of importance, that the safety-valve should be secured from improper interference; but, at the same time, that it should be so connected with the ordinary occupation of the engine-man, as to be put into almost hourly use. This must lessen, if not entirely prevent, the chance of it becoming fixed to its seat. Of the designs submitted to us, we consider that the plans in the Essays 4, 38, 55, and 56, are best adapted for this object, though they have been found liable to the inconvenience of becoming fixed at the joints which are inside of the boiler. Figures 33, 36, 38, and 40, are, we believe, in use in several steam vessels on the Thames, the Clyde, and the Mersey, and No. 36 has been seen on board the French Government steamer, "Le Meteore."

A number of the competitors recommend that the safety-valve should be locked up, to prevent all access to it by the engine-man; but in this recommendation we do not concur,—for, if those in charge of the engine be prevented from ascertaining the condition of the safety-valve, no reliance can be placed on it as a mean of preventing accident.

* The figures 1 and 2 will be found in another part of the Journal.—Ed. C. and E. Journal.

We also feel ourselves opposed to the majority of the competitors as regards a feeling which they evince against engine-men as a body. In any large class of society, there are always to be found individuals, whose improper conduct no laws can restrain; and we are inclined to think that the number of engine-men who recklessly endanger their own lives and the property under their charge, are nearly in the same proportion to the mass of engine-men, as felons are to the mass of society, notwithstanding of the watchful superintendence of the immense army of the law.

In a matter of such importance to the public, and to the proprietors of steam engines, we cannot avoid expressing our regret, that in the cases of explosion which have occurred, there are no scientific reports of the appearance and state of the engines, valves, or boilers. If a regulation were adopted by the local authorities, requiring intimation of every case of accident, and obtaining thereafter, before any alteration had been made on the damaged boiler, machinery, or buildings, a detailed report of their situation and appearance, we are of opinion that more certainty would soon be given to the conjectural causes which produce such accidents; and that, in consequence, in the construction or management of steam engines, means would be adopted which would lessen the chance of their recurrence.

In regard to the appointment of inspectors, which some of the competitors recommend, we beg to express our doubts as to the expediency of this measure. They must either be armed with discretionary powers, to admit or reject any alteration in construction or management of the machinery—in which case the immense amount of capital invested in steam vessels at each port must be subjected to the individual caprice of the inspector—or it will be necessary, in order to furnish them with precise instructions, that the Act of Parliament by which they are appointed, shall regulate what are and what are not infallible securities against accidents of every kind.

When we compare the almost innumerable multitude of persons who have annually availed themselves of steam conveyance at sea and on railways, for many years past, with the number of accidents that have occurred, it is gratifying to us to consider, that, with our attention so closely turned to the subject as it has been for some time, we not only cannot trace any cause of alarm, but are able to express our conviction, that it is the safest means of transport that now exists.

In conclusion, we beg to report our opinion, that a combination of the plans we have recommended to your notice might be advantageous, provided the attachments by which they are connected with the safety-valve be such, as that by no derangement of the new apparatus, can the former be prevented from acting. But we can view them only in the light of experiments, which will require some time of watchful superintendence, to ascertain their mode of operating under various circumstances, and to detect and remedy errors in their construction.

Extract from Additional Report.

In compliance with this instruction, we have no hesitation in recommending to you the plans marked by the Committee Nos. 2 and 41, lodged by Mr. James B. Neilson and Mr. George Mills, both of Glasgow. It will be evident on inspection, that they are identical in design, and that the difference in their proposed construction is quite immaterial. (See Figs. 1 and 2.)

For the reasons stated in our General Report, we conceive them to be the best of the designs submitted to the Trustees for preventing explosion.

You are farther pleased to request, that we should name "the three persons who have brought forward, in your opinion, the three *next* best plans, so as to enable the Trustees to consider whether any portion of the additional sum of One Hundred Pounds, allocated by the trustees, is, in the circumstances, fairly and justly due to any of the competitors who may be unsuccessful in obtaining the principal premium of One Hundred Pounds."

From the extreme similarity in design and execution of the plans which appear to us entitle to rank in the second class, we are unable to reduce their number to less than four, viz., those numbered by the Committee 4, 38, 55, and 56, which were severally lodged—the three first by Messrs. Allan Clarke and David Thompson of Glasgow, and Mr. John Baird of Shotts; and the last, the joint production of Messrs. William Neilson and William Muir of Glasgow.

Mr. David Thompson states that his design has been in use at Messrs. Boulton & Watt's Engine Factory at Soho; and, as stated in the General Report, the others are precisely similar to apparatus in common use in vessels on the Thames, the Clyde, and the Mersey; and, through the politeness of the commander, there was exhibited to one of the reporters, on board of the French Government steam vessel, "Le Meteore," arrangements for working the safety-valves, which were similar in design and mode of operation to the plans in Nos. 38, 55, and 56.

As we are of opinion that the premiums offered by the Clyde Trustees were for apparatus presenting some novelty of construction, and possessing means of security beyond that which the existing safety-valves and connexions have been supposed to afford, we do not, under this impression, consider these gentlemen *entitled* to participation in the second premium; but leave this to the decision of the Trustees.

We have no other remarks to offer to your consideration on the residue of the plans.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL SOCIETY.

March 12.—The Marquis of Northampton, President, in the Chair.

The following papers were read:—

"*On certain variations of the mean height of the Barometer, mean Temperature, and depth of Rain, connected with the Lunar Phases, in the cycle of years from* 1815 *to* 1823." By Luke Howard, Esq.

The table given in this paper contains the results of calculations relating to the objects specified in the title, cast into periods of six, seven, or eight days, so as to bring the day of the lunar phase belonging to it in the middle of the time. The observations were all made in the neighbourhood of London. It appears from them that in the period of the last quarter of the moon the barometer is highest, the temperature a little above the mean, and the depth of rain the smallest. In the period of the new moon, both the barometer and temperature are considerably depressed, and the rain increased in quantity. The influence of the first quarter shows itself by the further depression of the barometer; but the temperature rises almost to the point from which it had fallen, and the rain still increases, but not in an equal ratio. Lastly, the full moon again reduces the temperature, while the barometer attains its maximum mean height, and the quantity of rain is the greatest. Thus it appears, that during this lunar cycle, the approach of the last quarter is the signal for the clearing up of the air, and the return of sunshine.

"*On the theory of the Dark Bands formed in the Solar Spectrum, from partial interception by transparent plates.*" By the Rev. Baden Powell.

This paper contains the mathematical investigation of the phenomena of peculiar dark bands crossing the prismatic spectrum, when half the pupil of the eye, looking through the prism, is covered by a thin plate of any transparent substance, the edge being turned from the violet towards the red end of the spectrum; and which were first noticed by Mr. Fox Talbot, and were ascribed by Sir David Brewster to a new property of light, consisting of a peculiar kind of polarity. The author shows, that on the undulatory theory, in all cases, a difference of retardation between the two halves of each primary pencil throughout the spectrum, may give bands within certain limits; and that it affords a complete explanation of the phenomena in question.

March 19.—The Marquis of Northampton, President, in the Chair.

The following paper was read:—

"*Contributions to Terrestrial Magnetism.*" By Major E. Sabine.

An increased activity has recently been given to researches in terrestrial magnetism, with the definite object of obtaining correct maps of the magnetic phenomena, corresponding to the present epoch, over the whole surface of the globe. To aid these researches, and to facilitate the comparison of the general theory of M. Gauss with the facts of observation, maps have been constructed of the magnetical lines, both as computed by the theory, and as derived from observations already obtained. The theoretical and actual lines of the declination and intensity have thus been represented in maps recently published in Germany and England, as have also the lines of the inclination computed by theory; but the corresponding map or the latter element derived from observations is yet wanting. The object of the present communication is to supply this desideratum, as far as regards the portion of the globe contained between the parallels of 55° N. and 55° S., and the meridians of 20° E. and 80° W.; comprising the Atlantic ocean and the adjacent coasts of the continents on either side. The observations chiefly employed for this purpose are two series *made at sea*; one by Mr. Dunlop, of the Paramatta observatory, in a voyage from England to New South Wales, in 1831; the other by Lieut. Sulivan, of the Royal Navy, in a voyage from England to the Falkland Islands and back, in 1838 and 1839. The observation of the magnetic dip at sea, which was commonly practised by the distinguished navigators of the last century, was unfortunately not resumed when the interest in such researches was revived on the restoration of peace; but it is by such observations only that the lines of inclination can be independently traced over those large portions of the globe which are covered by the ocean. The difficulties which attend the observation, occasioned by the motion and the iron of the ship, require the adoption of several precautions, which it is particularly desirable at this time to make generally known. The series of Messrs. Dunlop and Sulivan are discussed in this view; and the value of results obtained under circumstances of due precaution is pointed out by their success. The position of the lines on the land portion of the map is derived from 120 determinations in various parts of Europe, Africa, and America, between the years 1834 and 1839, of which about the half are now first communicated. The series of Messrs. Dunlop and Sulivan contain also observations of the magnetic intensity made at sea; Mr. Dunlop's by the method of horizontal vibrations, and Lieut. Sulivan's by the instrument and method devised by Mr. Fox. The degree of precision which may be obtained by experiments thus conducted, is shown by the comparison of these observations with each other, and with the isodynamic lines previously derived from observations made on land. The first section of this paper concludes with discussions on the relative positions of the lines of least intensity and of no dip, and of the secular change which the latter line has undergone in the ten years preceding 1837. In the second section, the observations of Mr. Dunlop are combined with recent observations on the coasts of Australia, by

Captains Fitz Roy, Bethune, and Wickham, of the Royal Navy, to furnish a first approximation to the position and direction of the isodynamic lines over that portion of the Indian ocean which is comprised between the meridian of the Cape of Good Hope and New South Wales.

March 26.—The MARQUIS OF NORTHAMPTON, President, in the Chair.

This evening was occupied by the reading of a paper, entitled "*Researches in Electricity, 17th series: on the source of power in the Voltaic Pile.*" By Michael Faraday, Esq.

May 11.—Major Sabine, R.A., V.P., in the chair.

The following paper was read:—

Experimental Researches into the Strength of Pillars of Cast Iron, and other Materials. By Eaton Hodgkinson, Esq.

The author finds that in all long pillars of the same dimensions, the resistance to crushing by flexure is about three times greater when the ends of the pillars are flat, than when they are rounded. A long uniform cast-iron pillar, with its ends firmly fixed, whether by means of discs or otherwise, has the same power to resist breaking as a pillar of the same diameter, and half the length, with the ends rounded, or turned so that the force would pass through the axis. The strength of a pillar with one end round and the other flat, is the arithmetical mean between that of a pillar of the same dimensions with both ends round, and one with both ends flat. Some additional strength is given to a pillar by enlarging its diameter in the middle part. The author next investigated the strength of long cast-iron pillars with relation to their diameter and length. He concludes that the index of the power of the diameter, to which the strength is proportional, is 3·736. He then proceeds to determine, by a comparison of experimental results, the inverse power of the length to which the strength of the pillar is proportional. The highest value of this power is 1·914, the lowest, 1·537, the mean of all the comparisons, 1·7117. He thus deduces, first, approximate empirical formulæ for the breaking weight of solid pillars, and then proceeds to deduce more correct methods of determining their strength. Experiments on hollow pillars of cast-iron are then described, and formulæ representing the strength of such pillars are deduced from these experiments. After giving some results of experiments still in progress for determining the power of cast-iron pillars to resist long-continued pressure, the author proceeds to determine from his experiments the strength of pillars of wrought-iron and timber, as dependent on their dimensions. The conclusion for wrought iron is, that the strength varies inversely as the square of the pillar's length, and directly as the power 3·75 of its diameter, the latter being nearly identical with the result obtained for cast-iron; for timber, the strength varies nearly as the fourth power of the side of the square forming the section of the pillar. Experiments for determining the relation of the strength to the length in pillars of timber, were not instituted, as, from the great flexure of the material, it was considered that no very satisfactory conclusions on this point could be derived experimentally. In conclusion, the author gives the relative strengths of long pillars of cast-iron, wrought-iron, steel, and timber.

INSTITUTION OF CIVIL ENGINEERS.

ADDRESS OF THE PRESIDENT.

General Meeting, February 4, 1840.

THIS being our first Meeting since my re-election as your President, allow me to thank you for the honour conferred upon me, and to congratulate you on the choice you have made of the other Members of Council, and Officers, who will I am sure be desirous of justifying the good opinion you have formed of them, by as frequent an attendance at the Meetings and attention to the business of the Institution, as their avocations will permit. This will indeed be but a proper return for the proof of your confidence in us, and I trust that the list of attendances, if again called for at the end of the season, will prove my anticipations to have been correct; for notwithstanding the truth of the old saying, that "where there is a will, there is a way," it must sometimes happen, that the attendance of some of us becomes impossible, from absence at too great distance or other cogent cause; yet I hope I may answer for my colleagues as for myself, that it is our determination to show that we have the "*will.*" But, gentlemen, be it remembered on your part also, that there is a reciprocal duty to perform—that of attendance at our Meetings, to give them the importance which the Council Table being full will not give, if the seats around the room are not respectably occupied; and that blame may not attach where praise is due, the Council (following the precedent set them) have desired a list to be made and tabulated of the attendance at the Meetings of each Member, Graduate, and Associate.

I trust, however, that there will be presented to your attention during the session so much new and interesting matter as will rather ensure your attendance as a personal gratification than as a bare discharge of a duty; unless this should be the case, mine would be an ungracious task to require your constant attendance, but if we succeed in exciting your attention, you will then come unasked. This good can only be attained by numerous and useful communications, which are valuable in themselves and give rise to instructive discussions. The Council therefore require plans and papers from you with the view of ensuring your personal attendance; and I wish to enforce this especially upon the country Members, from whom we receive very few communications. Looking at the extent and rapid progression of public works in this country at present, the new facts that are constantly being developed, the number and influence of the Members of our Institution, there ought not to be any dearth of important and interesting communications. That we have had many such, and that the number of them is increasing, I admit, but still they ought to be much more numerous. My remarks at the last Meeting referred more particularly to Graduates and Associates as defaulters on this head, but I must include the *Members*, not only for what they could themselves do, but more for the exercise of the influence they possess over Graduates in directing their attention to particular objects or works on which they might furnish communications. Half the work is done "when the subject is *fixed* on"—I say this from experience, as would be proved by reference to the communications that have been made through my suggestions at works which I have visited, or by individuals over whom I may be supposed to have some influence. If gentlemen would bear in mind the wants of the Institution whenever they visit any public work, they would rarely leave it without having reaped some knowledge that would be worth communicating, and they may be assured that their labours would be duly appreciated.

I named at the last Meeting the subject of the Library—I stated that which many gentlemen were not aware of, the understanding amongst ourselves, that each Member of the Council should contribute annually some Book, Picture, Drawing, or other present for the Library—I stated also that the Secretary was preparing a list of such books as it is desirable we should possess. This list will be printed and circulated, and I wish the Institution to understand that the Council do not desire to monopolize the right of presenting books but trust that their example will be followed by every one belonging to the Institution. We have space now for a good Library, and for an Institution like ours nothing can be of greater importance. It is especially necessary that our Library should contain as many good books of reference as possible, and I beg to suggest to Members possessing such books, that in presenting ing them to the Institution they do not deprive themselves of the advantage of them, but will have the satisfaction of permitting others to participate with them.

The increasing business of the Institution appearing to the Council to require now the whole and undivided time and attention of one properly qualified gentlemen as Secretary, they thought it their duty to make this a condition previous to appointment; I am glad to say Mr. Manby has accepted the office on these conditions. Mr. Webster, with whose abilities and science we are all well acquainted, has been elected Honorary Secretary, and the more of his time he can give us, the more, I am sure, we shall all feel obliged.

The question of qualification for Honorary Members has already engaged the attention of the new Council, and we may think it right shortly to bring the subject before the Institution. As the Bye Laws now stand, the necessary qualification for a candidate for election as an Honorary Member is, that "he be eminent for *science* and *experience* in pursuits connected with the profession of a Civil Engineer, but not engaged in the practice of that profession in Great Britain or Ireland." Now this distinction is so very circumscribed, that few men can be found who come strictly within its limits, whether we refer to the present list of Honorary Members, or even to the most distinguished individuals in this country who hold the highest places in science or scientific institutions, such as the President of the Royal Society—the Marquis of Northampton,—the Chancellor of the University of London, Lord Burlington. (I cite these two noblemen, whose love of and devotion to science, and whose eminence in certain departments of it, has entitled them to the high places they fill, as persons whom it might be very desirable to connect with the Institution, should such be their wish, but neither of whom can, so far as I know, be strictly said to be "eminent for *science* and *experience* in pursuits connected with the profession of a Civil Engineer.") If it be thought desirable to extend the terms of qualification, the definition may be altered to include individuals distinguished for their patronage and promotion of the studies and works of Civil Engineering, or a class of Patrons might be formed of such men. The Council will give this matter their best consideration, and will, I am sure, in any recommendation they may make, be guided by their desire only to extend the reputation and importance of the Institution.

My old and valued friend, Mr. Turner, of Rook's Nest, Surrey (formerly the friend and partner of Huddart), having presented me with an excellent portrait of that eminent philosopher and mechanic, I have thought that I could not do better than offer it to the Institution, having previously had Mr. Turner's entire approval of my so doing. Those who have seen Huddart's Rope Machinery, which was I believe as much the creation of his own brain as ever machine was of any man's, will not dispute my claiming for him the first rank for eminence in Mechanics: as a Navigator and Hydrographer, he was inferior to none: I had the pleasure of knowing him, and have always thought, that if the Mechanical Philosophers and Engineers of our days were to be ranked in pairs, Huddart was the man to be placed by the side of Watt. I am glad therefore to be the instrument of putting the Institution in possession of the portrait of Huddart, by Wildman, after Hoppner; but this is not unmixed with a feeling of jealousy, arising from our Member Mr. Burges having discovered that Mr. Whitbread had, at his seat in Bedfordshire, a portrait of *Smeaton* (a soul-stirring name to Engineers), by Gainsborough; he has, through Mr. Whitbread's kindness and by the aid of Mr. Turner, placed the picture in the hands of Mr. Wildman, the talented painter of Huddart's portrait, and I can answer for Mr. Burges's kind intentions towards the Institution in the trouble he has so taken.

I have only farther to add, that the Council have come to the resolution of devoting the rooms on the ground floor to the use of the Members of the Institution, and have directed the periodical publications to be placed there. We hope this arrangement will be found generally convenient and agreeable, and we think it will be particularly so to our junior branches and Members from the country, as they may there enjoy all the advantages of a club, with the additional one of being surrounded by their friends.

We trust our Funds will always admit of this arrangement being gratuitous, as well as suffer us hereafter to add to it other means of attraction.

In another point of view it may be found useful, as a central point where gentlemen may make known their being at liberty to accept engagements, and the Engineer may find the assistance he is in need of.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

June 1.—Mr. Kay, V.P., in the Chair.

At the ordinary meeting of this society, several very valuable donations were announced, amongst which a volume of Inigo Jones's designs for the Whitehall Palace, being the original drawings by Flitcroft, for Kent's publication. The council have been for some time engaged in forming a collection of all matters relating to Jones and his works, and this present was therefore a most valuable boon. A long conversation was held on the means of constructing flues, so as to render the employment of climbing boys unnecessary, and a strong desire was shown on the part of the meeting to aid the efforts now being made by the society established for the purpose. Mr. Fowler took occasion to mention to the meeting that the *Société Libre des Beaux Arts*, of Paris, had recently awarded to Mr. G. Godwin, jun., a silver medal, in testimony of their approbation of his published works, and commented upon the liberal feeling the society had thus evinced. A similar compliment was paid to Mr. Donaldson, on the publication of his work on doorways.

A paper was read "*On the Section of the London Bed of Clay.*" By Charles Parker, Fellow.

The principal subject of this paper was a description of the strata passed through in boring two wells in the village of East Acton, which we cannot follow without reference to the diagrams and tables by which it was accompanied. The result was, a further confirmation of the established geological fact, that a stratum of sand extends under the clay, and bears upon a chalk basin containing an immense quantity of pure water, and a further disproval of a commonly received opinion, that when two wells are formed in immediate vicinity, of unequal depths, the water passes from the shallower to the deeper. The two wells in this instance were 300 yards apart. In one, the water was found at the depth of 333 feet, in the other, the spring extended to the depth of 403 feet. In both, the water rose to within 18 feet of the surface, and then gradually subsided to 23 feet.

A section was also given of the strata in the vicinity of Shadwell, and some particulars of a well bored to the depth of 411 feet in the Temple, which emitted an odour so disagreeable as to render the water useless. This odour (having been satisfactorily proved not to proceed from any contact with drains) was supposed to arise from the disengagement of sulphuretted hydrogen. After three months had been expended in trying, without any benefit, the suggestions of several eminent chemists for obviating this inconvenience, the well was abandoned as a failure; but another trial of the water being accidentally made a year afterwards, it was then found to be free from smell, and of a remarkably good quality. A comparison of the chemical analyses made at the different periods, failed to explain in any way the cause of this alteration. The paper concluded with some observations on the employment of iron cylinders in well sinking, and a comparison with a similar mode of proceeding by the ancients with cylinders of baked clay, illustrated by sections of a well at Silinunte, and another at Girgenti.

Mr. Godwin read some observations on the modern state of painting on glass. This paper will be found in another part of the Journal.

June 15.—Mr. Moore in the Chair.

A paper "*On Original Composition in Architecture, illustrated by the works of Sir John Vanbrugh*," was read by James Thomson, Fellow. (This paper we shall give in full next month.)

Mr. Donaldson read "*A Memoir of the Life of Thomas Archer.*"

Thomas Archer, an English architect, who flourished during the early part of the eighteenth century. He was a pupil of Sir John Vanbrugh, who, being appointed surveyor-general for the new churches in London, which were to be built by the grant of Queen Anne, gave several of them to his pupils. The new church of St. John the Evangelist, in Westminster, fell to the lot of Archer, and was built in 1728. The plan consists of an oblong with rounded corners, having at the east and west ends deep recesses for the altar and vestry, and on the north and south sides, bold projecting enclosed porticoes, flanked on each side by a tower, making four in all, and which now have staircases, to afford access to the modern galleries. At first the interior was enriched by columns, and there were no galleries: so that the inside must have originally been extremely effective. In 1741, the interior and roof were consumed by fire, which left only the walls and columns standing. The church was then rebuilt, the columns being omitted; in 1758 galleries were added, and subsequently lengthened in 1826 by Mr. Inwood, architect. When this fine building was first completed, justice was not done to the originality and powers of the architect; and Horace Walpole, with some other critics of the day, unable to appreciate its beauties, reprobated its cumbrous aspect, and its four towers.

The outside consists of a bold Doric order, well proportioned and elegantly profiled; the columns are about three feet four inches in diameter, and stand upon a lofty pedestal or podium, eight feet high. The north and south porticos are hexastyle, each consisting of four outer pilasters and two central columns; the three centre intercolumniations being recessed, and the outer interpilastrations being solid, these latter serve as bases to the towers, which rise at each end of the tympana. The entablature is surmounted by a ballustrade, except over the porticos, where there are pediments broken through in the centre, for the width of three intercolumniations, to admit a kind of fantastic pedimental group, with a perforated niche. The four towers have square bases to the height of about eight feet above the springing of the pediments, and then assume a circular plan. At the angles there are isolated columns with circular pedestals and circular entablatures, projecting from the main body of the towers. Above the entablature there is a gradually receding roof of concave profile, surmounted by a pine apple. The east and west ends of the roof are enriched by grouped gables, flanked by large enriched scrolls or trusses in the Roman fashion.

The whole composition is impressive, and its boldness loses nothing by the graceful playfulness of the outline. There are some inaccuracies of detail, which a little more study of purer models might have corrected; but the whole is well worthy a distinguished place among the striking productions of the Vanbrugh school. The exterior being entirely faced with stone, its solid magnificence forms a striking contrast to the parsimonious meanness, which distinguishes the like buildings of the present day. In vol. iv. p. 70, of Dallaway's edition of Horace Walpole's Anecdotes of Painting, Hethrop, J. Phillip's church at Birmingham, a work of considerable merit, the quadrant porticoes at Chefden House, and a house at Roehampton, peculiar, but striking in its effect, given in the Vitruvius Britannicus, are mentioned as works of Archer. To him also is attributed the fanciful and attractive pavilion at the end of the piece of water which faces the centre of Wrest House, in Bedfordshire, the seat of the Earl de Grey. This pavilion is hexagonal in plan, with a porch at the entrance, and, with very little attention to effect, might be made a very graceful object, well worthy the splendid mansion which has been recently erected by the present noble possessor, from his own designs and under his own immediate direction, and in which his lordship has evinced a great feeling for art, sound discrimination, and a happy adaptation of the style chosen, which is that of the French château of the time of Louis XV.

Mr. Donaldson also read a brief memoir of the life of Chevalier Stefano Gasse, of Naples, an Honorary and Corresponding Member of the Institute.

THE ARCHITECTURAL SOCIETY.

W. Tite, Esq., President, in the Chair.

This society closed its session on the 2nd ult. with a conversazione, which was attended by Earl de Grey, the President, and many of the Fellows of the Institute of British Architects, also by Mr. Walker, the President, and numerous members of the Institution of Civil Engineers, besides many members of other scientific societies. The business of the meeting commenced by Mr. Grellier, the Hon. Sec. reading the report of the Committee detailing the lectures and papers that had been delivered, and the prizes awarded to the student members, and expressing their warmest thanks and acknowledgment to their President, Mr. Tite, for the energy and zeal with which he has forwarded the interests of the society.

The President then proceeded to award the prizes to the successful candidates, after which he read a paper of considerable research and interest, "*On Exchanges*," which we have the pleasure of giving in another part of the Journal.

NOTES OF THE MONTH.

The Dean and Chapter of Westminster, we are happy to announce, intend to have twelve of the windows in Westminster Abbey glazed with painted glass. We hope that they will be ordered at once of the artists, and not of dealers, by whom the artists will be screwed down. Painters and sculptors are not subjected to such a vexatious process, and we do not see why painters on glass should be deprived of a great portion of the reward of their exertions.—The authorities at the Temple are also engaged in the restoration of their ancient church.

In the National Gallery, a very fine painting, the Infant Jesus, by Murillo, has recently been placed.

The Thames Tunnel will soon make its appearance on the Middlesex side. The Company have commenced clearing the houses for the purpose of prosecuting their labours with energy.

Mr. Cottingham the architect, invited a numerous party to a conversazione at his Museum of English Antiquities, in the Waterloo Bridge-road, on Thursday, the 25th ult. We, certainly, were never so much surprised on passing through the numerous rooms, to witness such an immense collection of specimens (about 31,000 we understand) of domestic and ecclesiastical architecture, painting, sculpture, and furniture; every architect, artist, and lover of antiquities should not fail visiting this Museum—next month we intend to give a description of it.

We understand that a National Mausoleum has been projected upon a most magnificent scale, to erect a sort of "Second Westminster Abbey," for the interment of the noble, opulent, and illustrious dead, and we have heard that the drawings are now ready, though we have not yet been fortunate enough to see them. We do not know who the author of the grand scheme is, but it is whispered that Barry is the chief architect, and a friend who has been favoured with a sight of the drawings, informs us that the design is noble, chaste, and beautiful, and a most perfect specimen of art. No doubt such a building is much wanted, seeing that a nich in the Abbey is not now to be had for either "love or money," or within its precincts, and hence the necessity of the intended National Mausoleum. We shall endeavour to obtain permission to reduce and engrave the drawings for our next number.

The experiment of the New Water Company which has been going on to test the quantity of water which can be procured and brought by its own gravity to London from near Watford, is now nearly completed. As far as it has gone it has been most successful. Copious springs have been tapped to the depth of 97 feet, and the well of 20 feet diameter when only 16 feet deep, required 30 men to be incessantly pumping from 4 a. m. to 8 p. m. daily, to enable the sinkers to proceed. Telford never made a happier hit than in pointing out this spot for the supply of London.

The Annual Meeting of the Council of the Government School of Design for distributing the prizes, took place on Friday, the 26th ult. We were much gratified on witnessing the great progress made by the students since the last yearly meeting, and the marked improvements that could be traced in those drawings that were made from models and plants. The school is in a very flourishing state, and there are not less than 100 pupils. Mr. Labouchere, the President of the Board of Trade, distributed the prizes. Among the company present we noticed Sir R. Inglis, Bart., M.P., Sir D. Norreys, Bart., M.P., Henry T. Hope, Esq., M.P., T. Wyse, Esq., M.P., Sir David Wilkie, and C. R. Cockerell, Esq., R.A., the latter gentleman read the report of the committee.

At Paris they are now employed in engraving on the bronze of the column of July, the names of the combatants who were killed during the revolution. These names are 504 in number, consisting of about 4000 letters, and placed in alphabetical order, letter A at the top. Each letter is 8 centim. ($3\frac{1}{4}$ in.) high, and 3 millim. ($\frac{1}{8}$ in.) deep. A good specimen of *engraving on a large scale*. The artists have got as far as L. It it said that the elephant is to be cast at last, and erected at the Barriere du Trone, the decorations of which are to be finished; all this however is far from certain.—On the recommendation of the Commisioners for Preserving Historical Monuments, the Minister of the Interior has directed M. Viollet le Duc to prepare a plan for the restoration of the church of Vezelay (Yonne), and M. Questel plans for those of St. Giles (Gard), and Louillac (Lot), and for the cloister of Moissac (Tarn and Garonne).—The French naval authorities have directed experiments to be made at Brest on galvanized iron, and on gutters of zinc and of tin. The Commissioners appointed have already recommended the application of galvinized metal in several cases, in order to test its properties on a large scale. By police regulations the extent of the projections of plaster cornices is limited at Paris to 16 m. (6 in.)

REVIEWS.

Pictorial and Practical Illustrations of Windsor Castle, from original Drawings. By Messrs. Gandy and Baud. London: John Williams, 1840.

When Achilles died, Ajax and Ulysses contended for his arms, dire was the conflict, and great the perplexity of the Greeks in coming to a decision, they ended it, however, if we recollect aright, by making the award in favour of one of the competitors, not as we should propose to do by giving a bit to one, and a bit to another, or forcing them both to squeeze themselves into the same coat of mail. Since Sir Jeffry Wyatville's death, a similar contest has taken place, equally distressing as regards the parties engaged, and the difficulty of coming to a safe decision. Sir Jeffry anxious for his fame, and for the proper illustration of his great work, Windsor Castle, during his life time employed two of his pupils, Messrs. Gandy and Baud, and expended large sums on the preparations of the necessary drawings. His death left the enterprise unaccomplished, and by his will he directed his executor to provide for the completion of a task, dear to him even in death. Messrs. Gandy and Baud, artists of approved competence, who had been employed by Sir Jeffry himself in carrying out the works, had engaged to make the necessary drawings on condition that they should be the persons solely employed in carrying out a work, the importance of which they fully appreciated, and in which they also took an interest, as having their own reputation connected with it. From some cause, however, which has not been explained, a dissension has taken place between the executors and the artists, and each party has determined on producing a separate work. This step in such a case cannot but be deeply regretted, for neither the public nor the publishers can be benefitted by a contest of this kind, the latter must have a diminished sale, and the former a deteriorated work, instead of both parties making a profitable union, and devoting their whole capital and energies to the production of one magnificent volume.

The specimens we have seen of both the contending works are creditable and well executed, but we do hope that there is still time to conclude amicably a contest so distressing. The executors have the fame of Sir Jeffry in their keeping, and Messrs. Gandy and Baud, architects themselves, cannot be unmindful of the reputation of their former master, or of their own; the public are not so selfish as to wish for an injurious competition.

The illustrations of the Part before us consist, of a beautiful lithographic drawing of the North West View of the Winchester Tower, drawn by Mr. Gandy; of the North East View of the Prince of Wales and Brunswick Towers, drawn by Mr. Baud, and lithographed by Hawkins; and two engravings in outline exhibiting details.

A Treatise on Projection, with numerous Plates. By Peter Nicholson. London: Richard Groombridge. 1840.

Mr. Nicholson has laboured hard for the profession, but although far advanced in years, he is still as fresh as ever in supplying the wants of the professional student; to this class the volume before us will be of great service. We will give an extract from the preface, which in the author's own words best describes the utility of the work.

The theory of projection is of universal application; a knowledge of this useful branch of delineation will enable the designer to instruct the workman with nearly as much ease as if he had the model before him, and to explain the effect of an imaginary object as if it really existed; this knowledge in the workman will enable him to forsee how the different parts of an object will join upon each other, to understand drawings and designs with readiness, and to execute them with accuracy.

Among many other uses to which this truly admirable science extends its influence, may be mentioned the construction of the centerings of arches and groin vaults, the formation of hand-rails and stairs, the cutting of stones for bridges and oblique arches, and the delineation of plans, and elevations of buildings and machinery. But the utility of an intimate acquaintance with the principles of this useful art is not confined to the workshop alone, a certain knowledge of these principles should form a part of that stock of information which is essential to the student in the arts of design, and the rapid strides which have of late been made in other departments of the arts and sciences render it far from improbable that we shall shortly see the theory and practice of projection taught in our public schools, as a necessary branch of education.

Treatise on the Theory and Practice of Naval Architecture. By Augustin B. Crewse, Member of the late School of Naval Architecture, &c. Edinburgh: Black. 1840.

We regret that the space occupied by other matter prevents us from giving the remarks which we had prepared on Mr. Crewse's work. This is a reprint of the article Ship Building in the Encyclopedia Britannica, and gives in a short compass the elements of the history and theory of the art, and also a great deal of information upon construction. We recommend the work to the immediate notice of our readers, as we must ourselves defer the consideration of it until next month.

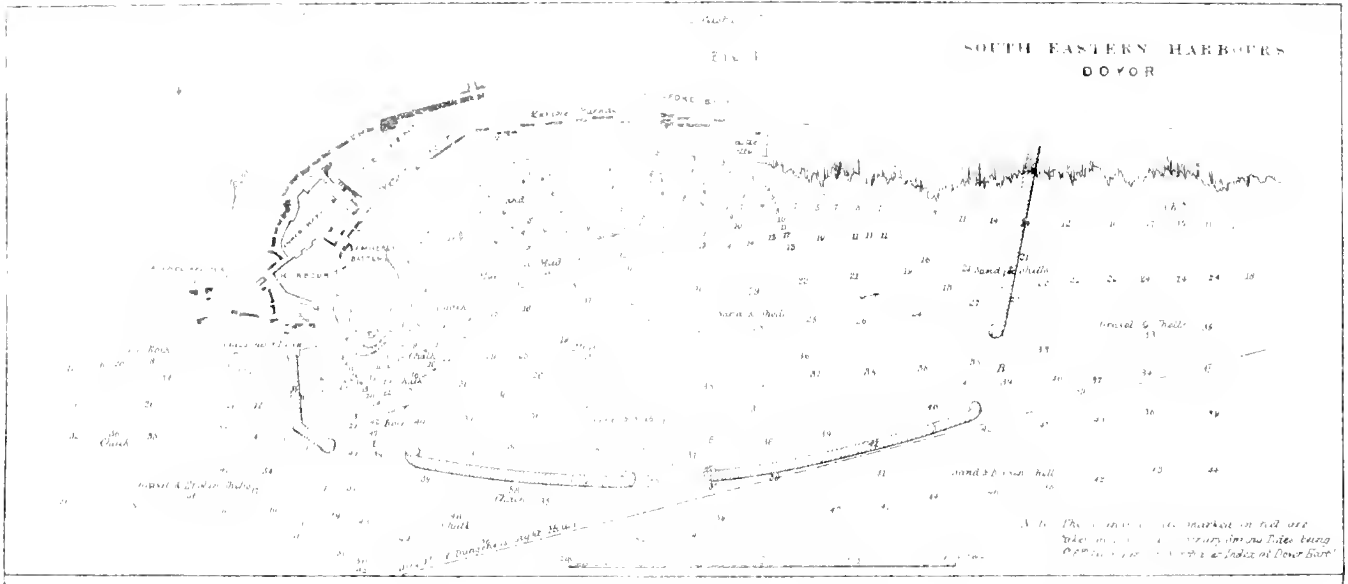
Chemistry of Science and Art, or Elements of Chemistry, adapted for reading, along with a Course of Lectures, for self instruction, &c. By Hugo Reid. Edinburgh: Maclachlan and Stewart. 1840.

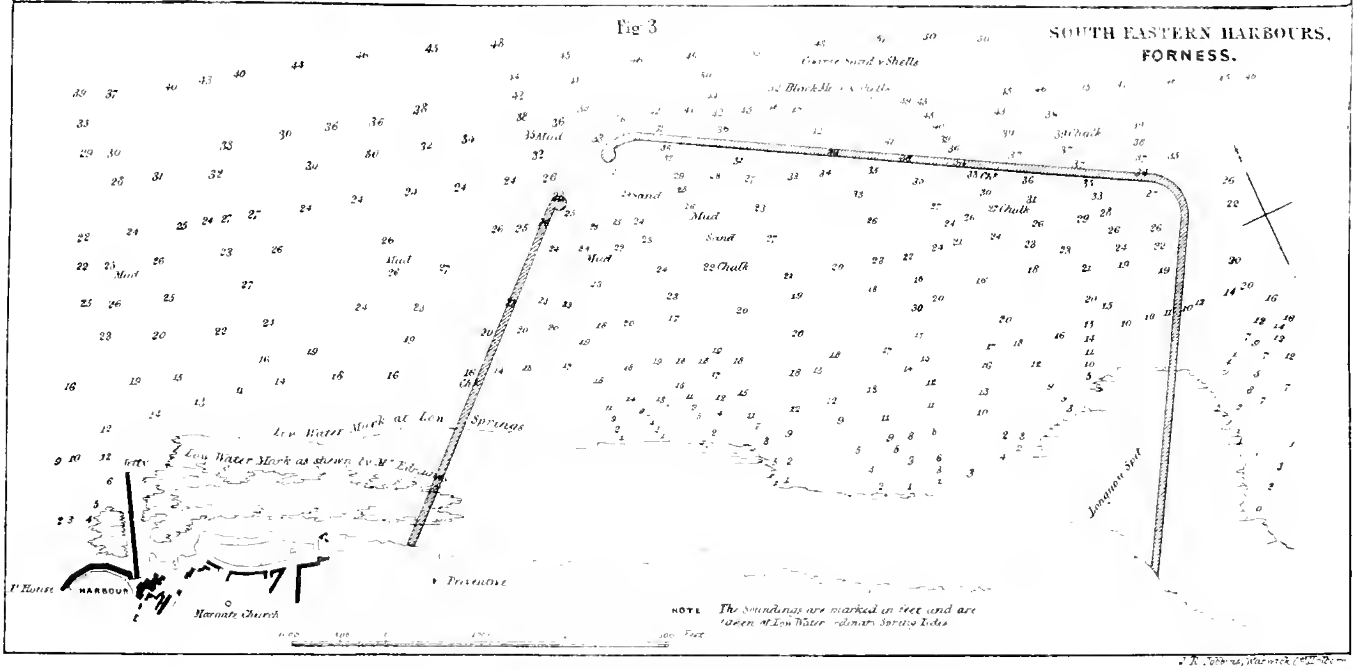
Mr. Reid's work is what it professes to be, a portable compendium of the principles of chemistry, not aiming at the extent and research of large works, but eschewing the superficiality of what are called cheap works. It is sound, cheap, and useful, eminently calculated for the artisan and the student, deriving its information from the highest sources, and giving all the improvements of the latest date. We have only one thing to quarrel with Mr. Reid about—and he has treated upon the subject so clearly, that we are half inclined to let it alone—and that is, that he has in the beginning of his work enlarged upon two or three subjects, which might better become the subject of his forthcoming treatise on the classiication of the sciences.

LITERARY NOTICES.

Mr. Rooke has brought out a new edition of his Geology as a Science applied to Engineering, in which he has detailed some of the results of his last year's tour in France.

Dr. Day will not think us inattentive to his pamphlet on the Doctrine of Parallels, in deferring our remarks upon it until next month, as it requires a serious perusal.



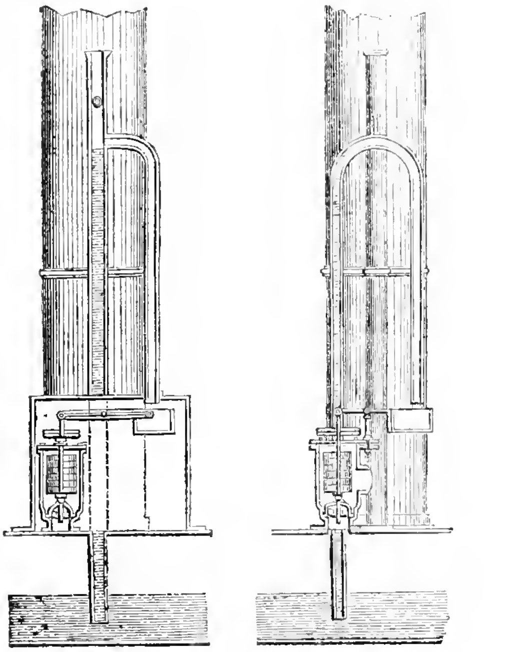


J. R. Jobbins, Warwick Ct

SAFETY VALVES.

The annexed engravings are referred to in the Report on the plans for preventing accidents on board Steam-vessels, at page 246.

Fig. 1. Fig. 2.



ON SUSPENSION BRIDGES.

Sir—I observe in your Journal of the past month, an engraving and description of "Dredge's Patent Suspension Bridge," you will find at page 23, vol. 1 of the Journal, an engraving and description of my bridge, which was presented to the British Association for Science at Newcastle, in 1838. Mr. Dredge's bridge was presented to the Association last year at Birmingham. The identity of principle in the two bridges is evident, and if it were desired to convert my construction into that proposed by Mr. Dredge, it would be merely necessary to unite each radial link with the one next it, but this would necessarily divert the rods from the diagonal line, representing the resultant of the two forces, tending to destroy the bridge, which would be a very unskilful arrangement, and attended with no practical benefit. I am not desirous to enter into a controversy upon this matter, but I think I may claim from you the small justice, of allowing me to state in your next number, my claims to be considered the author of this system of constructing suspension bridges; it may not be amiss to observe that my arrangement is much easier of construction than either that of Mr. Dredge, or the ordinary suspension bridge, and would be cheaper and stiffer than either.

I remain, your obedient servant,

W. J. Curtis.

15, *Stamford Street, Blackfriars Road,*
June 17, 1840.

WYRE LIGHTHOUSE.

In our last number we gave an engraving and description of the Wyre Lighthouse, together with the Specification, with the signature of "Henry Mangles Denham," at the end. by which it may appear that the design and specification was that of Captain Denham, instead of which it will appear by the following letter to have been entirely the production of Messrs. Mitchell and Son.'

TO THE EDITOR OF THE PRESTON PILOT.

60, Pall Mall, London, May 9th, 1840.

Sir—It is right that the public should clearly understand that the specification of the Wyre Lighthouse was the production of Messrs. Alexander Mitchell and Son, and only signed by me to show I had considered, approved, and caused its adoption. Your inserting this note in your next paper will oblige your humble servant,

H. M. Denham,
Consulting Marine Surveyor.

THE PROJECTED MERCHANT SEAMAN'S INSTITUTION.

(See Plate.)

The grandeur and great public importance of a project, the particulars of which accompany our Journal this month, will, we trust, excuse our departing somewhat from our usual course, in criticising a work at present to a certain extent undetermined, but which we prophecy will at no distant period be equally the pride and protection of the vast and deserving class for whose benefit it is especially intended, as a glorious and lasting monument of the national estimation in which they are so justly held.

The style selected, Palladian, so eminently suitable to buildings of large extent and intricate internal arrangement, and the boldness and simplicity of the ensemble, evince considerable judgment and taste in the artist, whose name however does not appear.

The plan is quadrangular, the entire length of the façade, we are informed, about 700 feet. The lower story consists of an arched and rusticated basement, supporting and subservient to the principal design which is of the Corinthian order; the entablature continued throughout and unbroken by those unnecessary and unmeaning projections which so frequently disfigure the best compositions; the central feature of the design is an octastyle portico of magnificent dimensions, upwards of 100 feet in extent, supported by an open loggia communicating with an arcade surrounding the quadrangle, and surmounted by a dome novel in design, but in harmony with the general character of the composition. Such are the leading features of the exterior;—of the interior we can give no opinion, the very excellent method having, we understand, been adopted of arranging it with reference to the opinion and advice of those who are practically acquainted with the purpose to which it will be devoted. We shall, however, keep a strict watch over its progress, and trust no petty interests or party feelings will interfere with the completion of so useful, so creditable, and so magnificent an undertaking.

STEAM NAVIGATION.

"THE RUBY" CHALLENGE.

Sir—The letter which appeared in the last number (for June) of your valuable Journal, signed by "A. Billings, Manager of the Diamond Steam Packet Company," has excited considerable stir amongst steam-boat parties. I do not, however, observe in that letter the public challenge* which the "Ruby" gave in the Nautical Magazine for this month, and in the latter periodical Mr. Billings, as "Manager of the Diamond Steam Packet Company," says, "I am *ready* to match the Ruby to run from Gravesend to Margate and back for 200 guineas against *any* boat afloat, whatever may be her size, power, or build."

Now your numerous readers may like to know if and how the match came off, and I beg a space in your columns to state the matter fairly.

I accepted the challenge through Mr. Roney, the Manager of the Polytechnic Institution immediately, and submitted that the conditions should be—to engage to run on a certain day, three weeks notice to be given.

To deposit 200 guineas each. The course to be from Gravesend round a boat moored off Margate wood pier. Time of st rting to be named at once, and to take all chances of weather.

Sails to be used or not as the challenger pleased. Here I will only observe that as I should have to get the "Fire King" round from the Clyde, a distance of 850 miles, I stipulated for the above conditions as to time, believing the "Ruby" to be "ready." On the 13th Mr. Roney received answer from Mr. Billings, (but not signed by him as Manager of the Diamond Company), asking the "name of the boat, her tonnage and power, and the time she has been running, *when* (*i. e.* Mr. B.) shall be willing to enter upon the terms of the match."

Having read so much of his answer, and finding that his former words "*any boat afloat*," and his being "*ready*," were now appearing in a new light, I was amused to find the following philanthropic evasion thrust in, "provided that your vessel is worked by low pressure steam, as I feel convinced that the Diamond Steam Packet Company would not on any account whatever endanger the lives of their fellow creatures, by permitting their boat to enter into a contest with any vessel propelled by so hazardous an agent as high pressure steam!" and his letter concluded, "I shall be obliged by an answer to the foregoing before entering on the details of the match."

I protest that my regard for the lives of my fellow creatures is just as great as that of Mr. Billings and his Company—and I do consider that part of the letter mawkish in the extreme.

But the Ruby was not to get off the match quite so easily. I answered in the following words: that "I accepted the published challenge on the part of the owner of the 'Fire King,' of 663 tons, and with 57½ inch cylinders low pressure. She is private property and on no station for passengers; she has been afloat to *my* knowledge seven months,† but that has nothing to do with *your* challenge, further than that the 'Fire King' comes within the words

* We purposely omitted the paragraph, as we did not wish the Journal to be made the medium of betting.—Ed. C. E. and A. Journal.

† She has been afloat much longer.

ned by you, 'any boat afloat, whatever may be her size, power, or build.'" Again I pressed him to conclude the terms of the match, and signed myself as agent for Robert Napier, of Glasgow, who owns the Fire King.

Again I found the Ruby at fault, for Mr. Billings replied on the 15th June, that as the "Fire King" is low pressure, there could be no objection to make the match, *but* that his challenge was published when the Ruby was "lying up in dock," "at the present time the season is at its heat, and all the boats of the Diamond Company are in full employment, and the Ruby could not be spared off her station just now, she being their principal boat, you must therefore let the match stand over until the end of the season, when the Ruby could be withdrawn from her station for a few days for the purpose, if (mark the saving word 'if') the conditions are agreed to."

To this I answered on the 16th June, "your favour of the 15th has, I must say, surprised me. In this month's "Nautical Magazine you published your challenge, wherein you had to repeat 'that you were *ready* to match the Ruby to run from Gravesend to Margate and back for 200 guineas, against any boat afloat, whatever may be her size, power, or build.' This was published on the 1st of this month. Mr. Robert Napier, the owner of the Fire King, met with your challenge some days afterwards in Glasgow, and although much disinclined to race, he could not allow it to pass unheeded, or your ship to be published as faster than the Fire King. He lost no time in instructing me, and on the 9th instant your challenge was accepted in London. You publicly stated that the Ruby was "*ready*," both last month and this month, after your season had commenced, but now when you have learned that the Fire King accepts your challenge, you object to run until after your "season" has finished.—I therefore now call upon you, and those concerned with you, to complete the match, as you are bound in honour to do within a reasonable time."

"Requesting the favour of an immediate answer, I am Sir, your's, &c."

My next and last letter from Mr. Billings "begs me to recollect that the Ruby is the property of a Public Company, whose engagements being completed for the season, they will not permit the boat to be withdrawn at present from the station."—So that the grand challenge ends thus in nothing; and I am confident your readers will conclude with me, that the Ruby shuns the trial altogether, and many of your readers will think as I do, that the Gasconade challenge was given in Mr. Billing's letter (which by-the-bye condemns "swaggering and boasting") merely to puff the Ruby or her engineers, in the vain confidence that no one would accept it. I beg to assure you I intend nothing disrespectful to Mr. Billings or his Company, or to those behind the scenes; it is a pity they should thus have tarnished the lustre of the Ruby.

I have now only to conclude by giving to you the "Fire King's" rate of steaming, as ascertained on the Gare-loch last October, in presence of Mr. John Wood the well known ship-builder, Mr. Lloyd the assistant-surveyor of steam machinery of the Navy, Mr J. Scott Russell, Mr. Robert Napier, and myself.

	min.	sec.		miles
No. 1 measured mile	4	9	=	14·45 per hour.
2 ..	3	43	=	16·14
3 ..	3	58	=	15·13
4 ..	4	13	=	14·22
5 ..	4	5	=	14·69
6 ..	3	42	=	16·21
7 ..	3	57	=	15·19
8 ..	4	16	=	14·06
				8) 120·09

Land miles on the average per hour. 15·01

The miles were measured by us in three different and distinct parties, and the times taken by each individually. The Fire King's measurements are as follows:—

	feet.	in.
Length over stem and stern posts aloft....	180	5
Length of keel and fore rake	175	5
Breadth between paddles	28	0½
Depth in engine-room	16	8½

Making in all 663 tons O. M.

I am, Sir, your most obedient servant,

Alexander Gordon,
Agent for Robert Napier of Glasgow.

22, *Fludyer-street, Westminster,*
June 23, 1840.

LAUNCH OF TWO IRON STEAM-SHIPS AT LIVERPOOL.

The confidence entertained in the good properties of iron vessels, and particularly their advantage in combining strength with that light draught of water requisite in some branches of trade, in peculiar localities, is becoming daily more and more confirmed, by the success, both at home and abroad, of the ships built of that material, and the improvements in their construction which experience enables the builders to introduce. It is not, therefore, improbable, but in twenty years hence, or perhaps within a shorter period, one half of our mercantile marine may be of iron, copper, or some composition of various metals that may be wrought by hammer, or cast in pieces, and afterwards jointed, to any given mould or model.

Be this as it may, the construction of "steam" vessels of strong sheet iron is evidently much on the increase, particularly here and at Glasgow, the two ports that were the first, we believe, in this country, and are still the most successful, (being put to their "metal") in directing their energies to steam navigation. The "iron fleet" of England is consequently receiving rapid accessions; and not contented with turning out one vessel at a time, Mr. John Laird, has several on the stocks at once, and on Saturday morning, 6th ultimo, launched two from his yard at North Birkenhead by the same tide! The time appointed (the tide being early) was about nine o'clock, and by that hour a large concourse of persons, including many ladies and gentlemen from the neighbourhood, and not a few from this side of the water, were in attendance. Both the vessels were decorated with flags, and some parties, besides the workmen, preferred going on board and being launched with them.

The first one launched was her Majesty's steam-vessel *Dover*, to be placed on the station between Dover and Calais, or Ostend. The following are her dimensions and capacity:—

Length (per measurement)	110 feet
Breadth, or beam do.	21 feet
Will admeasure about	230 tons.

The Dover is the first iron vessel belonging to the Admiralty, and on her success will, no doubt, depend the future adoption of vessels of her build by the government. She is of a remarkably fine model, having a degree of rotundity in her sides, with ample bearing, and a fineness in her lines, fore and aft, which will, in all probability, ensure her a degree of speed and safety not yet attained by any steam-vessel of her size. A few minutes after nine the word was given, and she rushed into her destined element in gallant style, amidst the hearty cheers of the spectators, followed by a salute fired from cannon on the quay adjoining the yard.

The second vessel launched was the *Phlegethon*:—

Length (per measurement)	157 feet 6 inches.
Breadth	26 feet.
Capacity, upwards of	500 tons.

She is intended for sea and river service, on, we believe, a foreign station, and will carry two long guns, one at the bow and one at the stern, to work within a circle. This vessel is also of a fine model, with ample bearings, so that she may carry sail when required, either with steam or without it, as her paddle-wheels, on a new principle, by Mr. Forrester, may, when required, be thrown out of gear. She is handsomely, and we may add, rakishly rigged as a two-masted schooner, and will, we doubt not, prove to be a clipper.

She was launched about half-past nine o'clock, and the sight was one of the most gratifying ever beheld. She had a considerable distance to run down the ways before her forefoot reached the water, which she took like a swan breasting its native lake. We need scarcely say that the welkin again rang with the acclamations of the spectators, who lined the yard and the neighbouring shores, and which were returned with equal enthusiasm by those who stood on her decks. When afloat, the impression she conveyed from her length and sharpness, was that of a very fast and mischievous looking craft. She has a fine flush deck, and her paddle-boxes do not rise to an unseemly height over her gunwale.

We believe this is the first instance of two iron vessels being launched from the same slip by the same tide, nor do we recollect a case occurring in Liverpool of two wooden vessels of so large size being launched in one tide.

Both vessels exhibit many improvements in their construction, not tried in any iron vessel previously built; and which render them two of the strongest iron vessels afloat. They are now receiving their machinery,—the Dover, from Messrs. Fawcett, Preston & Co., and the Phlegethon from Messrs. Forrester & Co's establishment. Both, it is expected, will be ready in the course of the present month.

Mr. Laird is now building three iron steam-vessels to compose the new expedition about to be sent by government up the river Niger, under the command of Captain Trotter.—*Liverpool paper.*

The Archimedes.—This experimental vessel is gradually working its way all round the coast, exhibiting its powers at the principal ports. It was at Liverpool last month. On the 10th ult., we find by the *Liverpool Standard*, she made a trip, and shortly before reaching the Crosby Light-ship, the Duchess of Lancaster steam-ship was perceived making directly for the port, and as she was known to be a remarkably fast sailer, and Mr. Smith being desirous of proving the capabilities of the Archimedes, immediately 'put about,' and awaited the arrival of the former vessel. On coming up, the screw was immediately put in motion, and the two vessels went admirably together for some distance, though we are bound in fairness to state that the Duchess had a very slight advantage in respect of speed, owing, as will be seen from the subjoined comparison, to her proportions as to power, draught, &c., being better adapted for quick sailing. The Archimedes had also the full strength of the tide to contend with, whilst her competitor ran the whole distance in the eddy. This is the first time the Archimedes has been beaten, with one or two slight exceptions.

Archimedes.		Duchess of Lancaster.	
Diameter of cylinder	37 in.	Diameter of cylinder	40 in.
Stroke	3 ft.	Stroke	3 ft.
Tonnage..................	237	Tonnage..................	238
Draught	10 ft.	Draught...... ;..........	6 ft.
Estimated steam-power ..	80-horse	Estimated steam-power ..	90-horse
Length between perpendiculars	107 ft.	Length between perpendiculars	120 ft.
Beam	22ft. 6 in.	Beam	20 ft.
Area of midship section at 10 feet draught...........	143 ft.	Area of midship section at 6 feet draught	100 ft.

As there was a feeling on board relative to the slip or loss of power from the screw, the following explanation will doubtless be satisfactory:—The screw, being 8 feet pitch, would, if working in a solid, advance 8 feet for each revolution; but, working in a fluid, the relative difference between the speed of the screw and the vessel appears, *at first sight*, to be considerable, from the *supposed* oblique action of the propeller. The following mode of calculating the speed of both will show that the difference is barely one-sixth, which is considerably less than that of ordinary paddle-wheels.

"The number of revolutions of the engine per minute is 26, which, multiplied by the spur wheels $5\frac{1}{3}$ times, gives that number of turns to the screw for one of the engine.

26	revolutions of the engine per minute.
$5\frac{1}{3}$	multiple.
138	revolutions of the screw per minute.
8	feet pitch of screw.
1104	*feet* travelled per minute.
20	being $\frac{1}{3}$ of 60, to bring it into
22,080	*yards* per hour.

which, divided by 1760 (the number of yards in a statute mile), gives us 12 miles 160 yards per hour as the speed of the screw. Speed of the vessel for 26 strokes per minute, 10 10-25 miles per hour by the log."—She left Liverpool on the 11th ult., for the Isle of Man, and performed the run in the short space of seven hours and 25 minutes, which is an unusually quick passage. The *Mona's Isle* was fully two hours longer doing the same distance on the same day, starting about half an hour later than the *Archimedes*. The *Mona* is 10 horses power more than the *Archimedes*, with considerable less tonnage, and drawing two feet less water.

Royal Mail Steam Packets.—The contract of the "Royal Mail Steam-packet Company" with the commissioners has just been printed, in return to an order of the House of Commons. The company covenant to keep a sufficient number (not less than 14) of good and efficient steam-vessels, which shall be able to carry guns of the largest calibre now used on board of steam-vessels of war, supplied with engines of not less than 400 collective horse power, as well as with men, apparel, &c., and be of at least 1,000 tons burden. One of these vessels is to leave a port in the British Channel twice in every calendar month, and proceed to Barbadoes, as soon as the mails are on board. After an interval not exceeding six hours from her arrival there, she is to proceed to Grenada, and after remaining a time not exceeding 12 hours, go with the mails on board to Santa Croz, thence to St. Thomas's, thence to Nicola Mole in Hayti, thence to Santiago de Cuba, and thence to Port Royal in Jamaica. After remaining at Port Royal for an interval not exceeding 24 hours, the vessel, after delivering her mails and receiving others, is to proceed to Savannah la Mer, and after a delivery and receipt of mails there, to Havannah in Cuba. After an interval not exceeding 48 hours she is on her return to proceed from Havannah to Savannah la Mer, thence to Port Royal, thence to Santiago de Cuba, thence to Nicola Mole, thence to Samana in Hayti, delivering and receiving mails at each place, care being taken that she shall always arrive at Samana, after performing her voyage from Barbadoes, on the 22nd day after the arrival of the mails at Barbadoes from England. From Samana she is to make the best of her way back to England. Immediately on the arrival at Barbadoes of every steamer employed under the contract, another of such steam-vessels is to proceed with her mails from Barbadoes successively to Tobago, Demerara, Berbice, and Paramaribo. The period of delay at Paramaribo is not to exceed 48 hours, and then the vessel is to proceed to Berbice, Demerara, Tobago, Grenada, and Barbadoes, always arriving at Barbadoes in time to depart immediately for Tobago on the arrival of one of the vessels at Barbadoes from England. On the arrival at Grenada of a mail from England, another of the steam-vessels is to proceed from Grenada successively to St. Vincent, St. Lucia, Martinique, Dominica, Guadaloupe, Antigua, Montserrat, Nevis, St. Kitt's, Santa Cruz, Tortola, St. Thomas's, St. Juan's (in Puerto Rico), Samana, Curaçoa, Porto Cabello, La Guayra, Trinidad, and thence back to Grenada, so as always to be ready to depart thence with the mails on their arrival from England. Another vessel likewise, on the arrival at Grenada of the mails from England, is to proceed with the mails successively to the Port of Spain (in Trinidad), La Guayra, Porto Cabello, Curaçoa, Samana, St. Juan's, St. Thomas's, Tortola, Santa Cruz, St. Kitt's, Nevis, Montserrat, Antigua, Guadaloupe, Dominica, Martinique, St. Lucia, St. Vincent, and thence back to Grenada, so as to be ready to depart immediately on the arrival of a mail from England. On the arrival of any vessel at Curaçoa from Grenada, a sailing vessel is to be ready then to proceed from Curaçoa to Santa Martha, and thence to Carthagena, where she is to remain 24 hours, and then return to Santa Martha and Curaçoa. On the arrival of a mail from England at Nicola Mole, another sailing vessel is to proceed thence to the Bahama Islands, and after remaining at New Providence for not more than 72 hours, return to Nicola Mole in time to meet the steam-vessel. On the arrival of the mail from England at Port Royal, another steam-vessel is to proceed thence to Chagres, Carthagena, Santa Martha, and thence back to Port Royal in time to meet the return vessels from Havannah. On the arrival of the mails from England at Savannah la Mer, another sailing vessel is to proceed thence to Trinidad de Cuba and Belize (in Honduras), where after remaining 48 hours, she is to return to Savannah la Mer by the same route. On the arrival at Havannah of the mails from England, another steam-vessel is to proceed thence with the mails to Vera Cruz, Tampico, Mobile, or such other port as the commissioners shall determine, returning from the last port to Havannah in time to depart for Vera Cruz immediately on the arrival of the English mail, and another to the Gulf of Mexico, Tampico, and Vera Cruz, and then back to Havannah to meet the mails. Another steam-packet, on the arrival of the mails from England at Havannah, is to proceed to Mantanzas in Cuba, and to New York, stopping at intermediate ports to be named by the commissioners, and thence to Halifax, returning back to Havannah, by the same route on the arrival of the mails from England. The contract is to commence on the 1st of December, 1841, or at an earlier period, if mutually agreed, and to continue in force for ten years from the first day on which the first vessel shall put to sea for Barbadoes, and for a longer period, unless determined by twelve months' notice in writing.

Transmission of the Mails to North America.—The contract entered into about a twelvemonth since for the conveyance of the mails by steam-packets of 300 horse power and upwards from England to North America will come into operation immediately, the Britannia steam-ship having arrived at Liverpool to carry out the first mail; she is to be followed by the Arcadia, Caledonia and Columbia, all large and powerful vessels. The terms of the contract are, that the mails shall be conveyed twice in every month from Liverpool to Halifax in Nova Scotia, and from Halifax to Boston in the United States, and, while the St. Lawrence is navigable in smaller steam-vessels, from Pictou in Nova Scotia to Quebec in Canada. The mails to return by the same route, twice a month to Liverpool. The contract is for seven years certain, and the contractor is to be paid for performing this service at the rate of 60,000*l*. per annum.

Steam to Alexandria, Egypt.—The steam ships *Oriental* (late the *United States*) and *Liverpool*, have been engaged by government to carry the mails between England and Egypt. The *Oriental* will be ready to sail from Falmouth for Alexandria on the 1st of August, to be succeeded by the *Liverpool*, which will depart on the 1st of September. These vessels will call at Gibraltar and Malta, in going and returning; and they are to be only 15 days on the passage to Egypt, and the same time on that back to England. Both ships will, it is expected, sail regularly from and to this port, calling at Falmouth to receive and deliver the mails and passengers; so that one may shortly take a trip hence direct to Egypt, and behold, in a brief visit, all the wonders of that once glorious land.

PROGRESS OF RAILWAYS.

ATMOSPHERIC RAILWAY.

We attended on Thursday, the 11th ult., at Wormholt Scrubbs, to witness an experiment on a portion of the Birmingham, Bristol and Thames Junction Railway, which had been laid down by Messrs. Clegg & Samuda, on their patent atmospheric principle; as might have been expected, the practical introduction of a system so different from that now in use on other railways, excited considerable interest.

The idea of employing the power of the atmosphere, against a vacuum created in an extended pipe, laid between the rails, and communicating the moving power thus obtained to propel carriages travelling on a road, we believe originated with Mr. Medhurst, who laid before the public details of his plan in a work he published in 1827, entitled "A New System of Inland Conveyance"; indeed so far back as 1812 he published some ideas on this method of locomotion. About 1835 some experiments were made with a model in Wigmore Street, by Mr. Pinkus, very similar to those described by Mr. Medhurst; these experiments, however, failed, from the same cause which probably prevented Mr. Medhurst from carrying his into effect, viz., the impossibility of making the continuous communication from the inside of the pipe to the carriage tight enough to allow a useful degree of rarefaction to be produced. Messrs. Clegg & Samuda's invention overcomes this difficulty in a very simple manner; indeed the constructing and closing this continuous valve, by *hermetically sealing it up with a composition* each time a train passes, forms the main feature in their invention.

The portion of the line selected on which the experiments were made is half a mile long, with a rise of 1 in 120 for rather more than half the distance, and 1 in 115 for the remainder. A continuous cast iron pipe or tube 9 inches in diameter, is fixed between the rails, and bolted to the sleepers which carry the rail chairs; the inside of this pipe, which is unbored, is lined with a strong lubrication of pressed tallow about $\frac{1}{10}$ of an inch thick, which equalizes the surface, and prevents any unnecessary friction from the passage of the travelling piston through it; along the upper surface of the pipe is a continuous slit or groove about $1\frac{1}{2}$ inch wide. This groove is covered by a valve extending the whole length of the railway, formed of a strip of leather rivetted between iron plates, the top plates being wider than the groove, and serving to prevent the external air forcing the leather into the pipe when the vacuum its formed within it, and the lower plates fitting into the groove when the valve is shut, makes up the circle of the pipe, and prevents the air entering the tube; one edge of this valve is securely held down by iron bars fastened by screw bolts to a longitudinal rib cast on the pipes, and thus allows the leather between the plates and the bar to act as a hinge, similar to common pump valves; the other edge of the valve falls into a groove which contains a composition of bees-wax and tallow; this composition is solid at the temperature of the atmosphere, and becomes fluid when heated a few degrees above it. Over this valve is a protecting cover, which serves to preserve it from snow or rain, formed of thin plates of iron about 5 feet long, hinged with leather, and the end of each plate underlaps the end of the next in the direction of the piston's motion, thus insuring the lifting of each in succession. To the underside of the first carriage in each train is attached the piston and its appurtenances; about six feet behind the piston, the horizontal piston-rod is attached to a connecting arm which passes through the continuous groove in the pipe, and being fixed to the carriage, imparts motion to the train as the tube becomes exhausted of the air; attached to the piston rod, and preceding the connecting arm, two steel wheels are fixed, which serve to lift the valve to allow the connecting arm to pass, and also for the atmospheric air to impinge immediately on the back of the piston; another steel wheel, which is attached to the carriage by a spring, serves to ensure the closing of the valve, by running over it immediately after the piston has passed, in case it should not fall by its own weight. A copper tube about 10 feet long, which is constantly kept hot by a small stove, also fixed to the under side of the carriage, passes over the surface of the composition (which has been broken up by lifting the valve out of it), and rendering it fluid, which, upon again cooling, becomes solid and hermetically seals the valve. Thus each train, in passing, leaves the pipe and valve in a fit state to receive the next train.

For the purpose of exhausting the tube a steam engine of 16 horse power is employed, which works an air-pump or exhauster 37½ inches diameter, and 22½ inches stroke, making from 40 to 43 strokes per minute. The air-pump is connected with the exhaust tube in the centre of the railway, by means of a branch pipe 9 inches diameter leading from the air-pump.

To calculate the power of this kind of apparatus, it is nesecessary to ascertain the state of vacuum and the difference of the pressure of the atmosphere which forces the piston forward; in the present experiments the vacuum was equivalent to from 18 to 20 inches of mercury, which will give for the useful pressure of the atmosphere on the piston about 9 lb. on the square inch. The area of the tube, 9 inches diameter, is equal to 63·62 square inches, and this multiplied by the pressure, will give

$$9 \times 63{\cdot}62 = 572{\cdot}58 \text{ lbs.}$$

for the pressure on the back of the piston, or the moving power.

The load conveyed at each experiment may be taken as follows:—

Two carriages	=	4 tons.
Apparatus attached		1 ton.
Forty-five passengers	=	3 tons.
Total load conveyed	=	8 tons.

The stationary engines and air pumps on this system may be fixed in distances varying from one to four miles apart, to suit the traffic and convenience of the line of road; each section or length of pipe acted on by one engine is confined between two valves; the vacuum is created to about 18 to 20 inches of mercury before the piston enters the pipe, and is maintained during the passing of the train by the engine being kept at work; having passed through one section of pipe, the momentum the train has attained, serves to carry it on to the next section, which commences at about 100 or 200 yards beyond, and the entrance separating valve of the second section being opened by the carriage immediately after it has entered, allows the vacuum prepared in this section to act upon the piston; thus the train can pass from section to section without end, and without any stoppage.

Experiments.—For the purpose of ascertaining the relative velocity on various portions of the half mile, it was divided into 20 sections of 2 chains or 44 yards each. The carriages were started from a state of rest at the foot of the inclined plane of one in 120, and allowed to run up the incline of half a mile before the break was applied to arrest the progress of the carriages. When two carriages were attached, they run over the ground, after passing the first 5 divisions at the velocities of 7, 6, 5, and 4 seconds to each section, which is equivalent to 13, 15, 18, and 22½ miles per hour; and when *one* carriage only was attached, it run over the ground at the velocities of 6, 5, 4, and 3 seconds to each division, which is equivalent to 15, 18, 22½, and 30 miles per hour. The last division in each experiment was done at the greatest velocity, which clearly shows that had the experiment been made on a mile run instead of a half mile, the experiment would have been far more favourable and satisfactory; and if the experiment had been made on a level, about four times the above load might have been conveyed at the same velocity.

We noticed that it took about 1½ minute to raise the vacuum each trip, to about 18 inches of mercury.

From the above experiments, the loads drawn, and the speed attained, will be as good a criterion of the success of the undertaking at we can have, and when we consider that in producing these results, the patentees must have been wholly unassisted by any previous examples, we think that the greatest credit is due to the talent and ingenuity they have displayed. The system appears to us to possess many advantages which must insure it the serious consideration of the engineer. The carriages travel without noise, and without the risk of explosion, or of getting off the rail. It does not seem possible that a collision of trains can take place, for two trains cannot receive power from the same section of pipe at the same time, neither can they receive power in opposite directions on the same rail. The speed on this system must be proportioned to the capacity of the air-pumps used to maintain the exhaustion in the tubes, and therefore any rate of travelling that may be deemed desirable may be easily attained.

French Railways.—The Railway Committee held another meeting last week in Paris, and after hearing parties interested in the five companies affected by the Government bill, took into special consideration that part of the measure which relates to the lines from Lille and Valenciennes to the Belgian frontiers. The Committee approved of these two lines being executed by Government, not only on account of precautions that might be rendered necessary by the defence of the frontier; but also because the formation of treaties with Belgium might render it desirable that these lines should be in the hands of the State. The Committee was of opinion that the termination of these lines was the more called for, since the Belgian lines to the frontier were already executed. The line from Lille to the frontier near Mouseron is 14,125 meters in length, or 47,000 English feet; and that from Valenciennes to the frontier near Quievrain is 63,128 metres, or 43,000 feet; the first is to cost 1,000,000f., the latter 4,000,000f. The Committee adopted this part of the bill almost unanimously, as also the lines and surveys as approved of by the administration of the Ponts et Chaussees.—*Railway Times.*

Llanelly Railway.—The present state of the new line is as follows:—From the Dock at Llanelly to Parkrhyn (main line) eleven miles, and from thence up to the terminus of Cwm Amman branch, six miles, altogether seventeen miles, the line has been completed and open for traffic, over which the locomotive engines of the Company are travelling.—From that point, viz. Parkrhyn, up to Duffryn Lodge (about a mile and a half further on the main line) the same is nearly completed, the rails having been laid, and the filling in in progress.—From that point on the main line, viz., Duffryn Lodge, the branch leading to Mr. Long Wrey's collieries, and Messrs. Morris, Sayce, and Co.'s, is in course of forward progress, and will be completed by 1st January next, this branch is altogether about four miles in length, and leads to several collieries of capital coal. The Company have entered into a contract with Mr. Wrey, to bring for seven years at least 10,000 tons yearly down this branch, which will yield railway and dock dues, as a minimum amount, the sum of 1,000*l* per annum.—The two new locomotive engines to which reference was made in the last annual Report as then ordered, are now at Llanelly, and one of them, the *Albert*, is engaged in traversing the line, in hauling coal down to Llanelly. The Committee are persuaded that the carrying trade which will thus be secured to them by locomotive power, will be a source of profit when the quantity of coal, iron, &c., shall be increased: whilst as an auxiliary to the general traffic the use of steam power is unquestionably of great importance.—*Directors Report.*

Preston and Wyre Railway.—The Directors have made an arrangement for one year with the North Union Railway to supply this Company with locomotive engines at 2s. 4*d*. per mile per train, and with the first-class carriages at a penny per mile each, and with second-class at a halfpenny per mile each. This will prevent the present outlay of a considerable capital, a circumstance particularly desirable until the extent of the traffic on the line has been ascertained.

Great North of England Railway.—The works of the Great North of England Railway between York and Darlington, are in so forward a state, that the Directors of the Company have employed Mr. Green, of Darlington, architect, to furnish designs for depôts upon the line.—*Leeds Intelligencer, May* 30.

The Cheltenham Railways.—Within the last few days the bank which separated the Birmingham and Gloucester works from the Cheltenham and Great Western, between the station and Lansdown Bridge, has been cut through, from which circumstance we should infer that a satisfactory arrangement has been entered into by the two Companies. The greatest exertions are making to complete the work up to the Lansdown bridge, and from the number of hands employed, and the activity displayed, we should fancy that a very short space of time will suffice for the attainment of that object.—*Cheltenham Journal.*

Locomotive Carriage.—Mr. Hills lately made a very successful trip to and from Camberwell and Brighton with his patent locomotive carriage, the distance from Camberwell to Brighton was performed in 5 hours and 10 minutes, out of which time one hour 21 minutes was lost by delays in obtaining a supply of water at the inns, and 10 minutes delay on the road. The return trip was accomplished in 5 hours 22 minutes, out of which time one hour four minutes was lost by delays in obtaining water, and 26 minutes delay by stoppages on the road; the delays in obtaining water will be reduced very considerably, when proper stations and stated periods for arrival are made, the whole of the stoppages need not occupy more than 12 minutes, which, according to the speed the carriage ran on the road, the journey from London to Brighton might be very well accomplished in about three hours and a half. Our correspondent, who accompanied Mr. Hill on his trip to London, states that the form of the carriage is a handsome britzka, that there is scarcely any noise from the working of the engine, or escape of steam, and no appearance of smoke; on descending hills it is easily regulated by powerful retarders, and guided with the greatest facility. We hope at some future time to be able to give some additional information connected with the cost of a carriage, and the working of the same.

NEW CHURCHES, &c

Plymouth.—On Tuesday 20th May the foundation stone was laid of a new Church in Southside-street, in this borough, and which is to be called "Trinity Church." From the peculiar circumstances of its locality, it differs greatly from the usual form of New Churches. Its interior may be described as a square of about 70 feet, divided into three parts by two parallel Tuscan colonnades, each surmounted by an attic range of semicircular windows, forming a *clerestory* as in our cathedral churches. The traverse section of the building, therefore, exhibits a nave of about 35 feet high, by 37 feet wide, and two aisles, each about 25 feet high, by 16 feet wide, the galleries being constructed along the latter. The building being surrounded by houses, &c. on the north, south, and west sides, the only light, in addition to that of the clerestories, is derived from three windows at the east end, the central one being a large three-light Venetian window over the altar, which terminates a recess extending about 14 feet eastward from the main body of the church; on each side of the altar projection is an entrance porch; and there is a third porch in the centre of the north side to afford an entrance from Southside-street. The bell turret, surmounting a pediment over the great east window, is in the simple form of an arch flanked by pilasters, and crowned with a small pediment, a repetition of the larger one below. It is anticipated that the perspective of the interior looking from the western end will be boldly picturesque and ecclesiastical; that the effect of the lofty clerestories will be not less striking, than novel, as a modern application of Italian architecture; and that the altar-piece, with its triple Venetian window over, will form an imposing termination to the vista. The church is calculated to afford accommodation for about 1100 sittings, of which 650 are free. George Wightwick, Esq., is the architect.

Northamptonshire.—The Hon. H. Watson, brother of Lord Sondes, with praiseworthy munificence, intends erecting a new church at Guilsborough, entirely at his own expense. The cost of the building, it is said, will amount to upwards of 5,000*l*.

The Temple Church.—This ancient and beautiful edifice is closed, in order to its being thoroughly cleansed, repaired, and restored, externally and internally. We understand that the benchers of the two Temples have determined that no efforts or expense shall be spared in this work of renovation. The richly ornamented Norman entrance, which is unfortunately so hidden by the adjacent buildings, is to be restored to its original perfection. The organ, one of the finest in London, is to undergo a complete examination and repair. Some changes more in keeping with the general style of the architecture are contemplated in the interior of the building; and the interesting monuments, and other decorations and antiquities, of this venerable pile, are to re-appear in a state more worthy of the characters and events they are intended to perpetuate, and more likely to command the attention and admiration of the spectator.

Cornwall.—On Thursday, 28th May last, Christ-church Chapel of Ease, at Lanner, in the parish of Gwennap, was opened. It is from designs by Mr. Wightwick, of Plymouth, in the Anglo-Italian style, neatly finished with granite dressings, having the timbers of the roof-trusses open to view, the under side of the rafters being ceiled, a plan consistent with economy, and affording ample breathing room for the 400 free sitters who occupy it. It has been built by subscription, aided by grants from the Diocesan Board and the Incorporated Society of London.—The foundation stone of another chapel, also from designs by Mr. Wightwick, was laid on Whit-Monday last, at Portreath, in the parish of Illogan, in the county of Cornwall. This chapel is of about the same capacity as the one at Lanner, but in the lancet pointed style; and like the former, is to be entirely occupied with free sittings.—Mr. Wightwick is also engaged in preparing plans for a free chapel in the Anglo-Norman style at Flushing, near Falmouth; and he is superintending the conversion of a building, formerly used as a Unitarian Meeting House, into an Episcopal Chapel, at Falmouth.

Sussex.—The new church in the parish of Lower Beeding, was consecrated on Tuesday, June 2.—The building of the new Chapel of Ease in Horsham is making satisfactory progress, the work being executed in a manner highly creditable to the builder, Mr. Darby.—In the quarry which is worked for the building stone of this chapel, several fossil bones, in good preservation, have lately been discovered. They are supposed to be portions of the Iguanodon. The best specimens have been added to the excellent local collection of Mr. G. B. Holmes.

Lincolnshire.—An addition to Thorney Abbey is now being made, the first stone of which was laid June 24, 1839, in the Norman style of architecture, consisting of a transept across the east end of the present part, which makes the Abbey in the form of a T; it is designed by Edward Blore, Esq., architect. The addition is 63 feet by 30 feet 6 inches, and will have a very handsome painted window, a copy from the one in Becket's crown in Canterbury Cathedral, which was put up in the old part, but was removed in a few months for the present work. The pulpit, reading, and clerk's desks will be at the altar, forming a very handsome screen, altogether executed in wainscot, and the old part painted in imitation of that wood; the fittings are in the Gothic style.

PUBLIC BUILDINGS, &c.

TRAFALGAR SQUARE.

RETURN to an order of the Hon. the House of Commons, dated June 10, 1840, for a return of the arrangements entered into between the Commissioners of Woods and Forests and the Committee for erecting the Nelson Monument in Trafalgar-square; and also a Statement of the Plan approved and sanctioned by the Commissioners of Woods and Forests for laying out the vacant Space in front of the National Gallery, and whether it will be all or in part open to the Public. Ordered by the House of Commons to be printed, June 15, 1840.

The Lords Commissioners of Her Majesty's Treasury having approved of the designs submitted to them for the Nelson Monument, and of the appropriation of a portion of Trafalgar-square as a site for the same, the Commissioners of Woods, &c., were authorised by Treasury letter, bearing date the 27th of January, 1840, to deliver over such site to the committee. The whole of the arrangements between the Commissioners of Woods and the committee for the erection of the monument up to the present time have been limited to the delivery of the site.

The plans submitted to the Commissioners of Woods, &c., in 1837, by the late Mr. Wilkins, contemplated an architectural appropriation of the square in accordance with, and intended to increase the effect of, the National Gallery. The Commissioners of Woods have adhered to the principle of the plan suggested to them by Mr. Wilkins; but, in consequence of his death, and the subsequent selection of the present design for the Nelson Monument, the Chief Commissioner of Woods, &c., has committed the laying out of the square to Mr. Barry.

According to the plan which he has suggested (and which, as regards the excavation of the ground originally proposed by Mr. Wilkins, is now in progress), the whole of the space in front of the National Gallery, with the exception of the roadways forming its respective boundaries, will be lowered from south to north to the level of the footway leading from Cockspur-street to the Strand. The roadway in front of the National Gallery, and consequently the whole of that building, will, by this arrangement, stand upon a terrace from eight to ten feet in elevation. The access to the square from this roadway will be by a terrace-landing and flight of steps opposite to, and of the width of, the portico of the building. The steps and the sustaining walls, by which it is intended, upon three sides, to enclose the square, will be of granite; the posts with which it is intended to surround the square are also to be of granite, and connected with a bar of iron, as a protection to the respective roadways. The square will be accessible on the north by the steps already mentioned, and on the south by openings to be left between the posts in front of the Nelson Monument. The whole of the area of the square not occupied by that monument is to be either flagged with stone or laid down with asphalte, and will be open to and traversable by the public at all hours of the day.

The whole area to be excavated and appropriated as a place or square will be in extent, from north to south, 250 feet, and from east to west, 340 feet. The site of the column will occupy a space immediately connected with the footway leading from Cockspur-street to the Strand of 82 feet square.

DUNCANNON, CHARLES GORE, } Commissioners of Her Majesty's Woods, Forests, Land Revenues, Works and Buildings.

N.B. The ground removed from Trafalgar-square is applied in levelling and improving the surface of the Green Park.

Office of Woods, &c., June 12, 1840.

[We highly approve of this arrangement, and have no doubt the effect of giving height to the National Gallery in the manner proposed, will greatly improve that building.—Ed. C. E. and A. Journal.]

Rochdale, Lancashire.—A bank and manager's residence, in connection with the Liverpool and Manchester District Banking Company, is in course of erection, from the designs, and under the superintendance of Mr. Harrison, architect, of this town. The building comprises a bank and board-room, strong room, and a private residence. It will present a neat façade to Baillie-street, the lower part being of rusticated masonry, and the whole crowned by a Grecian dentil cornice and blocking course. The contracts are under 1,100*l*.

The National Provincial Bank of England.—This establishment which with its numerous provincial branches, has been in active operation for seven or eight years, has lately taken possession of its new and extensive town premises in Bishopsgate-street, better known as Salvador House, the residence of the late William Mellish, Esq., at whose death the property was sold and purchased by the Company. To render the place suitable for its intended uses, the old houses in front abutting upon the street, and the stables intervening between them, and the mansion have all been taken down, and in their place the present alterations have been made, under the direction of John Burges Watson, Esq., architect. The entrance consists of a carriage and two foot gates, situated between two Greek Doric lodges, that on the south side for a porter, the opposite one, with the new ranges of offices behind, each being about 160 feet in depth, are for the occupation of other officers of the establishment; between the further termination of these and the mansion, (now called the Bank House in contradistinction to the front offices), is sufficient space for carriages to take up and set down. The bank-house is approached by a spacious porch and lobby, and leads to an entrance-hall, which retains its original ceiling with decorated compartments, being in character with the older parts of the house. It is paved throughout with black and white marble; in the right of the entrance, is the public banking room, of large dimensions, and which has been procured by throwing two rooms into one, this affords accommodation for about 40 clerks in addition to the usual counter for cashiers, &c., and enclosures for other functionaries; the whole has been finished in the most complete manner. The walls are jointed and coloured to imitate stone, having mahogany fittings, scagliola pilasters, and a richly decorated cornice; on the left of the hall are waiting rooms, and on the same floor the accomptants' room, inspectors' room, and two strong rooms. The hall leads to the principal staircase, which is unique, and consists of a centre and two side flights leading to the landing on the first floor, in this staircase the ends of the steps, are carved and a decorated baluster rests on each in which is introduced, a medallion of the late king, in which reign the company was first established, on the obverse is a figure emblematical of commerce. The apartments on the first floor comprise the board-room for directors, the room for sub-committees, manager's room, secretary's room, &c., and the remaining portion of the house forms a residence for one of two of the principal clerks. The pediment, which is of Portland stone, has been added to the Bank-house, and is charged with the Arms of England and Wales, to which portions of the United Kingdom, the operations the Company are limited by Act of Parliament.

Liverpool.—A building for the use of an Institution to be called the Collegiate Institution for the Education of the Commercial Trading and Working Classes, is about to be erected in this town. Designs have been advertised for, and two premiums £50 and £25 proposed. The cost is to be £15,000, and the style of architecture Tudor pointed. The drawings to be sent in on the 1st July.

Ashton-under-Lyne.—A Town-hall is in course of erection here, under the direction of Messrs. Young and Westall, architects of Manchester. The building, which is to be faced entirely with stone, is in the Roman style of architecture; and consists in front of an attached Corinthian colonnade *in antis*, surmounted by a balustrade of the same order, which forms a parapet to the centre of the façade, and is crowned by a group of sculpture. The wings consist of a single interpilaster, and terminate above with a plain parapet. The order itself, which is divided into first and second floor, and is continued uninterruptedly round the edifice, is elevated upon a lofty stylobate. Its proportions are chiefly taken from the Pantheon at Rome. The interior will contain a large room 83 feet by 40 feet, and 28 feet high. It also comprises accommodation for the town's authorities, committees, &c., a constable's residence, fireman's house, and six lockups in the basement, which is principally fire-proof. The works, as contracted for, amount to about £6,000.

Road-Bricks Duty Free.—During a discussion at the last East Riding sessions, on one of the applications relative to parochial highways, it was stated by a surveyor that a request having been made to Government for leave to manufacture bricks free of duty, for the purpose of repairing highways, the Chancellor of the Exchequer had granted the required permission to those parishes in which cliffstone could not be obtained for the purpose of such repairs.—*Stockport Advertiser.*

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 28TH MAY TO 24TH JUNE, 1840.

Henry Augustus Taylor, of New York, now of Milk Street, Cheapside, Merchant, for "*improvements in the manufacture of braid and plaits.*" Communicated by a foreigner residing abroad.—Sealed May 28; six months for enrolment.

Alexander Francis Campbell, of Great Plumstead, Norfolk, Esquire, and Charles White, of the city of Norwich, Mechanic, for "*improvements in ploughs and certain other agricultural implements.*"—May 28; six months.

Sir Josiah John Guest, of the Dowlais Iron Works, Glamorgan, Bart., and Thomas Evans, of the same place, Agent, for "*certain improvements in the manufacture of iron and other metals.*"—May 28; four months.

Edmund Leach, of Rochdale, Lancaster, Machine Maker, for "*certain improvements in machinery or apparatus for carding, doubling, and preparing wool, cotton, silk, flax, and other fibrous substances.*"—May 28; six months.

Daniel Gooch, of Paddington Green, Engineer, for "*certain improvements in wheels and locomotive engines to be used on railways.*—May 28; six months.

William Henry Smith, of York Road, Lambeth, Civil Engineer, for "*an improvement or improvements in the mode of resisting shocks to railway carriages and trains, and also in the mode of connecting and disconnecting railway carriages, also in the application of springs to carriages.*"—May 28; six months.

George Henry Bursill, of River Lane, Islington, Gentleman, for "*an improved method or methods of weighing, and certain improvements in weighing machines.*"—May 28; six months.

James Allison, of Monkwearmouth, Durham, Iron Master, and Roger Lumsden, of the same place, Chain and Anchor Manufacturer, for "*improvements in the manufacture of iron knees for ships and vessels.*"—May 30; six months.

John Baptist Wicks, of Leicester, Frame-work Knitter, for "*improvements in machinery employed in frame-work knitting or stocking fabrics.*"—May 30; six months.

William Pettitt, of Bradwell, Bucks, Gentleman, for "*a communicating apparatus to be applied to railroad carriages.*"—May 30; two months.

John Hawley, of Frith Street, Soho, Watch Maker, for "*improvements in pianos and harps.*" Communicated by a foreigner residing abroad.—June 1; six months.

Pierre Defaure De Montmiral, of London Wall, Gentleman, for "*certain improvements in the manufacture of bread.*" Communicated by a foreigner residing abroad.—June 2; six months.

Richard Freen Martin, of Derby, Gentleman, for "*certain improvements in the manufacture of certain descriptions of cement.*"—June 2; six months.

Samuel Salisbury Egales, of Liverpool, Engineer, for "*certain improvements in obtaining motive power.*"—June 2; six months.

James Harvey, of Basing Place, Waterloo Road, Timber Merchant, for "*certain improvements in paving streets, roads, and ways, with blocks of wood, and in the machinery or apparatus for cutting or forming such blocks.*"—June 2; six months.

William Southwood Stoker, of Birmingham, for "*certain improvements in machinery applicable to making nails, pins, and rivets.*"—June 2; six months.

Christopher Dain, of Edgbarton, Warwick, Gentleman, for "*certain improvements in the construction of vessels for containing and supplying ink and other fluids.*"—June 2; six months.

James Roberts, of Sheffield, Merchant, for "*an improved mode of fastening certain kinds of horn and hoof handles to the instruments requiring the same.*"—June 3; six months.

Samuel Wagstaff Smith, of Leamington, Iron Founder, for "*improvements in apparatus for supplying and consuming gas.*"—June 9; six months.

Robert Hampson, of Mayfield Print-Works, Manchester, Calico Printer, for "*an improved method of block-printing on woven fabrics of cotton, linen, silk, or woollen, or of any two or more of them intermixed, with improved machinery, apparatus, and implements for that purpose.*"—June 9; six months.

Alexander Southwood Stoker, of Birmingham, for "*improvements in the manufacture of tubes for gas and other purposes.*"—June 9; six months.

Christopher Nickels, of York Road, Lambeth, Gentleman, for "*improvements in the manufacture of braids and plaits.*" Communicated by a foreigner residing abroad.—June 9; six months.

Thomas Edmonson, of Manchester, Clerk, for "*certain improvements in printing presses.*"—June 9; six months.

John George Shuttleworth, of Feamley Place, Glossop Road, Sheffield, Gentleman, for "*certain improvements in railway and other propulsion.*"—June 9; six months.

Francis Greaves, of Radford Street, Sheffield, Manufacturer of Knives and Forks, for "*improvements in the manufacture of knives and forks.*"—July 11; six months.

William Lance, of George Yard, Lombard Street, Insurance Broker, for "*a new and improved instrument or apparatus, to be used in whale fishery, part or parts of which, upon an increased scale, are also applicable as a motive power for driving machinery.*"—June 11; six months.

Benjamin Winkles, of Northampton Street, Islington, Copper Plate Manufacturer, for "*certain improvements in the arrangement and construction of paddle-wheels, and water-wheels.*"—June 11; six months.

Joseph Wolverson, of Willenhall, Stafford, Locksmith, and William Rawlett, of the same place, Latch-maker, for "*certain improvements in locks, latches, and other fastenings for doors.*"—June 13; six months.

Ezra Jenks Coates, of Bread Street, Cheapside, Merchant, for "*certain improvements in propelling canal and other boats.*" Communicated by a foreigner residing abroad.—June 13; six months.

Edward John Carpenter, of Toft Monks, Norfolk, a Commander in the Royal Navy, for "*improvements in the application of machinery for assisting vessels in performing certain evolutions upon the water, especially tacking, veering, propelling, steering, casting or winding, and backing astern.*"—June 13; six months.

Richard Beard, of Egremont Place, New Road, Gentleman, for "*improvements in apparatus for taking or obtaining likenesses and representations of nature and drawings and other objects.*" Communicated by a foreigner residing abroad.—June 13; six months.

Richard Prosser, of Birmingham, Civil Engineer, and John James Rippon, of Wells Street, Middlesex, Ironmonger, for "*certain improvements in apparatus for heating apartments, and in apparatus for cooking.*"—June 17; six months.

Richard Prosser, of Birmingham, Civil Engineer, for "*certain improvements in manufacturing buttons for certain materials, which improvements in manufacturing are applicable in whole or in part to the production of knobs, rings, and other articles from the same materials.*"—June 17; six months.

Thomas De la Rue, of Bunhill Row, Manufacturer, for "*improvements in printing calicoes and other surfaces.*"—June 20; six months.

John Aitchison, of Glasgow, Merchant, and Archibald Hastie, of West Street, Finsbury Square, Merchant, for "*certain improvements in generating and condensing steam, heating, cooling, and evaporating fluids.*"—June 24; six months.

William Hickling Bennett, of Wharton Street, Bagnigge Wells Road, Gentleman, for "*improved machinery for cutting or working wood.*"—June 24; six months.

William Wood, of Wilton, Carpet Manufacturer, for "*certain improvements in looms for weaving carpets and other fabrics.*"—June 24; six months.

William Ash, of Sheffield, Manufacturer, for "*certain improvements in augers, or tools for boring.*" Communicated by a foreigner residing abroad. June 24; six months.

Joseph Leese, Jun., of Manchester, Calico Printer, for "*certain improvements in the art of printing calico and other surfaces.*"—June 24: six months.

TO CORRESPONDENTS.

ERRATA IN LAST MONTH'S JOURNAL.

The 11 last lines of col. 1, p. 194, ought to have been placed at the *top* of the column.

Page 195, col. 2, 14 lines from the bottom, for "*more than,*" read "*less than.*"

Page 196, col. 1, 26 lines from the bottom, for "*I with deference,*" read "*With deference.*"

Page 213, col. 2, 18 lines from the bottom, for "*diameter*" read "*circumference.*"

We have received a letter from Mr. Peppercorne *on the subject of our review of his pamphlet on the supply of water to the metropolis. He seems entirely to have misunderstood what we said; in mentioning his "temerity" in proposing a plan for filtering Thames water, we only intended to give him an ironical hint that he had, by such proposition, placed himself in the category of those "artful and mischievous persons," who raise doubts as to the purity of Thames water.*

Communications received from Mr. East, Mr. Sheppard, Mr. Neville, Mr. Barrett, *and* B., *will be inserted next month.*

The Drawings of the Bridge over the River Dove, do not enter sufficiently into detail to render them suitable for the Journal.

We shall be happy to receive, from our correspondent at Liverpool, the notice he offers.

We thank Mr. Radford *and* E. *for their attention.*

We continue to receive several communications on the subject of competitions, which would half fill our Journal, and the insertion of them, we are fearful, would not be of much service. The remedy lies with the profession as a body.

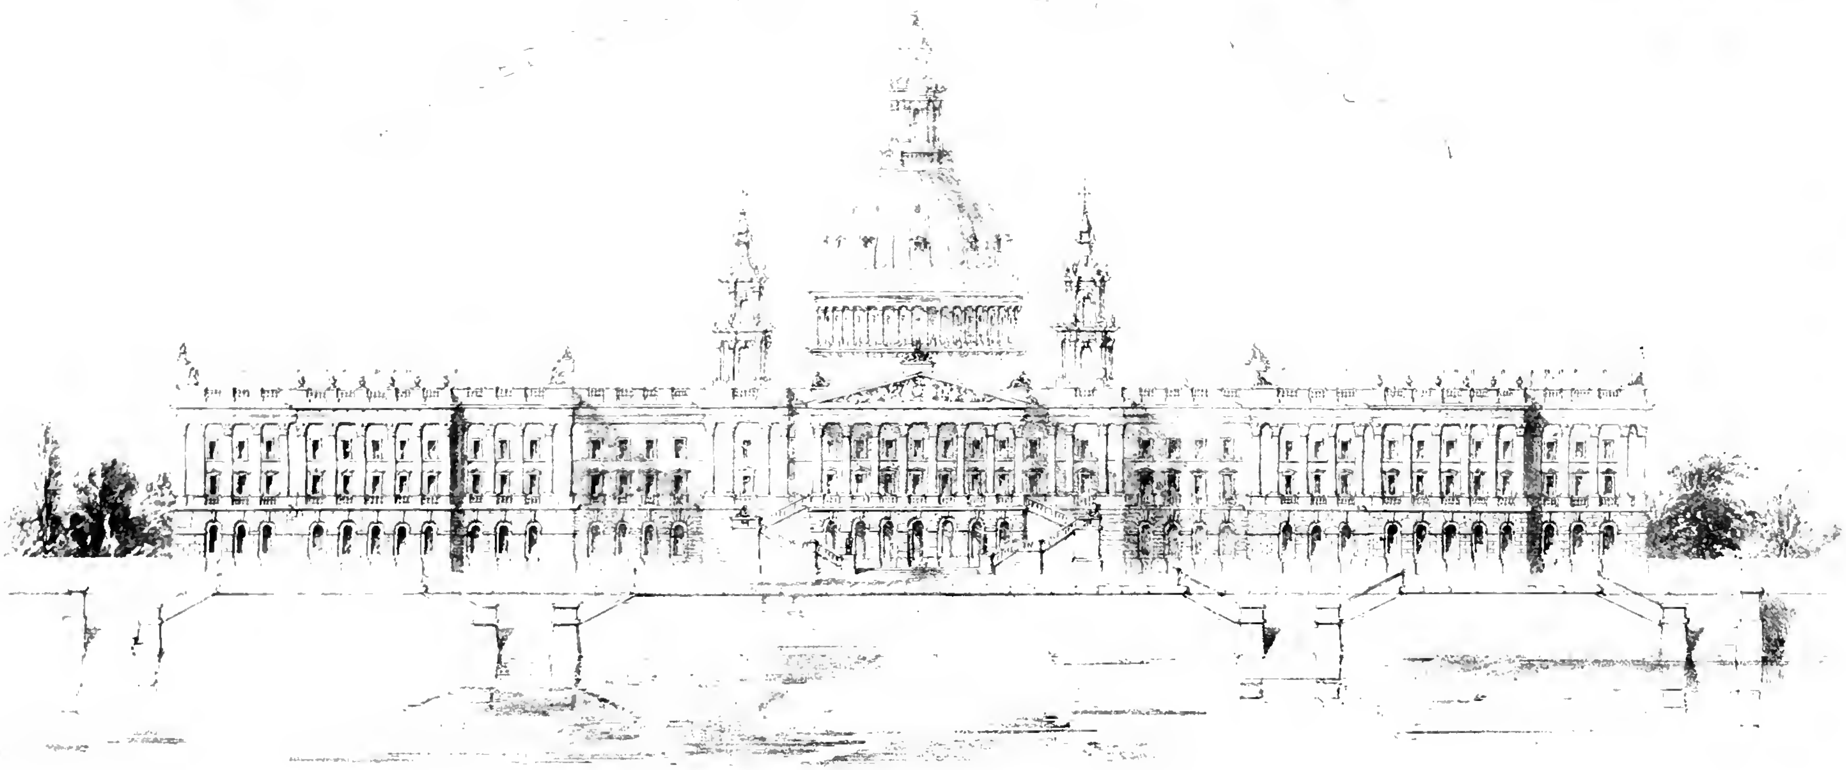
Mr. Phillips *will find an acknowledgment of his communication in last month's Journal; it is unavoidably deferred.*

Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," *No. 11, Parliament Street, Westminster.*

Books for review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

The First Volume may be had, bound in cloth and lettered in gold; Price 17s.

*** The Second Volume may also be had, Price 20s.



PRELIMINARY PROSPECTUS

OF THE

MERCANTILE MARINERS' HOME AND HOSPITAL,

TO BE ERECTED AND PROVIDED FOR, IN THE FIRST INSTANCE, BY A CAPITAL OF FIVE HUNDRED THOUSAND POUNDS.

SUSCEPTIBLE OF A PERPETUAL INCREASE BOTH BY PROPRIETORS AND DONORS, OWNERS AND SAILORS.

SIR,

The great leading objects of this national undertaking are, to provide a *Second Greenwich Hospital* for seamen not in the Royal Service; to erect a species of *Insurance on Life* against Age, Illness, or Accident—to offer an inducement, unparalleled in any other Country, to our Commercial Mariners, not to be tempted to enter into the Service of America or other States, where no such provision is, or can be made for British subjects—and, in an especial degree, to cultivate habits of prudence in those who hitherto have been proverbially imprudent, by offering them, for a very small portion of those earnings, generally sacrificed to intemperance or to trickery, a noble Institution, Food, Clothing, and Lodging, or an adequate Income to enjoy each; and the whole conferred, not as a matter of charity, but as a matter of property, being at once "The Seaman's Refuge and Right."

All these things are of easy accomplishment. The Sailor, should he live to be fifty years of age and have paid his quota of the Insurance, may calculate on receiving at least ten times the value of the amount he has paid, partly by the accumulations of Compound Interest; partly by the deaths of those who pay, but do not live to enjoy; partly by the joint Subscriptions of Owners and Merchants; partly by the Contributions of the Patriotic and Philanthropic, many of whom are ardently disposed to assist the Institution; and, generally, from the nationality of its character and objects.

In addition to these sources of Income and objects of utility, it is contemplated to add to the Profits, and at the same time protect the Mercantile Seaman from those whom he most emphatically and most truly calls "Land Sharks," by uniting the benefits of a Saving Bank and a Loan Institution to the other, and more important, features of the plan.

It is proposed that a large proportion of the original Capital shall be devoted to the erection of the Building, upon some site near the Thames; and that the whole of the proprietary Capital, amounting to £500,000, shall be raised by the sale of terminable annuities for sixty years, at seven per cent. per annum interest, redeemable at the market price, when above par, by the Trustees of the Institution, at their option; and when the whole are redeemed, or have expired, the entire property to belong to British Mercantile Mariners and their successors, as a Home and an Hospital for ever.

It will be necessary in the construction of the building to divide it into classes; hence, under the sanction and superintendence of the ablest and the best practical men, all disorder will be avoided; and station and position in Society will be preserved to meet the views as well as to conduce to the comforts of the occupants.

Parliament will be applied to for an Act, or the Government for a Royal Charter, to limit the responsibility of those who may take Shares as Proprietors. Of course, Bequests, Donations, or Annual Subscriptions, create no risk, and hence require no protection—the latter, it is hoped, will furnish a very large and constantly increasing proportion of the Funds of the Institution, which, in addition to the small payments by the Sailors themselves, who shall, in all cases, have a latitude of at least two years, to make up their deficiencies, will, in time, dispense with the necessity of proprietorship altogether. In the year 1900, if not before, the Institution will belong to the nation.

These general views are thrown out for consideration and advice. The only grand principle which can never be departed from, is, A HOME AND ITS COMFORTS, FOR AGED, DECAYED, OR DISABLED SEAMEN, NOT OTHERWISE PROVIDED FOR. With thankfulness, will any suggestion be received, and with cheerfulness adopted, to alter and amend any part of the plan. Already, individuals of distinction have expressed their determination to support the object by every means in their power. When a sufficient number to form a General Committee, have signified their adhesion to that object, without being expected to adhere to the plan, as sketched out, they will be called together, and asked to elect a Council or Board of Management, from among themselves, of qualified Members. Such Committee and such Council, if entirely approving of each other, but not otherwise, will have their names published. It is hoped that this may be effected during the present Session of Parliament, and nothing but a want of sufficient consideration of its great public and private benefits, can impede or retard its speedy completion.

Every suggestion or adhesion is requested to be made in writing, and will be forthwith acknowledged by,

Sir,

Your most obedient and humble Servant,

W. S. NORTHHOUSE,

Temporary Manager.

At the Office of the Solicitors to the Institution,

Messrs. Wilkinson & Page, *Guildhall Yard, London.*

June 1840.

ELIZABETHAN SHOP FRONT.

CORNER OF OXFORD STREET AND BERNERS STREET.

With an Engraving, Plate XIII.

OUR readers will recollect that last year the decline of the Louis Quatorze style, and approaching rise of the revival was announced in the Journal, and already to a certain extent is this realized, the Louis Quatorze after a long and widely extended rule has already gone to the tomb of its predecessors, and will leave scarcely a wreck behind. Known to us only in one of its very worst forms, that of its decline during the reign of Louis the Fifteenth, it became here the most unmeaning and unintellectual mass of patching and gilding by which the public taste has ever been perverted. Still, such as it was, it was a style harmonizing with itself however low in its degree, and as symmetry even in a morrice or a chimney sweeper's dance will attract the public, we need not wonder that it was so successful, when we have been so often tortured by styles that show no style at all. Perhaps the reign of this trumpery was one of the evils leading to good, one of the accidents in our artistical destiny which is to minister to our future progress, for it may have taught the public a greater feeling for unity of purpose, and may so far have performed a useful duty.

Slowly the revival has entered upon its career, and it is already evident that it is destined to be popular, and to take its place among the passing fashions of the age. We are inclined to view its advent with the greater pleasure as it is at any rate higher in the scale than its predecessor, but we must not be considered as pledging ourselves to an admiration of it per se, or a vindication of it as a paragon of art. We are not so enthusiastic as our French neighbours, nor so much disposed to succumb to the fashion of the hour, we like the revival, not for itself, not even for the good it may do, but as a type of the coming of that better time of art, which is still we fear too distant, we look upon it as one of the sets of artistical dumbells, with which the public taste must be invigorated, rubbishy materials with a tawdry outside, but which still in their exercise fortify our intellectual strength and health. If we thought this style of itself calculated to produce any permanent influence, if we thought it a part of the lesson to be retained in after years, we should be prepared to denounce its errors in all their extent, to expose its meritriciousness, to strip it of its tinsel gewgaws, and to point it out as a stumbling-block to be avoided. For we are convinced that there is nothing more to be dreaded than the system of swimming with corks, particularly if bad ones, for we are sure to cling to their use, or to recur to their aid, when we ought long since to have flung them totally away. The revival has the advantage of its predecessor, that instead of representing foreign and unknown associations, it appeals to those which are common to all count ies and all ranks. It is more intellectual in its scope, is obliged to refer back to higher sources, and requires the exercise of a better class of art, so that if we reap no other fruit, we shall have the advantage in more practised workmen, and in the demand for a greater degree of instruction. The schools of design could never have come at a better time than when their capabilities are likely to be so much called out. So much is the style of revival in advance of English workmen, that when, as we mentioned last year, its introduction was seriously contemplated, it was feared that it would be necessary to import the artisans as well as well as the style. We hope, however, to see a different state of things.

Most of our readers have seen the shop in Regent-street, we have now to call their attention to another in the same style, that of Messrs. Battam, Craske and Coleby, decorators, at the corner of Oxford and Berners-streets, represented in the engraving. As the details are visible in the engraving, we shall merely describe the materials employed, a knowledge of which as a point of economy is most important to our architectural readers. The general ground of the whole including the mezzanine story is of wood, parts of the upper dressings as the trusses and dressings to lights are of cement, and the rest of paste composition. The enrichments of the entablature, mouldings, modillions, block dressings, heads, &c. are in paste; part of the lower dressings in deal, the figures cast in Atkinson's cement. The whole was designed and executed by Messrs. Jackson and Son, of Rathbone-place, and we think will not only get for them present applause, but future patronage, the task was arduous, and as far as they are concerned, they have performed it well. We wish, however, that both here and in Regent-street, the character of the style had been kept up in colour as well as in form, as otherwise our works will be but the mere ghosts of the Parisian style. We hope no fear of the expense will deter tradesmen from having the decorations complete, for we are convinced that they would derive more benefit from a properly finished building than from the dead white phantoms that have been produced. These want all the light and all the life of the style, they want that provocative to luxurious appetite that leads us into the Parisian shop whether we will or not. The shutters are Bunnett and Corpe's patent, and which when down take greatly from the effect, a defect avoided in the original design, which provided embossed, pannelled and moulded shutters in accordance with the general character.

EXHIBITION—ROYAL ACADEMY.

(Concluded from page 222.)

MANY architects seem to entertain as great a horror of exhibition as Bartholomew does of competition, in regard to which he is even rabidly furious. How else happens it, that among the number of designs sent to the Academy, we invariably meet with so exceedingly few which afford us any information as to public buildings and other works that have either been just completed, or are in progress in different parts of the country? Why does not Mr. Pugin, for instance, we ask, exhibit, by way of *contrast*, and for the needful edification of his Protestant brethren in the profession, some of those Catholic chapels "in the purest taste," on which he recently has been, or is now, actually employed?* We miss several things that, if we may trust what we have heard concerning them, we think would have been creditable to their authors, and should have been glad to find here, among others, Mr. Hosking's Egyptian Propylæum to the new cemetery at Abney Park; the Gothic church lately completed by Mr. Basevi, in Hans Place, Sloane Street, the Dorset County Hospital, now erecting after designs by Mr. Ferrey, and the mansion just commenced, we believe, by Mr. Blore, for Lord Francis Egerton, near Manchester; besides many other works which, even if of no particular merit in themselves, would afford information as to what is actually going on, but of which we seldom find more than a very small sprinkling at the Annual Exhibitions of the Academy. Even what subjects of this class we do meet with, are not always the best productions that might have been furnished; many of them, indeed, neither tasteful as designs, nor of interest as representations of buildings of any importance. This remark applies only in part to No. 968, "Entrance Lodge, as erected, West of London and Westminster Cemetery, at Earl's Court, Kensington," B. Baud; for the structure itself is of considerable extent, and of a kind affording scope for design, and for marked expression of character. As it is, it presents only a very tame composition of Roman Doric architecture, which is, besides, altogether marred by being filled in with windows that are equally at variance both with the style indicated by the order, and with what seems suitable for the particular occasion, inasmuch as they too strongly suggest the idea of a mere dwelling, not otherwise distinguished than by having an archway leading through it. For structures of this kind, and also for those intended for railway terminusses, some useful hints and studies, we may observe, are to be found in Sanmicheli's designs, for entrance gates and similar works, demanding mass and solidity, yet not rejecting architectural decoration.

No. 914. "Façade of the Wesleyan Centenary Hall, now building in the city of London," W. T. Pocock, is another drawing that shows a building of some magnitude now in execution. We cannot say that we greatly admire the design, either as we behold it here entire, or judging of it from the building itself, (in Bishopsgate Street,) as far as it is already advanced. On the contrary, we decidedly object to the basement, which has small arches, and is merely scored by a few horizontal stripes—a sort of apology for rustic joints—which produce a most harsh and disagreeable effect, where, instead of radiating towards the centres of the arches, they are cut off by the archivolts of the

---

* We rejoice to have assurance afforded us by the letter from "A Protestant Architect," given at page 228, that the structures alluded to are so creditable to Mr. Pugin's taste and ability; but we think that the writer altogether overlooks a serious difficulty when he says, "it now remains for Protestant architects to display their zeal and their talents in a similar manner"; since neither the one nor the other can avail them much, so long as they are obliged to move in the shackles imposed upon them by the Church Commissioners, and by the pig-headed obstinacy of those who regard all originality of design, any abandonment of the barbarisms and the penuriousness displayed in our churches—of our squeezed up pews and piled up galleries, for the sake of architectural character and effect,—as scandalous and dangerous innovations, savouring of Popery and the Scarlet Lady with the title unmentionable. The regulations enforced by Church Commissioners are of themselves calculated to operate as a "wet blanket" upon all but mere plodders, who may even find their account in the proscription of aught approaching to originality. We fancy it would puzzle Pugin himself to produce much effect, were he similarly circumstanced, unless his ability be such that he could make a Quaker's meeting-house magnificent, without depriving it of its primitive plainness.

latter. We had hoped that the examples revived by Mr. Barry would, by this time, have fairly put every one out of conceit with that equally poor, monotonous, and unmeaning fashion, which certainly is not classical—neither Greek, Roman, nor Italian—nor has it anything whatever in it itself, to reconcile us to it as a desirable innovation. If the upper part of the façade satisfies us very little better, it certainly is not because ornament has been begrudged it, for it has large fluted attached columns, and pilasters of the Corinthian order, between which are two series of decorated windows (five on each floor), besides an attic or podium over the three middle intercolumns, surmounted in turn by a lofty lanthorn or turret copied from the well-known choragic monument of Lysicrates. For what particular purpose this last may be intended, we are wholly at a loss to conjecture, the purpose of the building itself seeming to require no such appendage, while, as regards the design, it might very well be spared, as the façade will be quite lofty enough without it. Of finery, indeed, there is enough and to spare, and we shall. therefore, probably hear the structure spoken of as a fine piece of architecture; but in vain do we look here for originality, for study, or for taste.

We are infinitely better satisfied with No. 924, which shows us—though not to particular advantage, the drawing itself being anything but an attractive one—the "Terminus of the London and Blackwall Railway," which has just been completed by Mr. Tite. It is a pleasing specimen of italian architecture, simple in character, but free from the mock simplicity of poverty and baldness.

Nos. 1000 and 1001, the S.W. and N.W. fronts of "Roehampton Priory, Surrey," with the alterations and additions in progress, from the designs and under the direction of Gough and Roumieu, exhibit a Gothic mansion of considerable extent, to which, we presume, the conservatories are the chief additions: but what may be the other alterations we know not, consequently cannot judge how far they have contributed to improve the building generally.

Though a small sepia drawing, and rather unfavourably hung, No. 983, "Bailiff's Cottage, recently erected at Chequers, Bucks, for Sir R. Frankland Russell, Bt.," E. B. Lamb, possesses great merit as a design, both in regard to character and picturesque effect, for it realizes the ideal of a cottage residence of that kind, and when it comes to be a little mellowed by time, will offer a pleasing study to the artist. We may also express our approbation of Mr. Walker's designs for the New Hospital or Almshouses at Bedworth, of which Nos. 1011 and 1014 afford us two perspective views. And we wish we could say as much in favour of No. 1067, "View of the Casino Promenade Concert Room, à la Musard, about to be erected on the east side of Leicester Square," S. Beazley; but our liking for it is so little, that we trust what the catalogue says will never be verified; or that if any building of the kind is to be erected there at all, it will be something totally different from such a Vauxhallish affair. For aught we know, Mr. Beazley may rival Vanbrugh as a dramatist, but as an architect, we do not think he is *quite* equal to him. In one sense, indeed, his buildings may very well be called *theatrical*, but *scenic*, they most assuredly are not: while in point of taste, they are the very antipodes of those of his predecessors, being as remarkable for flimsiness, as the others are for ponderous solidity.

Though we might point out several other designs, some for censure, and one or two for commendation, we must here conclude our notice of this year's exhibition, and look forward to a better one next season; as we may do with some degree of confidence, unless the present Decline is to terminate in a total Fall of the Academy's Architectural *Room*.

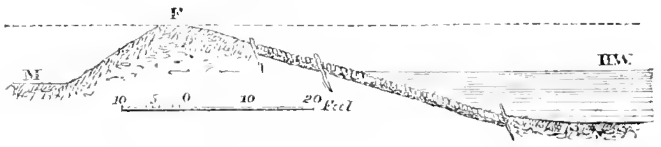
SEA EMBANKMENT.

The work about to be described has lately been executed at the mouth of the Thames, near the entrance to the Medway, in the parish of St. Mary's, for the Right Honourable Lord de Vesci, who has an estate adjoining it.

The land bounding the sea at this place being marsh, and formerly covered with salt water every spring tide, was of very little value till it was embanked, which took place about two centuries back, and said to have been executed by a Dutch engineer, probably Vermuyden, who was in England about that time, having been engaged in similar works, of which was the embanking of the Dagenham marshes on the Essex side of the river, likewise the drainage of Hatfield Chase, near Doncaster, and he was afterwards employed in the Bedford Level. Considerable damage had been done to this wall at different periods, from the prevalence of north easterly winds, which are severely felt on this shore, the violence of the sea washing the stones from the slope and thereby causing breaches in the bank. The old wall was protected with stones and piles, but sufficient care had not been taken in the formation of the bank, otherwise breaches would not have so frequently taken place.

In the formation of the new wall, which is nearly three quarters of a mile in length, the old formed the neclens of the new work, the material for which was got by cutting on the land side a back delph which was kept to a regular section at about four yards from the foot of the back slope. The inclination of the back slope of the wall is $1\frac{3}{4}$ horizontal to 1 perpendicular, and that of the sea slope 4 horizontal to 1 perpendicular; the top of the wall is 3 feet in width, and raised 7 feet above high water of a spring tide, (Trinity datum). The bank was formed in regular courses about 12 inches in thickness, chopped and puddled to form a water-tight body; the face of the sea slope after being sufficiently consolidated, was covered with a thickness of four inches of concrete, and afterwards pitched with Kentish Wrag stone laid by hand, and rammed solid to a regular surface, the depth or thickness of the stone pitching varied from 10 to 12 inches, the stones being placed as closely as possible, and when the stones were not too large, placed with the largest dimension downwards to expose the least surface to the action of the water, and the joints filled in by wedging small pieces of stone into them by hand hammers. The surface of the paving was covered by an inch in thickness of fine gravel, which by the action of the water was washed into the interstices, so that the whole formed a solid and compact mass. From the regular slope of the sea side of this wall, and on account of its gradual rise, the waves meet with no abrupt impediment so injurious in works of this description, but on the contrary, spend themselves in running up the slope, thereby much lessening the effect of the concussion. The face of the sea slope above the stone pitching, and likewise the top of the wall was covered with a thickness of sand and shells, thus forming a footpath and preventing the heat of the sun from injuring the bank: the back or land slope was also properly trimmed and soiled or sown with grass seed.

The foot of the pitching is protected by a row of piling or stakes driven 6 to 7 feet into the ground, and 3 to 4 inches apart; and likewise protected on the sea side by a footing of stone and chalk, the refuse of the old wall, which has embedded itself in the foreshore, and thus forms quite a compact mass. There are also two rows of similar stake piling driven into the bank at the top of the slope, for the protection of the stone pitching; the following section will more fully explain the nature of the work.



M, marsh. F, footpath. H. W., high water Trinity Standard.

The novelty in the work is the introduction of concrete between the stone pitching and the clay substratum, by which the water is prevented soaking into the clay, and so wearing it away, and depriving the pitching of its support, from whence hollows necessarily arise, and shortly patches of stone pitching are removed by this gradual but sure process. In the event likewise of stones being displaced, the concrete prevents the evil spreading, forming itself a protection until the pitching be restored.

Breakwaters of stone encompassed with piling are constructed at the two most prominent points, to protect the wall from the sea during north-east gales, and likewise to encourage the accumulation of sand along the foot of the wall.

The work has been executed by Mr. Rowland, the contractor, of Strood, under the direction of Messrs. Walker and Burges; it was commenced during the latter end of 1838, and has been in progress with the exception of the winter months, till last April, when it was completed, so that during the greater part of that time, a principal portion of the work has been put to a fair trial.

GLASS PAINTING.

Sir—In consequence of the receipt of several letters since the publication of the brief remarks on the above subject, which appeared in the last number of your Journal, I am induced to mention, that I fully intend when leisure affords an opportunity, to endeavour to make that notice more complete, and that I shall be very glad therefore, to receive information concerning *any* glass-painter now, or lately practising in England,—his peculiarities, a list of his principal works, &c.

I am, Sir, your's,

Pelham Crescent, Brompton. Geo. Godwin, Jun.

REPORT ON THE HARBOURS OF THE SOUTH EASTERN COAST.

We should have liked to have gone at some length into this report, but other matter, we cannot say more important, has prevented us. We may briefly characterize it as destitute of all principle, first proposing one principle, then another, then contradicting both, and but ill calculated to give satisfaction to the public or to men of science. Upon none of the great physical questions, the operations of which upon this coast have been the subject of so much controversy, does it give any elucidation, indeed it does not enter upon them. With regard to the numerous plans suggested for making harbours on these coasts, many of them ingenious, some good, and all entitled to attention, the commissioners pass them over with silent contempt.

Just to show the blowing hot and cold system which characterizes the proceedings of the commissioners with regard to the great principles at issue, we shall call attention to the following extracts from the last number of the Journal.

Margate.—"The power of sluicing at so great a distance as that proposed in this plan, could only be applied with advantage to a surface dry, or nearly so, at low water; and the idea of keeping a deep-water harbour of any useful width, clear by means of such sluicing, appears to us to be impracticable."

Ramsgate.—"There is no natural backwater so essential for the purpose of scouring."

Deal and Sandwich.—"The shingle is continually moving by the action of the waves, in the direction of the prevailing winds."

Dover.—"It should be observed that these sluices, though efficacious to a certain extent, are not capable of removing the obstruction altogether. The force of the water, which at its exit from the culverts is very great, loses its impetus as it spreads over a larger surface, and forces the shingle to a comparatively small distance, where it is liable to form banks beyond the power of the sluices."

Folkstone.—"A small stream is pent up at the north-west side of the harbour, for the purpose of scouring at low water; and with the assistance of manual labour, in addition to this very inadequate backwater, the channel is kept open so as to allow vessels of 10 to 12 feet draught to come alongside of the main pier at the top of high water." "In our opinion no scouring power would be able to keep the channels clear below the level of low water." "Constant motion of shingle."

Rye.—"Shingle accumulated by winds." "Powerful backwater thereby acquired, operated as a scour during the ebb, to clear the channel and keep the entrance open."

Hastings.—"There is no natural backwater, nor the facility of making an artificial one to any useful extent."

Newhaven.—"The river affords a powerful backwater for scouring the entrance."

Shoreham.—"A bar rises occasionally above the low water level, and shifts its position from 60 to 160 feet from the pier-heads."

Littlehampton.—"The backwater not enough."

These are *materials for thinking*, and we have no doubt will create some excitement among the advocates and opposers of backwater. We shall show, on a subsequent occasion, how beautifully this independence of attachment to principles is preserved in the plans of the commissioners themselves.

RETORT UPON RETORT.

Sir—Having myself animadverted in the first instance upon what Mr. Bartholomew had said of the new façade of the College of Surgeons, Lincoln's Inn Fields, which he is pleased to call both "ill-favoured" in itself, and not merely a cracking but "a *creaking* mass of fracture,"—it would ill-become me to complain of his animadverting upon me in return, in the preface to his "Specifications;" where he has introduced a long note, in which he says: "Mr. Leeds having with some coarseness of diction chosen to go out of his way in his '*Essay on Modern English Architecture*,' to comment upon my supposed admiration of the former façade of the College of Surgeons, I here tell him, that in this place as elsewhere, his quotations whether of the sense or words, are not accurate. I have put forth no such sentiment either by word or implication. I admired its portico as formerly existing, &c., &c."

Not being able at this moment to refer to the passage in question, I cannot pretend to be certain as to the precise words, yet whether so intended or not, the impression it left upon me was that Mr. Bartholomew considered the building to be altered greatly for the worse. That he admired the portico as formerly existing, the words I have quoted sufficiently prove; nor do I dispute his right to admire, more especially as there is scarcely any production of the present day which his taste will permit him to admire at all. He is now, it seems, however anxious to have it understood that he confined his admiration exclusively to the portico, by which I suppose he means merely the columns, for all that was behind them was most barbarous in design. But then by not protesting against the deformity of the other parts, and by again expressing his approbation of a portico, the interior of which was most detestable, he certainly does leave it to be inferred that he was not at all shocked at the architectural incongruities it presented. Very possibly he may have regarded with profound contempt and abhorrence all but the mere columns; still as he did not chose to make that clear to his readers, he ought not now to complain if he has been misunderstood, and his real meaning misrepresented.

With regard to the coarseness of diction which he lays to my charge, I allow that my expressions may have seemed coarse to one who is so guarded and refined in his own language, as to speak of modern architecture as being no better than a "fraudulent, pickpocket system," and of those who practice it, as ignorant pretenders and quacks, utterly ignorant of scientific principles of construction. The horrible coarseness of which I was guilty consisted in remarking: "after this, should any one obtain that writer's approbation or good words, he will have reason to consider it a most unfortunate symptom, and to take himself to task very strictly in order to ascertain what can have excited such ominous sympathy:" which no doubt sounds bearishly rude and indelicate to "ears polite," and in comparison with the delicate and dulcet, Mr. Bartholomew himself invariably employs.

Though he has done me the honour to single out myself, he might find, did he care to look about, other critics and other publications which have treated him with as little ceremony as he himself has treated his own brother-architects. By no means therefore am I a solitary offender; on the contrary, there are others still more *coarsely* blunt, and—what is perhaps worse, some who are still more keen.

W. H. L.

CLEGG AND SAMUDA'S ATMOSPHERIC RAILWAY.

With an Engraving, Plate XIV.

In our last number we gave some particulars regarding the first experiment, made on the Atmospheric Railway; we are now enabled through the kindness of the inventors to give drawings and descriptions of the railway and apparatus, together with some calculations.

In Clegg and Samuda's Atmospheric Railway, the power employed is the pressure of the atmosphere, brought into action by exhaustion. By reference to the plate, the following description of the apparatus will be rendered more clear:—

Fig. 1, is a general elevation of the railway, with a train of carriages passing over it.

Fig. 2, is a plan of the railway, with the upper surface of the pipe, at the part containing the entrance separating valve, removed to show its construction.

Fig. 3, is a longitudinal section of the railway, taken at the dotted line *m m* fig. 4, showing the connection between the piston and the train carriage and the method of lifting the continuous valve.

Fig. 4, is a transverse section of the same.

Fig. 5, is a transverse section of the pipe on an enlarged scale, showing the continuous valve and cover, and also the heater N, in dotted lines.

Fig. 6, a plan of the continuous valve on an enlarged scale.

The moving power is communicated to the train through a continuous pipe or main, A, laid between the rails, which is exhausted by air pumps worked by stationary steam engines, fixed on the road side, the distance between them varying from one to three miles, according to the nature and traffic of the road. A piston, B, which is introduced into this pipe, is attached to the leading carriage in each train, through a lateral opening, and is made to travel forward by means of the exhaustion created in front of it. The continuous pipe is fixed between the rails and bolted to the sleepers which carry them; the inside of the tube is unbored, but lined or coated with tallow $\frac{1}{10}$th of an inch thick, to equalize the surface and prevent any unnecessary friction from the passage of the travelling piston through it. Along the upper surface of the pipe is a continuous slit or groove about two inches wide. This groove is covered by a valve, G, extending the whole length of the railway, formed of a strip of leather rivetted between iron plates, as shown at fig. 5, the top plates being wider than the groove and serving to prevent the external air forcing the leather into the pipe when the vacuum is formed within it; and the lower plates fitting into the groove when the valve is shut, makes up the circle of the pipe, and prevents the air from passing the piston; one edge of this valve is securely held down by iron bars, No. 2, (fig. 5), fastened by screw bolts, No. 4, to a longitudinal rib cast on the pipe, and allows the leather between the plates and the bar to act as a hinge, similar to a common pump valve; the other edge of the valve falls into a groove which contains a composition of beeswax and tallow: this composition is solid at the temperature of the atmosphere, and becomes fluid when heated a few degrees above it. Over this valve is a protecting cover, I, which serves to preserve it from snow or rain, formed of thin plates of iron about five feet long hinged with leather, and the end of each plate underlaps the next in the direction of the piston's motion, thus ensuring the lifting of each in succession. To the underside of the first carriage in each train is attached the piston, B, and its appurtenances; a rod passing horizontally from the piston is attached to a connecting arm, C, about six feet behind the piston. This connecting arm passes through the continuous groove in the pipe, and being fixed to the carriage, imparts motion to the train as the tube becomes exhausted: to the piston rod are also attached four steel wheels, H H, (two in advance and two behind the connecting arm,) which serve to lift the valve, and form a space for the passage of the connecting arm, and also for the admission of air to the back of the piston; another steel wheel, D, is attached to the carriage, regulated by a spring, which serves to ensure the perfect closing of the valve, by running over the top plates immediately after the arm has passed. A copper tube or heater, X, about ten feet long, constantly kept hot by a small stove, Z, also fixed to the under side of the carriage, passes over and melts the surface of the composition (which has been broken by lifting the valve,) which upon cooling becomes solid, and hermetically seals the valve. Thus each train in passing leaves the pipe in a fit state to receive the next train.

The continuous pipe is divided into suitable sections (according to the respective distance of the fixed steam engines) by separating valves, *f* and Q, which are opened by the train as it goes along: these valves are so constructed that no stoppage or diminution of speed is necessary in passing from one section to another. The exit separating valve, Q, or that at the end of the section nearest to its steam engine, is opened by the compression of air in front of the piston, which necessarily takes place after it has passed the branch which communicates with the air-pump; the entrance separating valve, *f*, (that near the commencement of the next section of pipe,) is an equilibrium or balance valve, and opens immediately the piston has entered the pipe. The main pipe is put together with deep socket joints, in each of which an annular space is left about the middle of the packing, and filled with a semi-fluid: thus any possible leakage of air into the pipe is prevented.

From the result of the experiments already made, the inventors calculate that a main pipe of eighteen inches diameter will be sufficiently large for a traffic of 5,000 tons per day, viz., 2,500 tons in each direction, supposing the gradients of the road to average 1 in 100.

Note.—A main pipe, 18 inches diameter, will contain a piston of 254 inches area: the usual pressure on this piston, produced by exhausting the pipe, should be 8 lb. per square inch (as this is the most economical degree of vacuum to work at, and a large margin is left for obtaining higher vacuums to draw trains heavier than usual on emergencies)—a tractive force of 2,032 pounds is thus obtained, which will draw a train weighing 45 tons, at 30 miles per hour up an incline rising 1 in 100. Two and a half miles of this pipe will contain 23,324 cubic feet of air, $\frac{16}{30}$ of which, or 12,439 cubic feet, must be pumped out to effect a vacuum equal to 8 lb. per square inch; the air pump for this purpose should be 5 feet 7 in. diameter, or 24·7 feet area, and its piston should move through 220 feet per minute, thus discharging at the rate of $24{\cdot}7 \times 220 = 5{,}434$ cubic feet per minute at first, and at the rate of 2,536 cubic feet per minute when the vacuum has advanced to 16 inches mercury, or 8 lb. per square inch, the mean quantity discharged being thus 3,985 feet per minute; therefore $\frac{12439}{3985} = 3{\cdot}1$ minutes, the time required to exhaust the pipe; and as the area of the pump piston is 14 times as great as that in the pipe, so the velocity of the latter will be 14 times as great as that of the former, or 220 feet per minute × 14 = 3,080 feet per minute, or 35 miles per hour: but in consequence of the imperfect action of an air-pump, slight leakages, &c., this velocity will be reduced to 30 miles per hour, and the time requisite to make the vacuum increased to 4 minutes: the train will thus move over the $2\frac{1}{2}$ miles section in 5 minutes, and it can be prepared for the next train in 4 minutes more, together 9 minutes; 15 minutes is therefore ample time to allow between each train, and supposing the working day to consist of 14 hours, 56 trains can be started in each direction or 2,520 tons, making a total of 5,000 tons per day. The fixed engine to perform this duty will be 110 horses power, equivalent to 22 horses power per mile in each direction.

The next item to be considered is the comparative cost of the two systems.

1st. The necessity of having the railway comparatively level, causes the present enormous outlay for earth-work, viaducts and tunnelling: it also increases the cost of land, not only by lengthening the line to save cutting and embankment, by the quantity wasted on each side of the road wherever an embankment or cutting is required. Thus if an embankment or cutting has to be made of thirty feet, at least sixty feet of land must be covered on each side of the railway in order to obtain sufficient slope, making a width of 120 feet, besides the road, except where they occur in stone or chalk. The comparative expense of this item between the two systems can be ascertained by referring to the average cost of forming a turnpike road and that of the principal railways now in operation.*

LOCOMOTIVE SYSTEM.

	Per mile.
Taking five of the principal Railroads as the basis of the calculation, their average expense of formation has exceeded	£36,000
And the original stock of Locomotives	1,600
	£37,600

ATMOSPHERIC SYSTEM.

	Per mile.
The average expense of forming a turnpike road throughout England has been 3,000 per mile, but for the atmospheric railroad, say	£4,000
Allow extra for road-bridges	2,000
Rails, chairs, sleepers, and laying down	2,500
Main pipe and apparatus complete (on a scale for transporting 360 tons per hour, or 5,000 tons per day of fourteen hours, on a road with gradients of 1 in 100)	5,200
Fixed engines, air pumps, and engine-houses	1,400
Travelling pistons	20
	£15,120
Saving per mile in forming and furnishing on the Atmospheric system	22,480
	£37,600

Annual expenses of working per mile, when conveying *two thousand tons* per day. (This is beyond the average quantity conveyed on the Liverpool and Manchester Railroad):—

LOCOMOTIVE SYSTEM.

	Per mile.
5 per cent. interest on capital sunk £37,600	£1,880
Maintenance of way	450
Locomotive department, including coke	1,800
	£4,130

ATMOSPHERIC SYSTEM.

	Per mile.
5 per cent. interest on capital sunk, viz., £15,120....	£756
Maintenance of way, and attendance on mains	300
Wear and tear of fixed engines, 5 per cent. of cost	70
Coal ·75 lb. per ton per mile, 214 tons, at 20*s*.	214
Wages to engine men and stokers	60
Wages to train conductors	26
Renewal of travelling apparatus and composition, and sundries	200
	£1,626
Annual saving per mile on the Atmospheric system	2,504
	£4,130

Total expenses per ton per mile on the Locomotive system 1·54 pence.
Ditto ditto ditto on the Atmospheric ditto 0·6 do.
Exclusive of carriages and management, which may be taken as the same on both systems.

From the above description, and the calculations made by the ingenious inventors, together with the success of the experiments which have been made, almost daily, for the last month, our readers will be able to form some judgment as to the probable introduction of this new system into general use; we sincerely hope that the inventors will be able to obtain an ample reward for the great expence and labour they have devoted to the first experiment, which has, to say the least of it, been carried out by them in a very spirited manner.

* The calculations are founded on the reports of different companies whose railways are complete or in a forward state.

CORRECTION—CANDIDUS.

ALLOW me, Sir, to correct an error in Fasciculus, No. 16, by your Correspondent Candidus, in last month's Journal, he there states that the Medal was given by the Institute to the late Sir J. Soane. The Medal was by public subscription, as doubtless you remember.

AN ESSAY ON ORIGINAL COMPOSITION IN ARCHITECTURE, AS ILLUSTRATED IN THE WORKS OF SIR JOHN VANBURGH.

By James Thomson, Fellow.

(Read at the Royal Institute of British Architects.)

Sir,

I should feel bound to apologize for submitting any observations of mine to your notice, had they not been written in compliance with that general request which the council have made from time to time to every member of the Institute, viz., that each should in his turn contribute (though it be but a grain of information) touching the art which it is our business, and our pleasure, to pursue.

From the time that I have been able to trace the relation of cause and effect in architectural composition, it has appeared to me that "there is more in it, than is commonly dreamed of, in our philosophy"; or if dreamed of, that we want more general interpreters; not so much for the instruction of the professional student, or practitioner, as for the public mind, so that it may be known to all the world, in very deed and truth, to be a fine and liberal art. To be an art, on the one hand, dependant upon the observance of fixed principles, however variable the practice that arises out of them; and on the other, to inculcate a right apprehension of the impossibility to produce a work of any lively interest by mere attention to what are termed "the rules of architecture."

These rules in architecture I consider to stand in the place of grammar in a language, the due observance of which is as necessary to the one as the other.

We know very well that an author, to be lucid and comprehensive, must duly attend to all the relations of words and sentences, and that, without it, the most vigorous imagination will produce but a jargon of execrable nonsense; but on the other hand, I am sure you will agree that the utmost attention to the arrangement of thesis and antithesis, of versification or prose, (where the master mind is wanting,) will fail to realize a work of importance, even though the theme be one, of which but the mention, would awaken the liveliest anticipations. Just so in architecture, be the subject great or humble—the rules of composition must be duly observed to avoid incongruity, although they should but subserve to the development of works designed to possess contemplative interest.

And respecting this grammar of architecture, I would here observe that, except for Roman or Italian structures, we possess at present scarce any grammar at all! in those styles we have, from Vitruvius down to Chambers, so much to guide us in proportion and detail, that it is scarcely possible to err in them: but although we have *examples*, many, and valuable, in Greek and Gothic architecture, we have hardly any *principles*, set forth respecting them, to say nothing of Egyptian, Hindoo, and other Eastern styles, which, though they be but as dead languages to us, yet possess, like their language, deep soundings of the principles of art and science.

Now when we consider by what different means the end has been accomplished of giving importance and beauty to public and private erections, each amenable to certain laws that belong, not to an arbitrary set of forms and features, but to the workings of the human mind to which they have corresponding influence, I submit that it is to these laws that we should give peculiar attention, calculated as they are to guide, but not to fetter, the free will of the architect. For instance: in the ponderous masses of the Hindoo and Egyptian, the mind rests as complacently as on those of other climes; it is addressed and responded to in a particular way;—in the grace and simplicity of the Greeks, it is captivated in another;—in the harmonious combination of the Italians, it is equally (though differently) charmed and delighted: and so of the rest.

It is then I would submit the object of the architect, in an abstract sense, so to combine the masses and subdivisions of a building as to address themselves not merely to the eye, but to the imagination—that the subject, be what it may, shall vibrate some string of the mental frame as distinctly and tangibly as poetry or painting.

On this account it has appeared to me that it would be highly valuable, if we had set forth some chart of the vast region which lies before us, and which, if not sufficiently detailed to point out all that could be done, might indicate with sufficient precision, the rocks of offence to be avoided.

Thus it is obvious that a *Theatre*, and a *Mausoleum* should be very differently treated, even though they were to be in the same style of architecture—that the one could scarcely be too lively in its general character, and the other scarcely too broad and simple. That in the former every animation that form and colour combined could produce might be adopted,—while in the latter that simplicity and repose should prevail, so as to prepare the mind for the not less pleasing sympathies, which commonly associate themselves with the memorials of departed worth.

Again, it must be evident that a *Temple* for public worship should maintain a very different character to that of an *Exchange*, or hall of commercial festivity, and that apart from the mere internal fittings, it should outwardly bear some evidence of the purposes to which it is devoted.

Yet so little has this been attended to, that without particularizing any, I am sure it will occur to most whom I have the honour to address, that there are instances of which, if we had no previous knowledge, we could not possibly divine for what purpose they were erected. So far as to character of buildings, according with their objects. But now with reference to *style*.

I think Sir, it is to be lamented that we have at this period no *prevailing style* by which buildings of the present age, will be able in after times to be identified, and that in but few of them does there appear any recognition of the leading principles which seem to have governed the ancients. There is, in our own day a continual struggle in the adaptations of features at variance with the main object. The private individual demands novelty, and the judgment of the architect is too often called upon to bend to, instead of directing the work, from this—confusion has resulted in the public mind as to what is good or bad; and to this confusion I would ascribe the indifference which, it is to be regretted, has superinduced on the subject.

Thus we have at one and the same period of time, springing up in all quarters, and frequently in the same quarter, buildings of every era and of every style on the globe. So that they will with respect to date completely "puzzle posterity."

I do not of course include in my observations those restorations or rebuilding of ancient structures, by which are preserved for after ages the examples we ourselves so greatly admire, and with the perpetuation of which it must be a proud event to any architect to connect his name. I mean simply to allude to the practice we have of building in ancient styles for modern objects. And Sir, I would ask why should this be the case? seeing it is fraught with inconvenience at the present—confusion hereafter—and at variance with good taste at all times. It cannot be said that we have no other means, for we have seen that the means are so various, it would be only difficult to fix their limit, and as it was eloquently expressed, by a distinguished individual, not long since on the subject of general design—"Sources that can never be exhausted while the mind of man can conceive, or the hand transfix and embody the conceptions of the mind."

In the east we have characters so expressive that there is no possibility of mistaking their origin or their application. The solemn dignity of the Egyptian temples, pyramids, and obelisks, are totally different from those of the Hindoo, although both possess great boldness of outline and massive proportions. The prevalence of the pyre-like forms in the one, and the square or cubical parts of the other, produce in the mind varying though equally imposing effects.

So in the south—the simplicity and grace of the Greek temples, composed of columns and entablatures, totally distinct from the eastern, affect us by their peculiar and harmonious proportions.

Again, the Romans, borrowing it is true, the column and entablature of the Greeks, yet so resolved them into other proportions (making the front as well as the whole partake of the change), that by another avenue to the human mind, they yield to the imagination another, and a new delight.

They reduced the diameter of the columns and depth of entablature, widened the intercolumniations, and divided their buildings into separate stories; adapting them to the habits and pursuits of another people and another age. They retained the continuous and horizontal lines of the Greeks, but they traversed them by vertical ones, and by the introduction of the arch, they wove us in the loom of science a new and beautiful fabric.

Now let us consider another class of architecture, in which neither the pyramidal form of the Egyptians, nor the massive pillars of Hindoostan, nor the column and entablature of the Greeks, nor the arch of the Romans are at all, or materially discernible, yet while it adapts itself to almost every occupation of life, is calculated to affect the mind perhaps more deeply than all the rest.

I need hardly say to *you*, gentlemen, that I allude to Gothic architecture; or even to the non-professional to do more than mention it, but there springs up at once from the recesses of the memory the most vivid impressions of its venerable features. Of clustered pillars and intersecting arches, giving a kind of endless perspective to the nave and aisle of our cathedrals, and cloisters of our colleges.

Of capitals that appear to flourish with the more luxuriance because freed from the trammels of attic stringing.

Of spires and pinnacles, studded with crotchets, that by their gradual diminution seem to elude the sight.

Of massive buttresses that like giant champions arrange themselves with sturdy strength to protect the pile from the assaults of time or elemental strife.

And of windows. Oh! did we ever have windows before? Loopholes indeed we had, and an admirable frame-work surrounded them; but the windows of Gothic structures are high and wide enough to be supposed of diviner origin, designed to let in, and to diffuse the rays of heaven.

But then again, let us dwell for a moment on the "ever varying, ever new" changes which have been rung on this style, in the production of the Tudor arch as distinguished from the pointed, and both in their difference from the Saxon; let us also notice what appropriate "keeping" (as painters would term it) attended these different changes in the details of mouldings and enrichments; how abrupt and bold are the lozenge, zig-zag, and chevron, as the style to which they belong, and how flowing and graceful is the tracery of the apertures, canopied niches, and finials of the others.

But, Sir, I come now to speak more particularly to the subject which has induced these prefatory remarks, necessary, they appeared to me to be, though possibly too lengthy to you, they have been made in the attempt to show that in availing ourselves of the productions of art from the earliest times to the present, and of all countries; we should duly and carefully *Anglicize* the materials we so obtain, and that we should indeed make them *our own*, not by the mere plagiary of the works of our predecessors, whereby we abuse the talents which they have bequeathed us in adapting them to purpose for which they have no affinity! but that we should so study and trace the principles which guided them, as to work out, a legitimate and definite style for ourselves. In illustration of these remarks I purpose as a noble example to consider the peculiar style and character of Sir John Vanburgh.

I believe, Sir, I shall not be saying too much when I assert that he studied the characteristics of architecture of the whole eastern hemisphere, and that while his resources extended from the Nile to the Netherlands, he followed not any beaten track, but struck out for himself a new style and character of building which he not only adapted to the habits of English life, but so grouped the *subordinate* with the *stately* features—that as examples of domestic architecture he has produced some of the noblest piles of which our country can boast. To examine this style, to analyze its principles, is my present object, not, be it remarked for the purpose of recommending its adoption, no, but for that of illustrating the course which in my humble opinion he has shown us we should pursue. And which those who have had the gift and perseverance to pursue have invariably made for themselves a fame which (during life indeed) may be unattended with any corresponding celebrity; but to whose productions after ages will refer (as in our days the more ancient are), for the guidance of the student and admiration of the world.

I had intended here to allude to the works of some of the architects of our own day, as possessing more decided originality than most of us can lay claim to, but as this might seem adulatory on the one hand, and invidious on the other, I prefer to avoid it.

And now to come more closely to the style of Sir John Vanburgh. I have chosen the princely mansions of Blenheim and Castle Howard.

And first of Blenheim. It certainly is not Roman, though it has much affinity to Roman, but the intercolumniations are too close and divide the masses into proportions not often recognizable in the works of the Italian architects, besides which there is less variety and subdivisions of detail; it is therefore not strictly Roman.

It certainly is not Grecian. Yet how few compositions are there professing to be Greek which retains such continuity of line and quantity. The superior cornices range with each other, and the inferior are made to follow as a string course which binds the whole, simply and compactly together—still it is not Grecian.

It certainly is not Gothic, but it possesses (I submit) many of the qualities of Gothic—the frequency of the pillars and piers, break up the horizontal lines, not as in the Italian buildings where pillars are used with entablatures breaking round them, but continuing up and surmounting them with terminal-like decorations.

I might go further and allude to that other Italian style,—to the consideration of which the Institute was lately called by a paper favoured them by Sir Gardnor Wilkinson; one, that for the matter it contained, and the discussion it produced amongst the senior members as to its origin, was perhaps one of the most interesting of the present session. Here, however, was another style differing not in mere details, but in the main principles of compositions.

A broad and simple façade, unbroken by proportions either as to plan or decoration. A total absence of columns as a part of the superior building, but used subordinately for the decorations of the apertures—these apertures placed one above another in perpendicular lines by their uniform size preserved also the horizontal ones. And at the summit a *cornice* that for boldness of outline and richness of detail, casts into utter insignificance all former pretensions to it. And while it *really protects*, most *magnificently adorns*.

But even these, or all these, did not lead captive, they but excited the energies of Sir John Vanburgh.

Secondly, of Castle Howard.*

Now I think it is universally agreed that there is about this façade something strikingly simple, majestic, and harmonious, and as I have before said of Blenheim, neither Roman, Greek, or Gothic, yet possessing much of the characteristic of each.

The great excellence, however, which belongs to it is, that while all these styles are as I have said to be recognized, they are not crudely combined, but while the principles of each appear to have been fully perceived and understood by Sir John Vanburgh, he suffered them to pass as it were through the alembic of his mind, and bring into existence *a new combination*.

I have said, it is not Roman, though it possess Roman features—its moldings, its arches, are certainly of Roman origin, but with what simplicity are they here arranged.

If you compare it with the earlier or later masters of the Italian school, you will find that where the column and pilaster were introduced as parts of the main building, they were broken and unequal in their parts. That Palladio himself in most instances divided the height of the building into separate stories; piling up order above order; but with a felicity (it is true) that has ever since, and ever will command universal praise. Such also is the case with the palaces and basilica of Scammozi and San Michell as seen at Verona, Vicenza, and Venice.

They are all, or nearly so, divided into separate stories, which at once involves a distribution of other parts, essentially differing from the practice afterwards pursued by Sir John Vanburgh.

Neither does the colossal aspect of these buildings depend upon their size. They arise as I have before intimated, but in other words, upon that philosophical arrangement of *substance* and *void*, of *ordinate* and *subordinate* parts, that while each possesses its due interest, it becomes but an integral part of a sublime and beautiful whole.

Thus then did Sir John Vanburgh proceed—in the grand features, borrowing simplicity and breadth from the practice pursued from the Greeks, and, in the details, from the more tractable forms of Italian art he produced those stupendous works which are now visited and admired by persons of every rank and degree.

The rude and uncultivated mind finds something, (it knows not what), which impresses a kind of awe, while the poet and the painter, whose occupation and aim it is, to engage our finer sympathies, each have the principles of their own art expressed in another way.

Gentlemen, I have thus endeavoured to point out the principles of architectural composition as illustrated in the works of Sir John Vanburgh.

That it might have been much better done, I am fully aware; but inasmuch as the ground has not to my knowledge been trodden before,—inasmuch as that I could find no published work to assist me,—inasmuch as our Institute has been founded not only for imparting statistical information, but for the mutual interchange of professional thought and sentiment. I have ventured to offer you mine on this subject.

And as men commonly make an exchange *to benefit themselves*, I shall hope and trust some abler hand than mine may be induced to dilate upon it, more equal to its merit, so that from this small beginning now, we may all at a future period reap a *sterling, and lasting advantage*.

James Thomson.

June, 1840.

* Here were exhibited by Mr. Thompson the series of drawings illustrative of the subject of his essay, engravings of which we are sorry to omit, but have been obliged to do so on account of their extent, and the prescribed limits of our Journal.—Ed. C. E. & A. Jour.

Antiquity of Railways and Gas.—Railways were used in Northumberland in 1633, and Lord Keeper North mentions them in 1671 in his journey to this country. A Mr. Spedding, coal agent to Lord Lonsdale, at Whitehaven, in 1765, had the gas from his Lordship's coal-pits conveyed by pipes into his office, for the purpose of lighting it, and proposed to the magistrates of Whitehaven to convey the gas by pipes through the streets to light the town, which they refused.—*Carlisle Journal.*

PUBLIC BUILDINGS IN LONDON.

A Critical Review of the Public Buildings, Statues and Ornaments in and about London and Westminster—1734.

By Ralph.

(Continued from page 228.)

From the terrace of Lincoln's Inn Gardens, we have a prospect of one of the largest squares in Europe: it was originally laid out by the masterly hand of Inigo Jones, and intended to have been built all in the same stile and taste: but by the miscarriage of this, and many other such noble designs, there is too much reason to believe that England will never be able to produce people of taste enough to be of the same mind, or unite their sentiments for the public ornament and reputation. Several of the original houses still remain to be a reproach to the rest, and I wish the disadvantageous comparison had been a warning to others to have avoided the like mistake.

Great Queen Street is another instance of our national want of taste; on one side is a row of houses that Italy itself would not be ashamed of; on the other, all the variety of deformations that could be contrived as a foil to beauty, and the opposite of taste.

Covent Garden would have been, beyond dispute, one of the finest squares in the universe, if finished on the plan that Inigo Jones first designed for it; but even this was neglected too, and if he deserves the praise of the design, we very justly incur the censure for wanting spirit to put it in execution. The piazza is grand and noble, and the superstructure it supports, light and elegant.

The church here is, without a rival, one of the most perfect pieces of architecture that the art of man can produce; nothing can possibly be imagined more simple, and yet magnificence itself can hardly give greater pleasure: this is a strong proof of the force of harmony and proportion, and at the same time a demonstration that it is taste, and not expence which is the parent of beauty: if this building can be said to have any defect, it is in the form and manner of the windows, which are not only in a bad gusto, but out of proportion too.

Leicester Square has nothing remarkable in it, but the inclosure in the middle, which alone affords the inhabitants round about it something like the prospect of a garden, and preserves it from the rudeness of the populace too.

The portico to St. Martin's Church is at once elegant and august, and the steeple above it ought to be considered as one of the most tolerable in town; if the steps arising from the street to the front could have been made regular, and on a line from end to end, it would have given it a very considerable grace; but as the situation of the ground would not allow it, this is to be esteemed rather a misfortune than a fault. The round columns, at each angle of the church, are very well conceived, and have a very fine effect in the profile of the building; the east end is remarkably elegant, and very justly challenges a particular applause. In short, if there is any thing wanting in this fabric, it is a little more elevation, which I presume is apparently wanted within, and would create an additional beauty without. I cannot help thinking, too, that, in complaisance to the galleries, the architect has reversed the order of the windows, it being always usual to have the large ones nearest the eye, and the small by way of attic story on the top.

St. James's Square has an appearance of grandeur superior to any other plan in town, and yet there is not any one elegant house in it, and the side next Pall Mall is scandalously rude and irregular.

St. James's Church is finely situated, with regard to the prospect on the north side of the square; and if it had been built in suitable taste, would have appeared most nobly to fill the vista, and add a pomp to the whole view; but the builders of that pile did not trouble themselves much about beauty, and I believe it is mere accident that even the situation itself is so favourable.

We must now pass into Piccadilly, where we shall be entertained with a sight of the most expensive wall in England; I mean that before Burlington House. Nothing material can be objected to it, and much may be said in its praise. It is certain the height is wonderfully well proportioned to the length, and the decorations are both simple and magnificent; the grand entrance is august and beautiful, and by covering the house entirely from the eye, gives pleasure and surprise, at the opening of the whole front with the area before it, at once. If any thing can be found fault with in this structure, it is this—that the wall itself is not exactly on a line; that the columns of the gate are merely ornamental, and support nothing at all; that the rustic has not all the propriety in the world for a palace; and that the main body of the pile is hardly equal to the outside. But these may be rather imaginations of mine, than real imperfections; for which reason I submit them to the consideration of wiser heads.

That side of Arlington Street next the Green Park, is one of the most beautiful situations in Europe, for health, convenience, and beauty, the front of the street is in the midst of the hurry and splendour of the town, and the back in the quiet and simplicity of the country. It is not long since, too, that the whole row was harmonious and uniform, though not exactly in taste; but now, under the notion of improvement, is utterly spoilt and ruined, and for the sake of the prospect behind, the view before is disjointed and broken to pieces.

I have now finished one of my walks from Lincoln's Inn Fields to Hyde Park Corner, and, acco ding to promise, am now to go back to Temple Bar, in order to comment on the most remarkable things in my way to Westminster.

The New Church in the Strand is one of the strongest instances in the world, that it is not expense and decoration that are alone productive of harmony and taste: the architect of this pile appears to have set down with a resolution of making it as fine as possible, and, with this view, has crowded every inch of space about it with ornament: nay, he has even carried this humour so far, that it appears nothing but a cluster of ornaments, without the proper vacuities, to relieve the eye, and give a necessary contrast to the whole: he ought to have remembered that something should first appear as a plan or model to be adorned, and the decorations should be only subordinate to that design; the embellishments ought never to eclipse the outline but heighten and improve it. To this we may safely add, that the dividing so small a fabric into two lines or stories, utterly ruined its simplicity, and broke the whole into too many parts. The steeple is liable to as many objections as the church, it is abundantly too high, and, in the profile, loses all kind of proportion, both with regard to itself and the structure it belongs to. In short, this church will always please the ignorant, for the very same reasons that it is sure to displease the judge.

York-stairs is unquestionably the most perfect piece of building, that does honour to the name of Inigo Jones: it is planned in so exquisite a taste, formed of such equal and harmonious parts, and adorned with such proper and elegant decorations, that nothing can be censured, or added. It is, at once, happy in its situation, beyond comparison, and fancied in a style exactly suited to that situation. The rock-work, or rustic, can never be better introduced than in buildings by the side of water; and, indeed, it is a great question with me, whether it ought to be made use of any where else.

Northumberland House is very much in the Gothic taste, and, of course, cannot be supposed very elegant, and beautiful; and yet there is a grandeur and majesty in it that strikes every spectator with a veneration for it: this is owing intirely to the simplicity of its parts, the greatness of its extent, and the romantic air of the four towers at the angles. The middle of the front next the Strand, is certainly much more ancient than any other part of the building, and, though finished in a very expensive manner, is a very mean and trifling piece of work. It may serve indeed to preserve the idea of the original pile, and acquaint the moderns with the magnificence of their forefather; but then it breaks the uniformity of the whole, and might be spared with more propriety, than continued.

The statue at Charing-cross has the advantage of being well placed; the pedestal is finely elevated, and the horse full of fire and spirit; but the man is ill designed, and as tamely executed: there is nothing of expression in the face, nor character in the figure, and though it may be vulgarly admired, it ought to be generally condemned.

When I have stood at this place, I have often regretted that some such opening as this had not been contrived, to serve as a centre between the two cities of London and Westminster, and from whence, particularly, the cathedrals of St. Paul's and the Abbey might have been seen, as the terminations of the two vista's: I am of opinion that nothing in Europe would have had a finer effect; but now it is impossible it should ever take place, and I mention it only by way of hint, that private property is, generally speaking, the only bar to public ornament and beauty.

The new Admiralty was erected on a spot of ground, which afforded the architect room for all the beauties his imagination could suggest, and the expence it was raised at, enabled him to execute all that beauty in a grand, though simple manner; how he has succeeded, the building is a standing evidence; and very much concerned I am to see a pile of that dignity and importance, like to continue a lasting reproach of our national want of taste.

I must ingenuously confess that the number of pretty little boxes, that are built on the ruins of Whitehall, make me no satisfaction for the loss of that palace; not that I believe it ever was a fine structure, but because it might have been so; because no piece of ground, so near two great cities, could afford a finer situation; with so noble a river on one side, and so beautiful a park on the other: and because Inigo Jones's plan for rebuilding it is still forthcoming, and may be made use of to erect a structure equal to the situation.

The majestic sample he has given of his art in the Banquetting House, is a continued persuasive to incline us to wish for the rest of that magnificent pile, of which this was intended to be so inconsiderable a part: to be sure if ever this could be effected, Britain might boast of a palace, which might excel even the proud Versailles, and be as much visited too, in compliment to its superior taste.

I cannot leave this place without taking some notice of the admirable ceiling, performed by Rubens, which is beyond controversy, one of the finest things of the kind in Europe. It is indeed not so generally known as one could wish, but it needs only to be known to be esteemed according to its merit. In short, it is but an ill decoration for a place of religious worship: for in the first place, its contents are no ways akin to devotion, and in the next, the workmanship is so very extraordinary, that a man must have abundance of zeal, or no taste, that can attend to any thing beside.

Before I quit this place, I must take notice of the brazen statue, erected here in honour of James II. The attitude is fine, the manner free and easy, the execution finished and perfect, and the expression in the face inimitable: it explains the very soul of that unhappy monarch, and is therefore as valuable as if it commemorated the features and form of a hero. In short it is a pity it is not removed to some more public and open place, that it might be better known, and more admired.

Marlborough House is another instance of great expense, but no taste: it consists only of a range of windows or two; a certain quantity of unmeaning stone, which was intended for a decoration, and a weight of chimnies over all, enough to sink the roof to the foundation. It is certain the ground afforded the architect all the opportunity imaginable of exerting his utmost art and genius, and if he had, the very place itself would have secured him the highest applause.

It is with no small concern, I am obliged to own that the palace* of the British kings is so far from having one single beauty to recommend it, that it is at once the contempt of foreign nations, and the disgrace of our own: it will admit of no debate that the court of a monarch ought to be the centre of all politeness; and a grand and elegant outside would seem, at least, an indication of a like perfection within: we may safely add, that this is necessary even in a political sense: for strangers very naturally take their impressions of a whole people by what they see at court, and the people themselves are, and ought to be dazzled by the august appearance of majesty, in everything that has any relation to it. I could wish, therefore, that ways and means could be invented to bring about this necessary point; that Britain might assert her own taste and dignity, and vie in elegance, as well as power, with the most finished of her neighbours.

As we proceed on to Westminster,† a city long famous for its antiquity, yet producing very little worthy of attention, and less of admiration, we will begin with the house on the left hand of King Street, and near adjoining to Privy Garden; not that it is in any way remarkable in itself, but because it has one of the most elegant irregular views before it of any house in town; the street before it forms a very spacious and noble area. And yet, with all its advantages, the house is a public nuisance, as well as all those in King Street, Channel (Cannon) Row, and the entire space between; nothing in the universe can be more absurd than so wretched a communication between two such cities as London and Westminster, a passage which must be frequented by all foreigners, which is visited even by the sovereign himself many times a year, which is the road of all the justiciary business of the nation, which is the only thoroughfare to the seat of the legislature itself, and the rout of our most pompous cavalcades and processions: surely such a place as this ought, at least, to be large and convenient, if not costly and magnificent, though, in my opinion, it ought to be made the centre of our elegance and grandeur; and to do this effectually, all the buildings I have complained of ought to be levelled to the ground, and a space laid open from Privy Garden to Westminster Hall on one side, and from the west end of the Abbey to Storey's Gate on the other; this should be surrounded with stone buildings all in a taste, raised on a piazza or colonnade, with suitable decorations, and the middle should be adorned with a group of statues, answerable to the extent of the circuit round it. It is easy to imagine what an effect such an improvement as this would have on the spectator, and how much more agreeable it would be to the honour and credit of the nation.

I should farther desire, too, to see all the little hovels demolished which now incumber the Hall and the Abbey, that those buildings might be seen at least, and if they could not be admired for their beauty, they might be reverenced for their greatness and antiquity. If St. Margaret's were removed with the rest, it would be yet a farther advantage: for then the fine chapel of Henry VII. would come into play, and be attended to as it deserves. I am very far from expecting or even imagining that any of these alterations will ever come to pass; I mention them only to explode the miserable taste of our ancestors, who neglected, or did not understand, these beauties: and that their descendants may grow wiser at their expence, and prevent the like censures from falling upon them.

I am sometimes inclined to wish that the place which is now called Hell, was levelled, and that the new Parliament House should be erected there in its room: it would certainly have a noble effect on the prospect, and form a most admirable contrast to the ancient edifices of each side of it: I have indeed an objection or two to this part of the scheme; first, I apprehend there is not room enough there for such a pile: and, secondly, it would lose the advantage of a prospect from the river, which its present situation might so happily allow it.

At all events, however, I should be glad to see this noble project put into execution: it is certain nothing can be more unworthy of so august a body as the parliament of Great Britain, than the present place of their assembly: it must be undoubtedly a great surprize to a foreigner, to be forced to enquire for the Parliament House even at the doors; and when he found it, to see it so detached in parcels, so incumbered with wretched apartments, and so contemptible in the whole: I could wish therefore to see this evil remedied; to see so useful and necessary a scheme take place: and if it falls into the noble hands to execute, we have long been flattered to believe it would, there is no room to doubt but the grandeur of this appearance will answer the majestic purposes it is to be employed in. The British taste in architecture, is, to be sure, more obliged to that nobleman,(?) than any other person now living, and if Inigo Jones has any advantage, it is only in having lived before him.

It will be ridiculous and foolish therefore, in me, to give the least hint for the conduct or improvement of any design which he has engaged in: I shall therefore say no more than this, that I should be glad to have both houses under the same roof, built on the same line, exactly opposite to each other, the seats ranged theatrically, the throne in the midst of one semicircle, the speaker's chair in the other; and that when the king made his speech, ways and means might be found to remove the partitions from between the two houses, and present the whole parliament of Britain at one view, assembled in the most grand, solemn, and elegant manner, with the sovereign at their head, and all the decorations round them, which could strike the spectator dumb with admiration, at the profusion of majesty, which set off and adorned the whole.

After such a scene as this has been presented to the imagination, no other has importance enough to be attended to: I expect therefore that what has been said of Westminster Hall will meet with but a cool reception. The structure is remarkable only for being the largest room in Europe which has no column to support it: all that is excellent in it, therefore, is to be found in the contrivance and workmanship of the roof, and no doubt both are truly admirable: but as skill and contrivance are both thrown away, unless they are to be seen in effect, so a room of half the extent of this, supported on beautiful pillars, and graced with suitable cornices, according to the antique, would excite a great deal more applause, and deserve it infinitely better.

(To be continued.)

* St. James's.

† We have retained this part of Ralph, although several improvements have taken place since his day in this part of Westminster.—Ed.

NOTES ON ARTESIAN WELLS AND WELL BORING IN FRANCE.

(From French Publications.)

M. Champoiseau has communicated to "the Academy of Sciences" the result of the experiments which he made at Tours, to ascertain the relation which existed between the water of his artesian well, and that of the neighbouring rivers. These experiments were continued for more than three months (March, April and May), and did not show any variation in the produce at any time, whatever were the variations in the rivers round Tours, or in the tides; neither was the limpidity of the water at all affected. Indeed the apparatus did not exhibit any sensible change in the well water, and the conclusion drawn is that the artesian wells of Tours, from the great elevation of their feeding springs, are not exposed to the irregularities observed elsewhere.

A singular circumstance recently occurred during the construction of the Left Bank Versailles Railway, near Val de Fleury, varying in its operation, and its treatment from some similar instances, which occurred on the London and Birmingham, and other railways here. A large embankment was in progress to join the viaduct then building, but the deposit of earth had scarcely begun when an extraordinary motion was communicated to the adjoining soil. In two places it was lifted up 8 or 10 yards above the surface, the road was blocked up, and several houses on the disturbed site were upset. It was found that this operation proceeded from a stratum of clay, mixed with sand, and soaked with last year's rains, so as to become fluid; that the weight of the embankment 30 yards high, and that of the superincumbent strata had put this pulpy mass in motion, and that it had disturbed the adjoining soil on the slope of the valley, and had in several places lifted up and broken through the upper strata. The cause was apparent that water did the mischief, and though it might not have shown itself immediately if the season had been dry, yet ultimately it would have been productive of serious evil. To remedy this, there were no other means than to stop the flow of water arriving from the upper levels; to carry which into effect it was necessary to cut the clay stratum and replace by stone work, which would surround the site on which the embankment was to be formed and divert the water. This operation was found exceedingly difficult, having to be carried on at a depth of from 6 to 20 yards in a moving soil, saturated with water; it was long, very dangerous, and an accident might have wasted much valuable time, the works of the embankment being suspended in the meanwhile, and the stone-work itself being liable to be swallowed up in a few years, and the work to be done over again.

Under these circumstances the engineers thought it advisable to have recourse to boring for the purpose of absorbing the water, and applied to the General Well-boring Company at Paris. This mode was also difficult, as the boring tube got plugged up in the soft stratum as fast as it was emptied, but by means of good tools this was at last got over. The first boring reached 20 yards and got into the upper part of the chalk, notoriously full of fissures, and where the water was rapidly absorbed. The second and third borings were carried to 35 and 40 yards in order to get at the chalky fissures which communicate with the Seine, and feed the neighbouring wells. A series of borings will therefore be carried round the embankment at proper distances and drains if necessary made to carry the water into the borings which can easily be kept clear by means of a valve and cord. It is proposed also to apply this method to get rid of the water in sand, but this necessarily depends on the strata, for we believe that in the Kilsby tunnel it would not have been practicable.

SPEED ON RAILWAYS.

Diagram, showing the variations in the speed of a locomotive engine and train over a journey of 2½ miles, on a level railway. In the first instance starting from a state of rest and getting up the speed; then travelling one mile at the rate of thirty miles an hour; and ultimately being brought again (by the use of the break) to a state of rest.

From numerous observations, by R. SHEPPARD.

HYDRAULIC WORKS AT ALGIERS.

By M. Poirel, Engineer of Bridges and Roads.

Translated from the Annales des Ponts et Chaussées by W. H. Emory, Jun., U. S. Topl. Engrs., for the Franklin Journal.

The port of Algiers was established as far back as the year 1530, by Cheredin, brother of Barbarossa. Having made himself master of a little island, in front of the city, which Spaniards had fortified, he resolved, in order to secure it, and at the same time to make, at Algiers, a harbour that would afford protection from the winds and from the swell of the sea, to unite it to the town by means of a jetty. This is called the Cheredin jetty, and is two hundred and twenty-three yards long, and one hundred and twenty-seven yards wide. Its direction is nearly east north-east, or west south-west.

Besides the Cheredin jetty, another has been built on the prolongation of the island, which protects the harbour from easterly winds, and is called the mole. It is one hundred and seventy-four yards long, and forty-five yards in its greatest width. This mole runs north-east and south-west. These two jetties with the little mole on which the Lazaretto stands form the boundary of the basin. It contains forty thousand seven hundred and twenty-two superficial yards, and can float sixty vessels, of which about thirty, may be vessels of three hundred tons, and some few, eight hundred tons. Vessels of a larger class anchor outside the basin. The greatest depth of water is sixteen and a half feet; but this may be increased by dredging. The Cheredin jetty and the mole were found in a state of complete dilapidation when Algiers fell into the hands of the French. These two works constructed of loose stone, (rubble) were levelled to their base. The Deys were in the habit every year of having the stones replaced which were carried away in the winter by the sea.

Laugier de Tassy, one of the most faithful historians of the Algerine regency, who resided there in 1727, says:—

"The great mole (the Cheredin jetty,) being entirely exposed to the north, to prevent it from being carried away by the furious swells of the sea, which roll up the sand bank, stretching along this mole and out into the sea, they were obliged to keep the slaves of the beylick employed the whole year carrying hard stones from a place near point Pescade, to put them along the mole. The sea soon carried away the stones thus deposited, but care was always taken that they should be replaced."

Large magazines of military supplies are placed on the Cheredin jetty, and it naturally claimed the first attention of government.

The preservation of these magazines required that the loose stone upon which they rested, at the base of the jetty, should be secured.

This undertaking was confided to M. Noel, the engineer, in charge of the hydraulic works at Toulon, from which he was temporarily relieved.

He rebuilt the entire body of the jetty to a height of sixteen and a half feet above the water, with a thickness of six and a half feet. The new masonry is of the very best kind, and possesses great solidity; unfortunately the insufficiency of funds placed at the disposal of the engineer, and his limited time did not permit him to turn his attention to the foundation of the jetty which will soon require considerable repair.

The extremity of the mole, called the chop, in which the sea made a large breach, was repaired in 1831, but the new masonry being built upon the fragments which the action of the sea had brought down, was entirely destroyed by the first storm in the winter of 1832. All the repairs made to the top of the work were necessarily liable to the same catastrophe, as the base upon which they rested was insecure. It became necessary, therefore, before proceeding farther, to reconstruct the base permanently and durably.

The locality did not permit the engineer's resorting to the ordinary means of establishing a foundation by throwing over loose stones, (rubble.) The shore to the west, where the quarries are, has not a single creek or harbour where a vessel could load; it is open to the ocean and skirted by a reef of rocks which make the landing dangerous even in a calm. The transportation of blocks of stone could only be effected by carriages, a tedious and difficult operation with masses, which, to resist the action of the waves, should measure at least four cubic yards. Besides which it would have been necessary to carry these blocks through the most frequented and populous part of the city, very much to the inconvenience of the inhabitants passing to and fro. Another difficulty presented itself, even if the obstacles to an easy transportation had been overcome. To give sufficient stability to the work at the end of the mole, a long slope of at least one in ten was necessary, which would have entirely obstructed the navigation, as the entrance to the basin was already very narrow, being only one hundred and thirty-four yards wide, measuring from the end of the mole on which the Lazaretto stands, to that of the work in question.

Under these circumstances, the engineer was obliged to resort to other expedients, and he was thus led to form and execute a new plan for establishing foundations at sea, which five years experience of the works at Algiers has proved to be, according to all accounts, superior to all those which have heretofore been put in practice, and particularly to those made of rubble work; a method much approved of since the construction of the Cherbourg and Plymouth breakwaters, the two most important maritime works executed in modern times.

The principal feature of this plan is the use of blocks made of béton. These blocks are of two kinds; one being constructed in the water at the place it is intended to occupy, the other made on shore and launched.

The first is made by pouring the béton into cases without bottoms, sunk on the place where the block is to rest. The frames of these cases are made by putting together pieces of scantling in a rectangular form, to which are nailed two courses of plank placed at right angles to each other. The lower edges of the cases are cut out to fit the profile of the surface on which they are to rest. They are lined with tarred cloth, throughout the whole extent of the inside up to the level of the water. The cloth at the bottom is allowed sufficient fullness to accommodate itself to the inequalities of the ground. The cases are thus, in fact, converted into cloth sacks, the sides of which are strengthened by the timber work on which they are stretched and fastened. The cloth sacks enable the mass of béton to accommodate itself perfectly to the surface which receives it, the inequalities of which serve to bind together the rock forming the bottom, and the béton. This is a great advantage in the use of these cases, for with the flat bottomed ones generally used, it is necessary to level the surface to be built upon, which is a difficult and uncertain operation.

The cloth bottomed cases are built upon stocks, launched and floated to the place they are to occupy. They are then sunk by means of small wooden boxes, one foot square, filled with cannon balls or pig-iron strung entirely round on the outside of the case, about one foot and a half from the top, by means of a cable passing through iron rings fixed in the uprights.

A similar use of béton was made by the Italians to prevent the disintegration of masonry immersed in water. They filled, with béton, bags similar to those used in fortification for making earth defences, and placed them compactly, one upon the other, and in such a manner as to fill up the inequalities of the surface on which they rested. The cement which oozed out through the interstices of the cloth, bound the little rolls of béton together and soon formed a very compact and durable mass. The cloth between the joints rotted and disappeared in a few years. On one occasion, they filled a much larger sack with béton than those above described, and threw it into the sea in stormy weather; some days after the storm had subsided they found this block very hard and strong. From the result of this experiment it was natural that the adoption of very large blocks of béton should be thought of, but the difficulty consisted in making bags of these dimensions which would not burst, and fixing them in position, while being filled with béton.

When the case is moored, the béton is lowered and deposited in it by means of a trough, which has a vertical and semi-rotary motion communicated to it by a cylinder worked at each end by a crank. This trough which contains a little more than a cubic yard, gives the advantage of putting in the case a large quantity at a time. The operation is thus made more rapid and there are fewer seams.

The béton blocks made on shore are moulded in cases consisting of four sides made of thick planks and lined on the inside with another course of plank jointed together at the bottom and removable at pleasure. The bottom rests upon two large sills connected transversely, forming an inclined plane which terminates at the point where the block is to be launched. These cases like the others, are entirely empty and without shores. When they are filled with béton, and it becomes sufficiently hard, the sides are taken off and the block thus stripped is launched into the sea.

The mortar used in the large cases with cloth bottoms, is formed of one part fat lime and two parts of Italian puzzolana; that used for blocks on shore is composed of puzzolana and sand in equal proportions.

The lime should be made from the grey transition limestone, fine grained and very hard; slaked in the ordinary way, and reduced to the consistency of thick paste, it absorbs two and a half times its weight of water. Its bulk is increased in the proportion of 1 to 1·8.

The puzzolana is the same as that used along the Mediterranean coast in the formation of hydraulic mortars. It is to be found in the neighbourhood of Rome. The best comes from Saint Paul's cave, near the church of that name. This puzzolana is brought by waggons to the Tiber, and thence by batteaux to Civita Vecchia, whence it is exported. It is sent abroad in the natural condition in which it is found, the pieces varying in size from that of an egg to the smallest grain of sand. M. Jullien, the engineer, found by experiment that the very finest grains were the only ones that could be used with effect in hydraulic mortars, and that when it was used in grains as large, for example, as the largest grains of sea sand, it was as ineffectual as the sea sand itself. From this it appears to be necessary that the finest grained puzzolana alone should be used in hydraulic works; and as its efficacy and quickness in hardening are in proportion to the fineness, too much pains cannot be taken to pulverize it.

Acting on this principle, the puzzolana brought from Italy and Africa for the work on the mole was sifted at Algiers before being used. One half, forming the residue, was ground in a mortar mill and sifted again, leaving a residue of one-tenth.

That ground and sifted was of a quality inferior to that furnished by the first sifting. The price of the puzzolana delivered at the work was thirty-six francs per cubic yard, and the cost of sifting, grinding, &c., twelve francs, making the total cost forty-eight francs.

The cost of labour at Algiers, independently of the inferior quality of the puzzolana obtained by trituration, and the consequent increase of expense, made it desirable that it should be sifted at Rome and the refuse left there. The soil on which this city and its environs stand, is composed of this material, and is of course very cheap. The only difference in the price would therefore arise from the cost of sifting, which could be more than balanced by the freight saved in leaving the refuse.

Influenced by these considerations, the author, on the requisition of the Governor General was authorized by the Secretary of War to repair to Rome and superintend in person, the details of the operation. He there fixed up a number of strong bolting cloths pierced with small rectangular holes. The price of sifting one cubic yard of puzzolana with labour hired of the pontifical government, was about twenty cents.

The contractor who has leased from the Roman government, the monopoly in the puzzolana trade, regarding the project as impracticable, asked an exorbitant price for taking charge of it, but as soon as he discovered it was both easy and cheap, he came forward and offered for the future to send none but the sifted puzzolana to Algiers. It was delivered there in 1837, in this state, for forty-two francs the cubic yard, and could, without doubt, be delivered for forty francs. By adding one half sand, quite as good a commodity as the rough puzzolana is produced, and you get for twenty francs what formerly cost thirty-nine. At this price this material is likely to supersede all the hydraulic lime and artificial cements made at the different localities. It is easier worked, and the quality is superior, or at least equal.

Algiers is not the only place where this measure can be adopted advantageously; it can be practised with advantage on the whole Mediterranean coast and wherever the puzzolana of Italy is used. The engineers of Toulon and Marseilles have already made arrangements for the importation of the sifted puzzolana, and there is little doubt but that it will become an extensive article of traffic.

The mortar is made with one part lime in paste, and two parts puzzolana. If the puzzolana is in the rough state the mortar becomes hard in four days and resists the Vicat rod; if it is sifted through the bolting cloths it will become hard in two days, and if the puzzolana is sifted through a fine hair sieve, it will become hard in twenty-four hours.

It takes six days for mortar to become hard, which is made of one part lime, one of bolted puzzolana, and one of sand.

Béton is composed of one part mortar and two of stones broken to the size of from one to two inches,* making two parts of béton.

A cubic metre (35·317 cubic feet) of béton weighs 5886 pounds. It acquires in twenty-four hours, sufficient cohesion to withstand the shock of a heavy sea without disintegration. In November 1836, a block containing two hundred and fifty cubic yards, which had been immersed only thirty-six hours was stripped of its enclosure, and resisted the action of one of the most violent storms. M. Fénéon, a mining engineer, then at Algiers, was an eye witness of this remarkable fact.

The blocks made in the cases with cloth bottoms, measure generally from one hundred and eighty to two hundred and fifty cubic yards; those made on shore, from fifteen to sixty cubic yards. When constructing the mole at Algiers, they placed first a set of the large blocks, and then, in advance of them, to protect their bases, they placed a number of the second size. The large cases serve as a platform from which to launch the small blocks. The two lines of blocks are bound together at intervals by large blocks of béton, and these intervals are filled by stone measuring from five to eight cubic yards.

* Whether cubic or superficial measure, is not stated. Tr.

The following is an estimate of quantities and labour for a béton block, of thirty-six cubic yards, using mortar made of lime, sand and puzzolana:—

36 cubic yards of broken stone.
12 „ puzzolana.
12 „ lime in paste.
12 „ sand.
1 day's labour for a master workman.
3 „ three labourers.

The cases used cost about one hundred dollars, and one will answer for twenty blocks.

The whole cost of making and laying this béton at Algiers is about five dollars and seventy cents the cubic yard.

Estimate of quantities and labour for a béton block of one hundred and eighty-two cubic yards, sunk in a case with a tarred cloth bottom, caulked, using mortar made of lime and puzzolana:—

182 cubic yards of broken stone.
91 „ puzzolana.
45½ „ lime in paste.
1 master workman three days.
2 labourers for three days.

The construction and moving of the case cost about four hundred dollars; it can also be used twenty times.

The caulking at the angles, the cloth bottom and the removal of the case, cost about one hundred and seventy dollars.

The whole cost of making and laying this béton at Algiers, is estimated to be about eight dollars and seventy-five cents the cubic yard.

Colonel Emry published a work in 1831, containing many purely theoretical views, and at the same time many useful suggestions, in which he set forth, strongly, the inconveniences of the present system of building stone work in the sea, and proposed as a substitute, blocks made of béton.

The blocks that he proposed were also of two kinds, one kind made in the water, and the other on shore; the first was to be built in a flat bottomed case, and the other he proposed to transport to the place for immersion; a plan of doubtful success: he proposed, too, that these blocks, which were to be hexagonal prisms, should be laid regularly one upon the other, which we regard as impossible.

During the execution of the new system at Algiers, some engineers thought the success of it very doubtful; but the manner in which the end of the mole stands, puts all doubt to rest. This work projects into the sea towards the quarter whence the winds blow with most violence, and it stands without having sustained the slightest injury from the most furious tempests. Besides other unquestioned advantages presented by the use of béton blocks instead of loose stone, the difficulty is avoided of transporting the stone of the requisite size when the quarries are remote. This consideration amounts sometimes to an insuperable obstacle to the use of loose stone, while the béton can be used any where.

The Romans drew blocks of stone from Mount Circe to build the port of Anxium, a distance of ten miles; and the pontificial government was obliged to abandon the port of Auzo in consequence of the difficulty of finding a quarry in the neighbourhood, that would furnish proper stone to repair the jetties.

The Italians generally practise a mixed system. They build the foundation of loose stones, even in twenty or thirty feet water, and the top of masonry. The masonry is constructed in staunch cases, floated to the place required, and the workmen, secure from water, erect a wall usually of undressed stone and hydraulic mortar. The cases are thus sunk by degrees until they reach the loose stone. The details of this process are described in Belidor's Hydraulic Architecture, in his description of the manner in which the moles at Nice, Genoa and Naples were constructed.

The defects of this plan are very apparent; the bottom of the case rests upon an uneven and movable surface, and the consequence is, the masonry cracks open in many places. Moles thus constructed are soon destroyed; extensive repairs are required, which make it necessary to be continually throwing in loose stone. This is exemplified in the mole at Genoa, which shelters the harbour from the east winds, the end of which constantly requires repair.

When De Cessart projected his large conical cases, he was on the eve of discovering the simple and ingenious plan just described for establishing foundations; the great error which was committed, and which fully explained the difficulty encountered by so skilful an engineer, was in supposing that a wooden structure, however substantially constructed, could resist the action of the sea. Acting on this principle, he filled his cases with small stones to keep them in place; the consequence was that when the action of the sea beat these cases to pieces, the stones fell down and the whole fabric was swept away. De Cessart should have considered the case as simply a temporary enclosure to build masonry in, which would be capable of resisting the force acting against it after the cases were destroyed. If he had taken up this idea, it would probably have led him to the use of béton for filling his cases. Instead of making these cases as substantially as was proposed, it would be sufficient to give them the form of a large cask without a bottom, made with uprights and staves bound together by iron chains instead of hoops, in such manner that the uprights can be taken apart when the case is to be taken up. Another indispensable condition is, that the case should be filled in the shortest possible time. The sea at Algiers is very powerful considering the little range it has; and it would be necessary to make such arrangements that a case made to contain about 1300 cubic yards, should be filled in thirty-six, or forty-eight hours. This might be done by throwing in béton blocks, ready made, at the same time pouring in béton to bind them, by means of cloth funnels fixed to the cases. This suggestion has never been acted upon, but if the intention of making Algiers a military port be carried out, there will be an opportunity of trying it on a large scale, and it is believed with complete success.

Whatever may be the fate of this or other plans for using béton, one thing is certain, that sooner or later, the practice of making foundations at sea with loose stone will be entirely abandoned, and masses of the natural rock so costly in quarrying and transportation, and so insufficient in dimensions, will be replaced by artificial blocks made of béton.

THE EFFECT OF CURVES ON RAILWAY CARRIAGES.

Sir—The influence of railway curves on engines and carriages passing along them, appears to have been paid little attention to by those persons who have had the best opportunities of acquiring information on the subject; at least, I am not aware that the results of any observations on the subject have been made known to the world. The only remark bearing on the matter which I have seen published, is contained in a letter by Mr. J. Ely, at page 139, vol. 2, of your Journal, in which he asserts "that when an engine is entering upon a curve, it will be affected by the nature of the path it was previously describing, and that the wear and tear of the *outer* rail at the commencement of a sharp curve is *less* when the previous path is a curve in an opposite direction (forming an S), than when it is a straight line." I do not for a minute doubt the correctness of the latter part of his assertion, but think that the inference he would draw from it, that an S curve is preferable to a straight line connected with a single curve, is erroneous. If you consider the subject, you will instantly perceive that the outer rail at the *commencement* of a reversed curve, would scarcely be affected by the grinding of the wheels, but that the inner rail would have all the wear and tear which is, simply, not from the engine or carriages being influenced by the path they were previously describing, in the sense which he applies it, but from the centrifugal power throwing the carriages against the outer rail of a curve, and which, at the point where the curve is reversed, has not had time to be counteracted, and which will not be the case until the carriages have passed a considerable distance into the second or contrary curve, when the wheels will begin to grind the outer rail of this curve as they did that of the preceding. My principal reason for addressing you is to draw attention to the great wear and tear of engines and carriages caused by their traversing curves, and to induce an inquiry into the subject, for the purpose, if possible, of modifying the evil. My opinion on the matter is, that any engine or carriage, in traversing a curve, undergoes a degree of torsion in the framing, and thereby partially adapts itself to the path which it is traversing, and which, with a slight degree of sliding of the wheels on one side, enables it to pass along the line without such a vast increase of friction as might reasonably be inferred. Now if such is the case, and a carriage is drawn or propelled along an S curve, the extremes of torsion will almost instantly take place where the two curves join, the framing being then twisted in the contrary direction, and the destruction of carriages must be commensurately great with the suddenness or violence with which the change is effected. I would therefore offer, as a partial remedy, the laying in of a short tangent line to the two curves in every instance, instead of an S curve, whereby the extremes of torsion, in place of being sudden, and I presume destructive, as in the latter, would be gradually effected, first by the restoration of the framing to its square form, and then by the slight torsion in the contrary direction. If this plan was pursued, I have no doubt very much greater durability in the engines and carriages would be the consequence. Perhaps some of your readers who have opportunities of minutely observing the effects which I have described, and also the effect where sharp curves are connected with a tangent, will, at some future time, communicate the results.

June, 1840. B.

SUSPENSION BRIDGES.

On the Theory of Suspension Bridges, with some account of their early history. By Mr. C. F. F[illegible], *read at the Scientific Society, March* 12, 1849.

Suspension bridges appear to be of very ancient origin; travellers have discovered their existence in South America, in China, in Thibet, and in the Indian Peninsula. They are most frequently met with in mountainous regions, and being suspended across a deep ravine, or an impetuous torrent, permit the passage of the traveller where the construction of any other kind of bridge would be entirely impracticable. Humboldt informs us, that in South America there are numerous bridges of this kind formed of ropes made from the fibrous parts of the roots of the American agavey (*Agave americana*). These ropes, which are three or four inches in diameter, are attached on each bank to a clumsy frame work composed of the trunk of the *Schinus molle*; where, however, the banks are flat and low, this framework raises the bridge so much above the ground as to prevent it from being accessible. To remedy this inconvenience steps or ladders are, in these cases, placed at each extremity of the bridge, by ascending which all who wish to pass over, readily reach the roadway. The roadway is formed by covering the ropes transversely, with small cylindrical pieces of bamboo. The bridge of Penipé, erected over the Chambo, is described as being 120 feet long, and 8 feet broad, but there are others which have much larger dimensions. A bridge of this kind will generally remain in good condition 20 or 25 years, though some of the ropes require renewing every 8 or 10 years. It is worthy of remark, as evincing the high antiquity of these structures, that they are known to have existed in South America long prior to the arrival of Europeans. The utility of these bridges in mountainous countries, is placed in a striking point of view by the fact mentioned by Humboldt, of a permanent communication having been established between Quito and Lima, by means of a *rope* bridge of extraordinary length, after 40,000*l.* had been expended in a fruitless attempt to build a stone bridge over a torrent which rushes from the Cordilleras or the Andes. Over this bridge of *ropes*, which is erected near Santo, travellers with loaded mules can pass in safety.

But suspension bridges, composed of stronger and more durable materials than the twisted fibres and tendrils of plants, are found to exist in these remote and semi-barbarous regions; in Thibet as well as in China many *iron* suspension bridges have been discovered, and it is no improbable conjecture, that in countries so little known and visited by Europeans, others may exist of which we have as yet received no accounts. The most remarkable bridge of this kind, of which we have any knowledge in Thibet, is the bridge of Chuka-cha-zum, stretched over the Tehintchieu river, and situated about 18 miles from Murichom. "Only one horse is admitted to go over it at a time: it swings as you tread upon it, re-acting at the same time with a force that impels you every step you take to quicken your pace. It may be necessary to say, in explanation of its construction, that on the five chains which support the platform, are placed several layers of strong coarse mats of bamboo, loosely put down, so as to play with the swing of the bridge; and that a fence on each side contributes to the security of the passenger."* The date of the erection of this bridge is unknown to the inhabitants of the country, and they even ascribe to it a fabulous origin. The length of this bridge appears to be about 150 feet.

Turner describes in the following terms a bridge for foot passengers of an extraordinary construction. "It was composed of two chains stretched parallel to each other across the river, distant four feet from each other, and on either side resting upon a pile of stones, raised upon each bank about 8 feet high; they were carried down with an easy slope and buried in the rock, where being fastened round a large stone, they were confined by a quantity of broken rock heaped on them. A plank about 8 inches broad, hung, longitudinally suspended, across the river with roots and creepers, wound over the chains with a slackness sufficient to allow the centre to sink to the depth of four feet below the chains. This bridge, called Selo-cha-zum, measured, from one side of the water to the other, seventy feet. The creepers are changed annually, and the planks are all loose; so that if the creepers give way in any part, they can be removed, and the particular part repaired without disturbing the whole."

Numerous suspension bridges formed of iron chains exist also in China; and though the accounts which travellers have transmitted respecting them are less detailed and explicit than would have been desirable, descriptions of two of them have been furnished, which are sufficiently minute and intelligible to excite considerable interest. The first to which I refer is contained in Kircher's China Illustrata. The following is a translation of the author's words. "In the province of Junnan, over a valley of great depth, and through which a torrent of water runs with great force and rapidity, a bridge is to be seen said to have been built by the Emperor Mingus, of the family of the Hanæ, in the year of Christ 65, not constructed of brickwork, or of blocks of stone cemented together, but of chains of beaten iron and hooks, so secured to rings from both sides of the chasm, that it forms a bridge by planks placed upon them. There are 20 chains, each of which is 20 perches or 300 palms in length. When many persons pass over together, the bridge vibrates to and fro, affecting them with horror and giddiness, lest whilst passing it should be struck with ruin. It is impossible to admire sufficiently the dexterity of the architect Sinensius, who had the hardihood to attempt a work so arduous, and so conducive to the convenience of travelling." Another suspension bridge in this country is described in the 6th vol. of the "*Histoire générale des Voyages.*" The following is a translation: "The famous *Iron Bridge* (such is the name given to it) at Quay-Cheu, on the road to Yun-Nan (Junnan?) is the work of an ancient Chinese general. On the banks of the Pan-Ho, a torrent of inconsiderable breadth, but of great depth, a large gateway has been formed between two massive pillars, 6 or 7 feet broad, and from 17 to 18 feet in height. From the two pillars of the east depend four chains attached to large rings, which extend to the two pillars of the west, and which being connected together by smaller chains, assume, in some measure, the appearance of a net. On this bridge of chains a number of very thick planks have been placed, some means of connecting which have been adopted in order to obtain a continuous platform; but as a vacant space still remains between this platform and the gateways and pillars, on account of the curve assumed by the chains, especially when loaded, this defect has been remedied by the aid of planking supported on trusses or consoles. On each side of this planking small pilasters of wood have been erected, which support a roof of the same material, the two extremities of which rest on the pillars that stand on the banks of the river."* The writer proceeds to remark that, "the Chinese have made several other bridges in imitation of this. One, on the river Kin-cha-Hyang, in the ancient canton of Lo-Lo, which belongs to the province of Yun-Nan, is particularly known. In the province of Se-Chuen there are one or two others, which are sustained only by ropes, but though of an inconsiderable size, they are so unsteady and so little to be trusted that they cannot be crossed without sensations of fear."

While our attention is directed to early accounts, and to the origin of suspension bridges, it may be proper to remark, that although, as we have seen, the inhabitants of the mountainous districts of South America, or the wild and barbarous regions of Thibet, appear to have been well acquainted with the purposes for which these structures are best adapted, and to have practised their construction from the most remote ages, neither the Greeks, the Romans, nor the Egyptians, according to all we know of those nations had any knowledge of their uses or properties, or ever employed them as a means for crossing a river, or other natural impediment. It is not, therefore, from these celebrated nations of antiquity that the engineer has derived his first hints for the construction of suspension bridges, but from those rude and unpolished people, the results of whose ingenuity have just been described.

But it will now be interesting to inquire how far we can trace back the antiquity of suspension bridges in more civilized countries,—on the Continent, in the British Isles, and in the United States of America. Scamozzi speaks of suspension bridges existing in Europe in the beginning of the seventeenth century, but it is very questionable if he employed that term to designate the same structure to which it is now applied, and this is rendered the more improbable as no such bridges are now in existence, and other writers are totally silent upon the subject. It does not appear then that suspension bridges of other than recent erection have existed on the Continent, and in England the oldest of which we have any account has not been constructed more than a century. The first suspension bridge in the United States was erected in the year 1796. In England the oldest bridge of the kind is believed to have been the Winch Chain Bridge, suspended over the Tees, and thus forming a communication between the counties of Durham and York. Mr. Stevenson (Edinburgh Philosophical Journal) expresses his regret at not having been able to learn the precise date of the erection of this bridge; from good authority, however, he concludes it to be about the year 1741. It may also be mentioned here, that at Carric-a-rede, near Ballantoy, in Ireland, there is a rope bridge, which in 1800 was reported to have been in use longer than the present generation could remember.

In the years 1816 and 1817 some *wire* suspension bridges were executed in Scotland, and, though not of great extent, are the first example of this species of bridge architecture in Great Britain. As, however,

* Turner's Embassy to the Court of Thibet.

† See Navier. Memoire sur les Ponts suspendus.

full descriptions of these bridges are to be met with elsewhere, it will not be necessary to notice them farther.

In 1818, Mr. Telford was consulted by government as to the practicability of erecting a suspension bridge over the Menai Strait, and was commissioned to prepare a design, if, upon an examination of the localities, he found the project feasible. Having accordingly surveyed the spot, he was led to propose the construction of a suspension bridge near Bangor Ferry, and in 1819 an act was obtained authorizing the erection of the bridge, a sum of money having been previously voted by Parliament for that purpose. This structure, which will always be regarded as a monument of the engineering abilities of Telford, was commenced in August 1819, and opened to the public on the 30th January, 1826, having occupied six and a half years in its erection. The Union Bridge across the Tweed was designed and executed by Captain Brown, and was the first bar chain bridge of considerable size that was completed in this country. It was commenced in August 1819, and finished in the month of July 1820. After the completion of the Menai Bridge, bridges on the suspension principle began to be universally adopted throughout Europe; but it was not till *iron wires* had been proved to be more *firm* than *bars of a greater thickness* that these bridges received their most extensive applications.* Since 1821 Messrs Seguin have constructed more than 50 wire bridges in France, with the most complete success.* The wire suspension bridge at Freyburg, in Switzerland, the largest in the world, was erected by Mons. Challey, and depends across the valley of the Sarine. It was commenced in 1831, and thrown open to the pubic in 1834. A suspension bridge has also been erected at Montrose, the size of which is scarcely inferior to that of the Menai bridge. At Clifton a very large suspension bridge is now in progress of erection by Mr. Brunel, and a suspension bridge 1600 feet in length is about to be erected over the Danube, between Pest and Offen, the design for which is the production of Mr. W. Tierney Clark, and under whose able superintendence its construction will be effected.

Having completed this sketch of the early history and subsequent progress of these interesting structures, I shall now proceed to investigate the *principles* upon which their stability depends, and by whose aid we are enabled to deduce practical rules for their construction. In this inquiry I prefer proceeding entirely upon abstract grounds, as by disencumbering our ideas of *material circumstances*, a greater facility of thought is conferred, and the results of the investigation are made to rest upon a broader and more certain basis. When a principle has once been established in a *general form*, its application will be found with comparative ease, as we have then only to observe that in substituting the particular for the general case, we do not violate any of the fundamental conditions of the problem.

The theory of suspension bridges is susceptible of division into two parts. I. The statical theory. II. The dynamical theory. In the first, we consider the forces which are developed, and the laws which are brought into operation, when all the parts are at rest; in the second, we suppose the action of the impressed force is evinced by the production of motion, and upon that supposition proceed to investigate the behaviour of each particle, and infer the effect of their combined motions. In the present paper the statical theory alone will be considered. The statical theory of suspension bridges is evidently involved in the general problem, *to determine the conditions of equilibrium of any forces whatever, acting in space upon points connected by lines wholly flexible and inextensible.* In the solution of this problem, then, we shall be gradually approaching our subject.

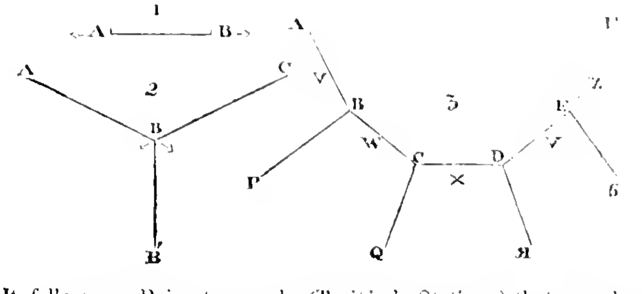
It is a principle in statical science, that when a body, acted on by any number of forces, is supposed to be at rest, all these forces must admit of being compounded into *two*, which are equal and opposite to each other. The same condition, it is evident, must exist with regard to each point, out of any number connected by flexible lines, provided the initial position of these lines be not a straight line, for then, it is clear, no medium exists through which the forces can be transmitted, and be made to act and re-act upon each other. This case may then be neglected in the present investigation, as it does not involve the *principle* of connecting lines, which here exert, in reality, no mechanical influence whatever. The same remark replies also when the connecting lines *are* right lines, if we still suppose that each point is in equilibrium by virtue of *those forces alone* which act upon itself. But since we easily conceive the transmission of force from one point to the adjacent one through the intervention of a connecting line, if that line be inextensible and a right line, it is perfectly clear that equilibrium may exist with regard to any number of points thus united, though each point should not, considered by itself, be in equilibrium by virtue of the forces applied to it, provided only we suppose that the interchange of force between two consecutive point be *mutual, equal* and *opposite*. Moreover, we shall suppose the forces to be receding forces, or such as tend to cause two bodies to proceed from each other. In general, then, it appears that in order that equilibrium may exist with regard to a system of points, which we suppose not to be in a state of independent equilibrium, it is only requisite that two simple conditions be observed. I. The line of connection must be a right line. II. The transmission of force between two points must be *mutual, equal* and *opposite*. It follows also, from the last condition, that the interchange of force will take place in the direction of the connecting line. We shall now proceed to show that these self-evident conditions being admitted, they may be resolved into others which have a more practical bearing. If, to begin with the simplest case, we take two points, A and B, fig. 1, we see at once, that equilibrium being supposed, each must be acted on by equal forces, whose direction are denoted by the arrows. If we now proceed to the case of three points, A, B, C, fig. 2, it is evident, that equilibrium subsisting, each two will be in equilibrium with respect to one another, and therefore, as we have seen, will be subject to equal and opposite forces. The directions of these are denoted by the arrows. Now, let the forces acting in the directions A B, C D, at the same point B, be compounded into B B' which represents their resultant, and we have, consequently, a system of three points kept in equilibrium by three forces, of which one is applied to each point. But as the forces acting at A and C, are transmitted through the connecting lines to the point B, and may be regarded as acting there, it is obvious the case differs in no respect from that of three forces in equilibrium around a single point. Consequently, calling the forces B A, B B' B C, P, Q, R, we have :—

$$P : Q :: \sin. B'BC : \sin. ABC$$
$$R : Q :: \sin. ABB : \sin. ABC$$
$$P : R :: \sin. B'BC : \sin. ABB'.$$

Hence also, from these propositions may be found the values of P, Q, and R, in terms of two of the angles and one of the other forces. By comparing the values, $Q\frac{\sin. B'BC}{\sin. ABC}$, $Q\frac{\sin. ABB'}{\sin. ABC}$, of P and R, we observe that when $\angle ABB' = \angle B'BC$, $P = R$, and B' B produced bisects the $\angle ABC$. Let $\angle ABC = 2\beta$, $\therefore \frac{\sin. B'BC}{\sin. ABC} = \frac{\sin. \beta}{\sin. 2\beta} = \frac{\sin. \beta}{2 \sin \beta \cos. \beta} = \frac{1}{2 \cos. \beta}$. Hence $P = R = \frac{Q}{2 \cos. \beta}$.

If Q remain constant, $P \propto \frac{1}{\cos. \beta}$, and if β remain constant, $P \propto Q$. If $\angle ABC$ be increased, $\cos. \beta$ is diminished, and it is therefore evident from the equation $P = \frac{Q}{2 \cos. \beta}$, that by increasing the $\angle ABC$ we increase the value of P; consequently, when A B C becomes a right line or $\beta = 90°$, the equation becomes $P = \frac{Q}{0} = \propto$.

Figs. 1, 2, and 3.



It follows, as Poinsot remarks (Traité de Statique) that a cord or thread stretched in a right line between two fixed points, will be necessarily broken by the smallest possible force that can be applied to it transversely, supposing the cord to be inextensible and not to have an infinite longitudinal resistance. It may be further remarked, that every material cord being composed of particles having weight, would, if extended between two fixed points lying in a horizontal line, be acted on by transverse forces of a definite magnitude; consequently no force, however large, would be sufficient to bring the cord into a horizontal position.

It is not difficult to extend the reasoning which has been used in re-

* See the Algemeine Bauzeitung.

ference to three points, to the case of any number of points, inextensibly and flexibly connected. Let the points be A, B, C, D, E, F, fig. 3; then, if the whole system be at rest, each pair of contiguous points will be at rest with respect to each other, and consequently will be connected by a straight line, and acted on by equal and opposite forces. By combining, as before, the forces at B, C, D, and E, we obtain their resultants P, Q, R, S, and we observe that, in general, any number of points may be kept in equilibrium by as many forces acting separately on each. For the sake of greater clearness, let us, however, imagine that two equal and opposite forces are made to act upon B, in the deductions B C, C B, respectively; then the system will be at rest as before, and if we suppose the force C B to act at C, the point B will be kept in equilibrium by three forces, B A, B C, B P. In the same manner, by superimposing equal and opposite forces at the points C and D, each will be kept at rest by three receding forces, two of which are always in the direction of the lines of connection. By calling the forces which act along the lines of connection V, W, X, Y, Z, we have therefore the following proportions:—

$$\begin{array}{llll} V : P & :: \text{sin. } PCB & : & \text{sin. } ABC \\ P : W & :: \text{sin. } ABC & : & \text{sin. } ABP \\ W : Q & :: \text{sin. } QCD & : & \text{sin. } BCD \\ Q : X & :: \text{sin. } BCD & : & \text{sin. } BCQ \\ X : R & :: \text{sin. } RDE & : & \text{sin. } CDE \\ R : Y & :: \text{sin. } CDE & : & \text{sin. } CDR \\ Y : S & :: \text{sin. } SEF & : & \text{sin. } DEF \\ S : Z & :: \text{sin. } DEF & : & \text{sin. } DES. \end{array}$$

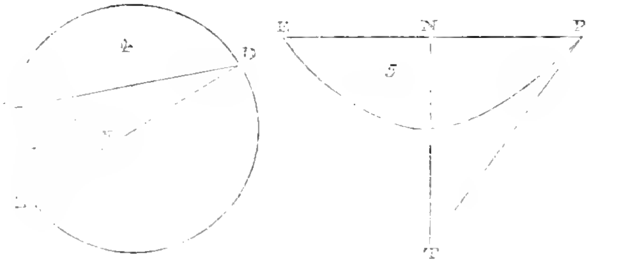
From these proportions the relation of any one force to any other may be determined, and consequently any force may be represented in terms of any other and the sines of the angles through which their lines of direction respectively pass. For example,

$$V = Z\,\frac{\text{sin. } PBC}{\text{sin. } DES},\ \text{and } P = S\,\frac{\text{sin. } ABC}{\text{sin. } DEF}.$$

If the original forces A B, C B, by the union of which the force P is obtained, were equal, P B produced will bisect the angle A B C, and the same is to be remarked of the forces Q, R, S; consequently, by the preceding proportions we have in this case, V = W = X = Y = Z. Moreover, denoting by 2α, 2β, 2γ, 2δ, the angles of the polygon, it follows:—

$$P : Q : R : S \ :: \ \cos.\alpha \ . \cos.\beta \ \cdot \cos.\gamma \ : \cos.\delta.$$

Figs. 4 and .



That is to say, the forces applied at the several angles of the polygon are proportional to the cosines of the halves of those angles. Let us now suppose that the lines A B and B C are equal to each other. Through the points A, B, C, fig. 4, describe the circle A B C D, draw the diameter B D, the arc A E, and E F at right angles to A B. Then B D bisects the ∠ A B C, and because B A D is a right angle (Euc. p. 31. b. 3):—

$$BA : BD :: BF : BE :: \cos.\alpha : \text{rad.}$$

$\therefore \cos. a = \dfrac{BA}{BD}$. Hence, as the forces P, Q, R, S, are proportional to cos. α, cos. β, &c., if we suppose all the sides of the polygon to be equal, it is evident they will be *inversely*, as the radius of the circle passing through the points terminating the two contiguous sides. But if we imagine the sides of the polygon to become indefinitely small, it then assumes the form of a curve, and the circle becomes the *osculating circle*, or the circle of equal curvature. If, then, a flexible curve, the two extremities of which are immoveably fixed, be acted on at points equidistant from each other by a number of normal forces, these forces will be *inversely as the radii of curvature* of the points of application, and the forces developed in the direction of the curve will be everywhere the same. If the normal forces be equal, the reciprocals of the radii of curvature will be equal, and therefore the radii of curvature themselves; consequently, in this case, the curve will be part of a circle.

If the normal force vary as the cube of the cosine of the angle formed by the ordinate and tangent at any point, the curve is a parabola, as is proved by the following investigation.

Let P A R, fig. 5, be a parabola generated by the action of normal forces, P T the tangent at the point P and N T, the subtangent. Let A N = x, N P = y, and p, the principal parameter or latus rectum; also call the radius of curvature R, and the normal force V.

$$\text{Then, } \cos.\ NPT = \frac{NP}{PT}$$

$$\text{But } BP^2 = NT^2 + NP^2 = 4AN^2 + NP^2$$

$$\therefore \cos.\ NPT = \frac{NP}{\sqrt{4AN^2 + NP^2}} = \frac{y}{\sqrt{4x^2 + y^2}}$$

$$\text{Or since } y^2 = px,\ \cos.\ NPT = \frac{\sqrt{px}}{\sqrt{4x^2 + px}}$$

$$\therefore \cos.^2 NPT = \frac{px}{4x^2 + px} = \frac{p}{4x + p};$$

$$\text{Hence } \cos.^2 NPT \propto \frac{1}{4x + p};\ \text{or } \cos.^3 NPT \propto \frac{1}{(4x + p)^{\frac{3}{2}}}.$$

$$\text{But in the parabola } R = \frac{(4x + p)^{\frac{1}{2}}}{2\sqrt{p}};$$

$$\text{Or } \frac{1}{R} \propto \frac{1}{(4x + p)^{\frac{3}{2}}};$$

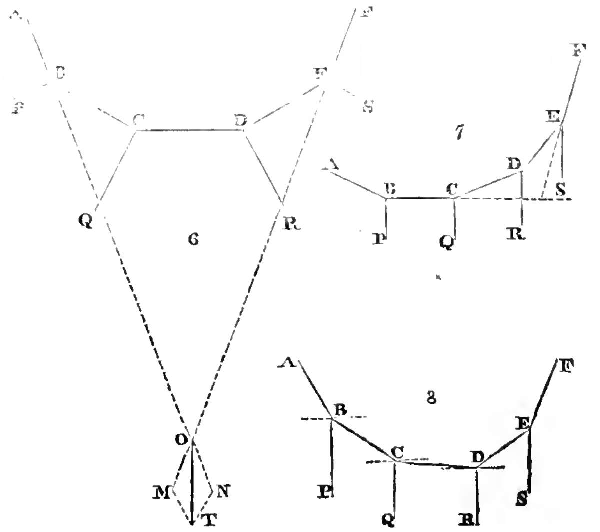
$$\text{Consequently } V \propto \frac{1}{R} \propto \cos.^3 NPT$$

Let v be the normal force at the vertex, and denote by ϕ the ∠ N P T:—hence, because at the vertex cos. ϕ = 1,

$$v : V :: 1 : \cos.^3 \phi \qquad \therefore V = v \cos.^3 \phi.$$

Again, since in the catenary, $R \propto \dfrac{1}{\cos.^2 \phi}$,* ϕ denoting the angle formed by the abscissa and tangent, it is seen at once, that when $V \propto \cos.^2 \phi$, the curve is a catenary.

Figs. 6, 7, and 8.



Assuming the system of points A, B, C, &c. fig. 6, to be in equilibrium, we shall now imagine the connecting lines to become perfectly rigid. It is evident that this supposition will not affect the equilibrium, as it does not involve the addition or abstraction of *force*, the only agent by which equilibrium is preserved or destroyed. If then the system was in equilibrium before, it will remain so now, and we have consequently a rigid body acted upon by the forces V, P, Q, R,

* Poinsot. Traité de Statique.

S, Z, which equilibrate each other. It follows, the resultant of two or more of these forces must be equal and directly opposed to the resultant of all the others, and if, therefore, A B, F E, be produced and intersect at O, the resultant of the forces P, Q, R, S will pass through the same point. Consequently, if the resultant be represented in magnitude and direction by the line O T, and a parallelogram be constructed, whose diagonal is this line, and whose sides, N O, M O, are drawn in the directions of B A, E F; N O, M O, will represent the directions and magnitudes of the forces to which the extreme points of the system, A and F, are subject. To proceed now to the case where P, Q, R, S, are parallel, fig. 7. The proportions we have before obtained will obviously apply here also, but in this case the supposition of equilibrium involves another condition, which was not before essential; all the forces must be situated in the same plane. For, as three forces are in equilibrium around the point B, they will necessarily be situated in the same plane, and the same can be asserted of C, D, and E; but B P, C Q, being parallel, B P, B C, and C Q are in the same plane (Euc. 7, 11); and consequently, all the forces acting at B and C are in one plane. By extending this reasoning to the points D and E, we observe that all the forces of the system will be situated in the same plane. Referring to the proportions already established, and remarking that sin. P B C = sin. B C Q; sin. Q C D = sin. R D C, &c. we have:—

$$V : W :: \text{sin. } BCQ : \text{sin. } ABP$$
$$W : X :: \text{sin. } RDC : \text{sin. } BCQ.$$

And so of Y and Z. From this it appears, that when a number of parallel forces act upon points flexibly connected, the forces developed in the directions of the connecting lines, are inversely as the sines of the angles made by these lines with the parallel forces. These forces are therefore inversely as the cosines of the angle made by the sides with lines at right angles to the directions of the parallel forces; or denoting the angle by ϕ, and calling t the force thus devoloped;

$$t \propto \frac{1}{\text{cos. } \phi} \propto \text{sec. } \phi$$

When B C is at right angles to the parallel forces, we obtain the relation of the force acting in the direction C B to the force acting in the direction E F, by supposing, as before, that the intermediate lines C D, D E, have become rigid. B C and F E being produced will intersect at O, through which will pass the resultant of Q, R, S, equal to their sum and parallel in direction. Let this be called w, and denote by a the force acting in C B; then t being the force in E F, and ϕ the $\angle$ made by its direction with the direction of a, we have

$$t : a :: 1 : \text{cos. } \phi;$$

$$\therefore t = \frac{a}{\text{cos. } \phi} = \text{sec. } \phi.$$

And $t : w :: 1 : \text{sin. } \phi$,

$$\therefore w = t \,\text{sin. } \phi.$$

It is also evident from these proportions, that

$$w : a :: \text{sin. } \phi : \text{cos. } \phi; \text{ from which } w = a \frac{\text{sin. } \phi}{\text{cos. } \phi}$$

$$\therefore w = a \tan \phi.$$

In order to compare the forces P, Q, R, S, let the angles formed by A B, B C, C D, fig. 8, with lines at right angles to the directions of the forces be called $\alpha, \beta, \gamma, \delta$. If therefore A B be produced, the $\angle$ C B b $= \alpha - \beta$, and in the same manner $\angle$ D C c $= \beta - \gamma$. Adopting this notation, we have these proportions:—

$$P : W :: \text{sin. } ABC \ (\text{sin } CBb) : \text{sin. } PBA$$
$$:: \text{sin. } (\alpha - \beta) : \text{cos. } \alpha$$

$$\therefore \frac{P}{W} = \frac{\text{sin. } \alpha \text{ cos. } \beta - \text{cos. } \alpha \text{ sin. } \beta}{\text{cos. } \alpha} = \text{cos. } \beta \,(\tan \alpha - \tan \beta)$$

$$\text{Again, } W : Q :: \text{sin. } QCD : \text{sin. } BCD \ (\text{sin. } DCc)$$
$$:: \text{cos. } \gamma : \text{sin. } (\beta - \gamma)$$

$$\therefore \frac{W}{Q} = \frac{\text{cos. } \gamma}{\text{sin. } \beta - \gamma} = \frac{\cos \gamma}{\text{sin. } \beta \cos \gamma - \cos \beta \sin \gamma} = \frac{1}{\text{cos. } \beta \,(\tan \beta - \tan \gamma)}$$

Finally, by multiplying these equations we have:—

$$\frac{P}{Q} = \frac{\text{tan. } \alpha - \text{tan. } \beta}{\text{tan. } \beta - \text{tan. } \gamma}.*$$

The other forces will be found to be related in a similar manner. Let C D become perpendicular to C Q or D R, then tan γ = Q, and P : Q :: tan. α — tan. β : tan. β; also, P + Q : Q :: tan. α : tan β.

* See Whewell's Elements of Mechanics.

The principles we have now been considering have been established with regard to a polygon, acted on by given forces, but they may receive a more extended application, by imagining that the equal sides of the polygon become continually diminished until they are less than any assignable quantity, when, it is evident, we obtain *a curve*, or in other words, a polygon, the number of whose sides is infinite. This curve will vary in its nature, according to the magnitude and position o the forces by which it is generated: if, for example, the forces be *equal*, and *radiate* from the centre of the ordinate, the curve will be a semi-circle; if the forces are *parallel*, *equal*, and equally distributed *along the curve*, we obtain the catenary, and if, while equal and parallel, they are equally distributed along the *ordinate*, the parabola is the curve produced. The nature of the forces employed in the production of the semi-circle has already been shown; and with respect to the catenary, it is clear that this curve being defined, as the form which a flexible thread or chain assumes when freely suspended from its extremities, we shall obtain the same curve, if we replace the forces of gravity by others which are equal and parallel, whether their magnitudes be less or greater than the forces they have supplanted. The production of a parabola by equal and parallel forces uniformily distributed along the ordinate. I have succeeded in proving in the following manner:—In the first place, it is clear from what has been said, that whatever be the form of the curve, if we denote by w the sum of the forces acting upon the arc included between the vertex and a given point, and denominate ϕ the angle formed by the tangent and ordinate, $w \propto$ tan. ϕ. If then we assume P A R, fig. 5, to be a parabola generated by the action of parallel forces, we have—

$$\text{tan. } \phi = \frac{NT}{NP} = \frac{2x}{y}$$

$$\text{But } y^2 = px, \text{ or } x = \frac{y^2}{p}, \text{ and by substitution,}$$

$$\text{tan. } \phi = \frac{2y}{p}$$

$$\text{Hence, } w \propto \frac{2y}{p} \propto y.$$

An attempt has thus been made to exhibit in the most simple and intelligible form, some elementary principles, which must tend to systemize and illuminate our ideas upon the nature and mode of action of the several forces to which a suspension bridge is subject. In the composition of this paper, I am much indebted to a chapter in Poinsot's "Traité de Statique;" but a somewhat different view of the subject has here been taken, and some new matter has also been added, which it is hoped will not be thought uninteresting.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XVII.

> "I must have liberty
> Withal, as large a charter as the winds,
> To blow on whom I please."

I. Much as has been said and written about styles of architecture the Consumptive Gothic has hitherto escaped notice, and consequently animadversion. This must not be confounded with so-called Carpenter's Gothic; for it is frequently correct as to outline, but nevertheless quite otherwise as to execution, the mouldings and details being terribly attenuated, whereby a disagreeable meagreness and insipidity take the place of relief and boldness, and instead of appearing carved, the ornaments look as if they had been stamped with a butter-print. Although its design may be exact as to mere pattern, yet if its mullions and transoms be pared away, as not unfrequently happens, to about half their due proportions, as regards the spaces between the former, a Gothic window becomes deficient in that which gives character to one. Nor is it a little strange that while architects affect as they do, to be scandalized at the slightest deviations from the proportions of Greek and Roman columns, they make no scruple whatever of deviating altogether from those proportions upon which the effect of Gothic architecture very materially depends; but because greater latitude and freedom are allowable in that style, with regard to composition, consider themselves at liberty to disregard what may fairly be called its constitutional principles.

II. Now that Brummagem silver, and other Brummagem productions, are distinguished by the name of 'Victoria,'—which, by the bye, is a most left-handed compliment to her Majesty,—we shall probably ere long have a 'Victorian' style, as well as an Elizabethan one, in architecture. Indeed, such style is now beginning to display itself in the rows of houses rising up about the church at Paddington, which are about the most Brummagem affairs in bricks and mortar I ever beheld. And such enormities are quietly perpetrated before our eyes, while good easy critics are comfortably twaddling about styles. That we should come to such abominations in taste—such frightful barbarisms! Better, infinitely better would it have been to have stuck to the unsophisticated, respectable dullness which stamps all the private streets at the West-end of the Town; inasmuch as the absence of all pretension at design is far more tolerable than design run mad—as we perceive it to be among the Paddingtonians. The name of a Wyatt has been mentioned to me—a descendant, I believe, of the illustrious James of 'execrable memory,'—as that of the offender:—yet can it be true? A law, it is to be hoped, will be passed, prohibiting foreigners from passing through Paddington, except they be blindfolded. Let the legislature look well to it: for the honour and credit of our beloved country are at stake. Already have we been sneered at,—nay, reviled and rated in good set terms by certain saucy foreign critics for our Boz-mania and Jack Shephard-mania, which they are pleased to represent as deplorably wretched in taste; and now we shall be cut-up, abused, ridiculed, and made laughing-stocks of, on account of our sins in brick and mortar at Paddington—the more suitable name for which would be Madding-town.

III. "And how," said I to a German friend, on his return from an excursion to the North of England—"how did Newcastle please you? if there be truth in Dibdin, its magnificence must have enchanted you. Come now, be sincere—put away all your continental prejudices: own that at last you have met with something to match the glories you have left behind you."—"Dibdin be d—d!" was the startling reply: "a man who could write greasy puffs on such a farrago of architectural balderdash, is fit only to be flunky to your George Robins. Dibdin must be an absolute dunce to gabble as he does about the 'Northumbrian Vitruvius,' and cry up as superior creations of art, a parcel of tawdrily bedizzened houses, among which there is not one single bit of design to be discovered." "All then that is to be said," returned I, "is that we Englishmen do make confounded fools of ourselves."

IV. The only symptom I have yet discovered of the so much talked of March of Intellect, is that there has been no "laying the first stone" of the New Houses of Parliament,—none of the fussy tomfoolery, with the "silver-trowel," and all the rest of it, which generally takes place upon such "important occasions." The sensible example thus set, will, I trust, be adhered to in future; for I suspect the silly ceremony hitherto in vogue, has frequently dipped rather deeply into the building funds—or into funds that might else have been added to them. In truth it is rather provoking to mortal patience to find that while a church or other building is frequently marred and spoiled for the sake of saving a paltry hundred pounds or so, the money can be found forthcoming freely enough for eating and drinking after the august ceremony alluded to,—for of course all such recreation must be paid for, though it should amount to double the architect's commission. As to the architect himself, he, poor fellow, is generally a nobody—a mere cypher on the occasion—a creature whom the newspapers do not think it worth while to name; the first fiddle on all such occasions being some bustling body, noble or otherwise, who compliments those around him, and is be-complimented by them as the hero of the day.

V. On the outside of his "Palace of Architecture," Wightwick gives us what he calls a Pyramid of Architecture, the *gradini* or courses of which are respectively inscribed with the name of some high authority in the art, the lowermost being that of Vitruvius, and the topmost that of Hosking. Whether this arrangement was merely accidental, or intended to have some particular meaning, I pretend not to say; but it certainly does look much like assigning the post of supremacy and honour to Hosking that staunch Anti-Vitruvianist, and terrible heretic and unorthodox writer, who has not scrupled to abuse the venerable Vitruvius in good set terms,—and to bring his authority into contempt by asserting that a man might just as well study Geography in Gulliver's Travels, as Architecture in the writings of the great Marcus Pollio.—We here also find placed in friendly conjunction, "cheek by jowl," the names of Britton and Pugin, an association that is almost enough to make the latter start from his grave, for in his life-time the association between them was of the most cat-and-dog kind; nor was P. at all sparing of most highly flavoured epithets towards his quandam co-partner,—of whom by the bye, Bartholomew has just spoken as "the immortal antiquary," and whom he no doubt considers to be a most profound and erudite etymologist also.

VI. "There are thieves and paupers of a very respectable kind in the literary world"!!—So sayeth one—whom I take to be no other than Carlyle, in a recent article on Lessing, in the Foreign Quarterly. How many respectable paupers—that is, very respectable people, yet very *poor creatures*, there may be in the architectural world, it might be dangerous to compute; but with regard to thieves there is no occasion to deny that there is abundance of them; since so far from being at all ashamed of thieving or making any secret of it, the greater part plume themselves mainly upon it, and hold plagiarism to be a proof not only of taste, but of talent. A literary thief—at least a "respectable" one, has generally the grace to blush when his pilferings are detected, and the fine peacock feathers with which, jackdaw-like, he has dressed himself up are plucked from him: not so the architectural one, for he boldly challenges your admiration of what notoriously does not belong to himself, yet in which consists all the design and taste his buildings can pretend to. Originality of any kind,—even that which extends to no more than giving a fresh turn to stale commonplace, is generally disclaimed altogether,—under the trumpery pretence that it is exceedingly hazardous to depart from actual precedent; and so undoubtedly it is for those who have no principles of taste to guide them, and who therefore find it most convenient and politic to decry all attempt at originality as dangerous innovation. Nolumus leges Angliæ mutari, is the maxim of our legislators, notwithstanding which they are perpetually tinkering our laws, quashing old ones, and enacting new ones—blundering ones let those say who choose. Why should architects not venture to follow their example?—at all events blunders in taste are not quite so dangerous in legislation.

VII. "Obest plerumque," says the great Roman philosopher, "iis qui discere volunt auctoritas:" which is certainly, unfortunately likewise, most true with respect to architecture, in which a superstitious respect to precedent has impeded the advancement of the art, and hindered that progressive developement which might else take place. Truly fortunate was it for the art that the writings of Vitruvius were not brought to light and studied some centuries earlier, for otherwise the world had, in all probability never beheld that exquisite Gothic style which now enchants us. We of the present day are content to be copyists—to do what has been done before, and nothing more. The consequence is that when we have copied one particular style till we are actually cloyed with it, we go back to some other, not because it is at all better—perhaps not even so good as that we are become sick of; but because it is, at any rate a change. Thus after a most servile and so far erroneous admiration of Grecian examples, we suddenly, with a High Presto! become ardent admirers of Elizabethan architecture, copying all its grotesque whims, its monstrous extravagancies, its absurdities, and puerilities, instead of selecting out its good qualities, and rejecting its vices. But to do this requires more taste and discrimination than fall to every one's lot. Perhaps the recent application of this style to some dashing shops at the West-end of the Town, may help to bring it into discredit for other purposes, and stamp it with the gentility-mongers,—a tolerably numerous class, as vulgar, slow, and of course quite frightful. It happens oddly enough that Wightwick has not given a single instance of this *fashionable* style in his new work, mentioned above in the 5th section of this Fasciculus.

VIII. "The Lord deliver us from patronage," was the half-serious, half-jesting exclamation of one who had had some experience of the pig-headed obstinacy of ignoramusses who, because they hold the purse, fancy their own blundering whims ought to over-rule all other taste. No wonder that poor Peruzzi declined the patronage of Clement VII., who would fain have employed him—not to decorate another Farnesina, but to act as military engineer at the siege of Florence; Such a Mecænas would engage a Ude to cut bread and butter, or one like myself to make a spelling-book. The patronage of the tasteless is the very bane and corruption of art; and the tyranny of those who devote themselves to it in the true spirit of artists. His most gracious Majesty king Midas was a royal patron of the above class; and it is to be regretted that our modern Midasses are not similarly decorated with donkey-ears.

IX. No doubt it will be thought by many that I have already expressed my opinion of Palladio both frequently and plainly enough: but inveterate prejudices are not to be put down by a few blows. They must be attacked again and again, until the mere repetition of the same censures attracts notice, and impresses them on people's attention. I do not pretend to affirm that Palladio possesses no merit whatever, or that he is the worst possible model an architect can follow; yet I certainly do think that he does not deserve to be regarded as a model or authority at all, because there is hardly a vice or solecism which such authority will not be found to justify, if his precedent is considered of any avail. Those whose indolence disposes them to take up with ready-made opinions, which once adopted they do not care to have disturbed, will of course be scandalized at this, and are welcome to be so, in like manner as many would be shocked at what *the* Weber, that is Karl Julius (the most witty and entertaining of all philosophers) has said of the author of Waverley, whom he speaks of as "des zur mode gewordenen *Vielschmierers*, und dustern Schotten Walter Scott," and *Vielschmierer*, be it observed, is a far stronger term of reproach than our English "Scribbler." Poor Sir Walter! a hundred volumes are, in fact, somewhat too heavy a cargo for an author to venture himself with upon the stream of time, for as Voltaire remarks "on ne va point à la posterité avec tant de bagage."

SUTCLIFFE'S PATENT ROTATORY PUMP AND GENERAL LEWIS.

Sir—The following is a description of Sutcliffe's pump with the result of an experiment on the discharging power of one now at work at the Limerick Docks, where it is found far superior to the chain and sucking pumps before in use. From the facility with which it can be applied in all those cases where pumps are required, and not being subject to get out of repair or choaked, it promises to be soon very generally used, not only in hydraulic works, but also in the navy, and those cases where the common pump was before used for household purposes. The patentee has been almost constantly connected with the execution of extensive works, as superintendant under Sir Thomas Deane and Company, and his attention was directed to the subject by the frequency of repairs required for the pumps usually employed in clearing out water from foundations and dams, their great friction, and the unequal flow of water from them; and I am informed that his invention has received the approval of Mr. Rhodes the engineer, and Sir Thomas Deane and Company, the contractors for the Limerick Docks.

In this pump a vacuum is formed by the revolution of an elliptical frame within a cylinder, when the water rising it is carried round in the lunar space between the ellipse and circle shown on section and discharged.

Fig. 1.

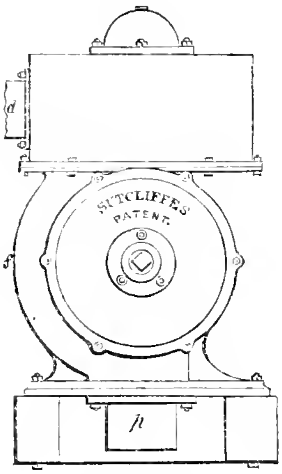


Fig. 2.

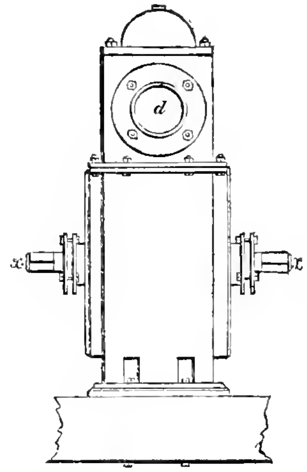

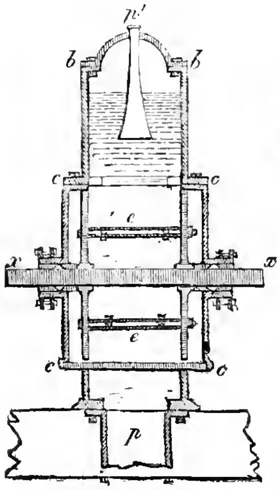

Fig. 3.

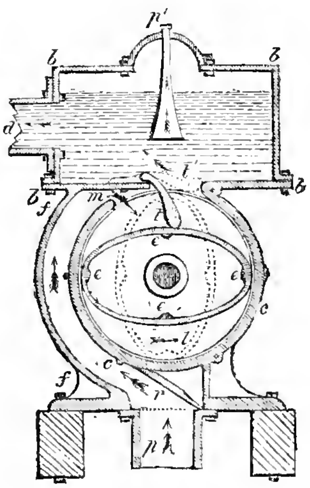

Fig. 4.

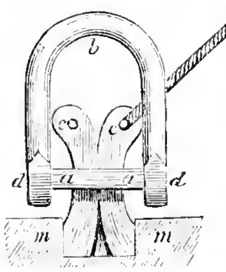
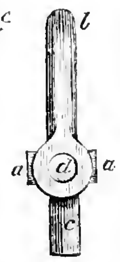
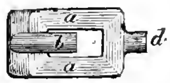
In the annexed figures, fig. 1 is a side elevation, fig. 2 an end elevation, fig. 3 a vertical section along the length, and fig. 4 a vertical section across the width of the pump, and the same letters refer to the same parts in each figure; *x*, *x*, the axis by the rotation of which the elliptical frame *e*, *e*, *e*, *e*, is carried round in the direction indicated by the arrow *l*, in fig. 3; *c*, *c*, *c*, *c*, the cylinder in which *e*, *e*, *e*, *e*, moves both, having the common axis *x*, *x*; *f*, *f*, a jacket forming with the exterior of the cylinder a passage for the rising water from the pipe *p*; *l*, and *l'*, fig. 3, two extreme positions of a tongue which hinders the water brought round in the lunes from *m*, of escaping again at the same place, and which keeps touching the surface of the ellipse in its revolution; *b*, *b*, *b*, *b*, a box into which the water is received and discharged through the discharging pipe *d*, and when *d* is closed, forces the water by the reaction of the air above through the forcing pipe *p'*. When the pump is to be used, water is thrown in from above, which renders the contact between the elliptical valve or frame and the cylinder water tight; after a few revolutions the air is exhausted, and the water rising is carried into *b*, *b*, *b*, *b*, and discharged by *d* or *p'* as before described. It is evident the discharge will depend conjointly on the velocity and sectional area of the water passing from the jacket into the lunes, and the area of the lunes and the velocity with which they are formed, or carried round. When the velocity and sectional area at *m* is sufficient to fill a lune in the time of half a revolution, a maximum effect is produced, and the discharge is found; when the velocity at *m* is sufficient to fill the lunes, by multiplying the velocity of the lunes by twice their area of one. The foregoing figures are drawn from a pump of this construction now at work, and are laid down on a scale of 5-8ths of an inch to the foot, but the handles and fly are not shown. Four men discharge 128 gallons through a mean lift of 8 feet 6 inches in 30 seconds, two men working at each handle, and the fly being about 4 feet 6 inches in diameter. It should not be forgot that the facility this construction of pump affords for the application of a fly wheel, affords one though not the first of its recommendations. The water issues in one regular and continued stream from the discharging pipe, chips and clay attached to them when passed into the pump, getting through without injuring the motion or apparently taking from the discharge.

Fig. 1. Fig. 2. Fig. 3.







The following are sketches of a lewis invented by the same ingenious person, one of which construction is now used in setting the heavy facing to the quays of the before-mentioned docks; some of the stones are $3\frac{1}{2}$ tons in weight. Fig. 1, front elevation; fig. 2, side elevation; and fig. 3, a plan with half the upper ring removed. The same letters refer to the same parts in each, *b* a ring as in the common lewis; *a*, *a*, a collar turning on the axis; *d* and *d*, and *c*, *c*, two pieces inserted into the collar when the lewis is to be used, and also into the mortice, *m*, *m*, in the stone to be set. When the lewis is drawn up, the collar *a*, *a*, presses against the outside sloping shoulders of *c*, *c*, and causes both pieces to approach at top and separate at bottom, thereby pressing the pieces against the cheeks *m*, and *m* of the mortice, by means of which pressure the stone rises with the lewis. The upper portions of *c* and *c*, are perforated to admit a line being tied to them, and by giving this line, when the stone is set, a few smart pulls in the direction *c c*, the piece *c* is easily drawn up through the collar *a*, *a*, or sufficiently to set the lewis at liberty. This lewis has a great advantage over those in ordinary use, as it is more simple in its construction, and general in its application, than any I have yet seen; it will set at all depths of water with equal ease, and when the stone is set, can speedily be drawn up again. The collar *a*, *a*, and the construction of the pieces *c* and *c*, form the distinctive marks between this and the common lewis. It is similar in its manner of acting to the "Devil's Nippers," but is more extensive in its application. By placing the lewis hole over the centre of gravity of a stone, the stone can be let down to its place with its bed horizontal.

Your's, obediently,

John Neville, C. E.

Limerick, June 1840.

ON OBLIQUE ARCHES.—MR. BUCK IN REPLY TO MR. NICHOLSON.

SIR,—After the flourish which has appeared in your last Journal from the pen of Mr. Peter Nicholson, I trust to your candour for the insertion of the following remarks thereon. With them I have sent a copy of my reply to him which was published in the Railway Magazine on the 25th of January last. I have sent it for the purpose of begging the favour of your giving it a place in the Civil Engineer and Architect's Journal, immediately after this, because without it the correspondence is incomplete, and neither Mr. Nicholson's letter nor my observations thereon can be properly understood by those who have not seen the former: and the republication of my letter of that date is the more necessary, inasmuch as Mr. Nicholson in several instances has repeated mistakes which were *satisfactorily* exposed, to every one except himself, in that reply. Relying therefore on your doing so I will proceed.

It may be first proper to state that since my "Essay on Oblique Bridges" made its appearance, Mr. Nicholson has published on the same subject, his "Guide to Railway Masonry," in the commencement of which he has very freely criticised the works of others as well as mine, and if he had done so ably and impartially, I should have had nothing to complain of; but it will be seen by referring to my former letter that he had affected not to have had sufficient leisure to read the work; is it therefore to be wondered at that he should have fallen into errors in criticising it? From the tone of his remarks it is quite obvious that the first and great offence which I have committed in his sight, is the fact of my having published anything on that subject, which he appears to claim exclusively as his own: the second unpardonable offence is the fact of my having, in reply to him, in the Railway Magazine, exposed and refuted the errors into which he had fallen, by putting forth his imaginary "inconsistencies in certain formulæ."

Mr. Nicholson has chosen to sit in judgment upon others and made the preface to his book, where no one could reply to him, the vehicle of his denunciations: and I chose to set the public and himself right upon the subject, so far as I was concerned, by replying to him elsewhere, for which purpose I selected a Journal extensively circulated, and almost exclusively devoted to railway business.

In the latter part of Mr. Nicholson's address, he tells your readers he "has given vent to his feelings at the ingratitude which Mr. Buck has shewn." Therefore, before advancing any further, I beg to observe, I know nothing of Mr. Nicholson except through his writings, I have never seen him, nor have I ever had any correspondence with him except this.

In the introduction to my Essay I made mention of him in the following terms.

"In Nicholson's work on stone cutting, published in 1828, the method of constructing oblique arches with spiral courses is briefly explained, and to it we are indebted for the first principles of the art, but it does not enter sufficiently into detail. Having stated thus much, the author will not hesitate to make use of the principles set forth in that work without further acknowledgement; at the same time it is proper to mention, that the matter which may be found common to both, does not extend beyond a small portion of the first and third chapters of this Essay." Surely any one but Mr. Nicholson would have been satisfied with this.

Alluding to the templates Mr. Nicholson has also given "vent to his feelings," and made use of the following reprehensible language. "Now, Sir, that Mr. Buck should have made these assertions is, to me, a matter of the utmost surprise, seeing that he must have known, when he made them, that he was deliberately stating that which was incorrect."

Here Mr. Nicholson has put himself out of the pale of civilised society, and I most unequivocally repel his accusation, and conscientiously reassert the truth of every word contained in my reply, to which he refers. Mr. Nicholson will be disappointed if after this he looks for very gentle criticism at my hands.

In Mr. Nicholson's letter he has laboured very hard to show that the strictures contained in my reply of last January were erroneous; but I am under the necessity of declaring he has completely failed in the attempt, and moreover that every thing stated by me remains unrefuted, as an attentive reference thereto will make apparent. He has taken especial pains to rebut the following: "this dilemma leads me to infer that Mr. Nicholson is not practically familiar with the subject upon which he has written." And probably it will astonish many when I say that Mr. Nicholson has, but very unintentionally no doubt, confessed that I was correct in coming to such a conclusion; a conclusion at which I arrived from the internal evidence afforded by his writings. He now says in his defence, "I have seen *nine* Oblique Bridges on the Newcastle and North Shields Railway, and *five* on the Brandling Junction Railway, all executed in stone on the principle laid down by me, making, upon the two railways *fourteen* bridges within a distance of about eight miles of Newcastle, and built, AS IT WERE, under my own immediate inspection." This is precisely what I expected; it is a confession that he is "*not practically familiar with the subject on which he has written.*" He "*has seen*" fourteen oblique bridges built within eight miles of Newcastle, and there are thousands of ladies and gentlemen as well as others who can say so likewise.

Mr. Nicholson is highly indignant at my having stated that he adopted from my "Essay," the correct method of showing the joints in the elevation of the face of an oblique arch. Here I beg to observe that the method shown in his work on "Stone Cutting," is erroneous: in his "Guide" he has given that, and added the other which I considered him to have "adopted." No doubt it is just possible he might have found it out by watching the progress of the fourteen bridges which he has *seen* near Newcastle.

Mr. Nicholson exclaims against his having adopted anything as follows: "even if I had been driven to such a strait as to think of, or to stoop to such a thing:" and he also reminds me that "facts are stubborn things." Well, be it so. I think the following is internal evidence afforded by his "Guide," of his having been driven to such a "strait." In my "Essay" reference is made to a line which I have denominated the "*Axial length.*" This term never appeared in any previous work of Mr. Nicholson's, or of any other writer, and I coined the word *axial* to suit the occasion: it is not to be found in any dictionary: but it is found in Mr. Nicholson's recent work, and he has thought proper to insert its signification in his "Descriptive Definitions."

Nearly at the beginning of his letter he says: "I have examined the third chapter of Mr. Buck's Essay, and I can find no method explaining the making of the curved edges of the templates Nos. 1 and 2, plate 26, in my work, to which I refer when I say they are not shown by any other author who has written on the subject: and I have also examined the fifth plate in his 'Essay' which Mr. Buck says contains eight diagrams exhibiting the form of these templates, and I have been equally disappointed, for I can find no such templates exhibited. Mr. Buck does not even show how the radius of curvature of these templates may be found; neither does he give a hint that they are necessary."

Mr. Nicholson appears to state by the above that I have not given diagrams for the *two particular* templates: this is true, because that exhibited by figure 13, in my Essay, and which is very unlike any of his, renders those particular templates unnecessary, and if he were "*practically familiar with the subject,*" he would have discovered that fact, and would have been able to see that it is a much more efficient instrument than those, the omission of which appears to have so much disturbed him. For the same reason I have not shown "how the radius of curvature of those omitted templates may be found," namely, because it is not necessary.

Here I will make a remark which I should not have done had not Mr. Nicholson brought the subject under my immediate notice; and it is that the method given by him for finding the radius referred to is fallacious; but the intolerance manifested by him excludes him from the privilege of being put right.

Mr. Nicholson quotes my statement as to the difficulty of finding a demonstration for the curious property of the mutual convergence of the chords of the curves of the joints of the face of the arch, and then adds most illogically: "This, Sir, I consider to be a sufficient admission of the justness of my remarks, and one which renders it perfectly unnecessary for me to allude further to those remarks at this time." Now it so happens that Mr. Nicholson had never made any remarks upon this subject, it being absolutely impossible for him to have done so, inasmuch as he was previously perfectly ignorant of the facts, and of the property for which a demonstration was sought. He has garbled the quotation and misapplied it. I went on to say that subsequently to the publication of the "Essay," a friend of mine had found one, a beautiful geometrical demonstration; it has not been published however, and I challenge Mr. Nicholson to produce one.

Mr. Nicholson draws a comparison between his work and mine in the following words.

"Mr. Buck's work is only intended for the use of those who may happen to have been trained in a proper course of mathematical study, and which, I believe, is not the case with a tithe of the young men, for whose use chiefly, Mr. B. has written his book. On the other hand, mine is intended as a purely practical work, and as such, I have shown in it how every useful length, distance, or angle of an oblique arch may be found, principally by common arithmetic, from the doctrine of similar triangles."

The young men who are rising in the engineering profession no doubt will properly appreciate the value of the complement here paid to their acquirements by Mr. Nicholson. But I am happy to say that not one with whom I have the pleasure of being connected is deficient of the mathematical knowledge requisite to understand it; indeed, I have in my employ a stonemason, acting as inspector, who makes use of the formulæ, and prefers them to the circuitous and "*clumsy*" rules given by Mr. Nicholson. "Mine is intended as a purely practical work," says he: nevertheless the third part of his "Guide" is headed "Theory of the Oblique Arch." But the fact is, in consequence of his not being "*practically familiar with the subject on which he has written*," his work is altogether *theoretical*, and in some respects very objectionable in practise, which I could easily show, were I disposed to waste my time in doing so.

Mr. Nicholson calls his letter *an address* to me, and concludes it in a dreamy vision of the fame to be awarded to him by "*posterity*," and assuming the motto of the hero of Trafalgar, seems almost ready to exclaim, "Victory, or Westminster Abbey," but to prove how easy is the transition from the sublime to the ridiculous, he closes by saying, "I have now done with him." Very like Nelson indeed!—He fires his pop-gun and runs away!

Your most obedient servant,

George W. Buck.

Manchester, July 18, 1840.

To The Editor of the Railway Magazine.

Sir,—Mr. Peter Nicholson has recently published a work under the title "Guide to Railway Masonry, comprising a complete Treatise on the Oblique Arch." In his preface and introduction he has made some observations and references to a work on the same subject published last June by me, and to which I am anxious of making the following reply, requesting the favour of your inserting it in your valuable Journal.

At page 8 of his preface, in speaking of the forms of the templates which are necessary for working the stones, Mr. Nicholson says, "they are not shown by any other author who has written upon the subject. Now, if Mr. Nicholson will refer to the 3rd chapter of my "Essay," he will find that chapter to be exclusively devoted to an explanation of the method of making the templates and working the voussoirs; moreover, the 5th plate contains eight diagrams exhibiting the forms of those templates.

At page xiv of his "History," at the commencement of the "Guide," Mr. Nicholson says, "The formula CO $=(r+e)$ cot θ tan β, is due to Mr. Buck. It gives the distance below the centre to the point of convergence, into which all the joints in the elevation of the arch meet in the axis minor, supposing that the joints are straight lines, which they are not exactly; having given the angle of obliquity $=\theta$, and the angle in which the bed lines cross the axis of the cylinders $=\beta$, or the angle which a bed line makes with the adjacent springing line. In this formula also $r=$ the radius of the cylinder, $r+e$ the radius of the extrados, e being the breadth of the bed or thickness of the arch." In reference to this remark. I beg to observe that not only is the *formula* due to me, but so also is the discovery of the beautiful and remarkable property of the oblique arch to which it applies. At page 5 of the "Essay," I stated that the joints of the face "are not straight lines, but curves concave on the upper side": and at page 6 I stated that the *chords of these curves* produced, meet in the point to which I have given the name of the focus of the elliptic face. I no sooner discovered this property than I made it subservient to practical utility, of which any one may be convinced by reference to the "Essay." The stability of oblique bridges is intimately connected with, and dependent upon, this property, and the investigation of the problems relating to the limit of obliquity, and the best proportions for oblique arches, cannot be made without it. At the same page Mr. Nicholson, alluding to myself, writes as follows:—"He says the expression CO $=(r+e)$ cot. θ, tan β, included among some others, 'are general, that is, they are applicable to segments as well as to semicircles; but in page 9 he gives $\frac{c \text{ cot.}^2 \theta}{a}$ $(r+e)$ = CO, the eccentricity or focal distance below the axis of the cylinder in the oblique segment.'"

This way of stating it will lead any one to the erroneous inference that I have fallen into a discrepancy, and given irreconcileable formulæ. The explanation is as follows: when it is said "these expressions are general, that is, they are applicable to segments as well as semicircles," reference was made to the two formulæ then immediately before given, namely, CO $=$ r cot θ tan ϕ, and CO $=(r+e)$ cot θ, tan β.

Now at pages 6 and 7, it is shown that the tangent of the intradosal angle, or of the angle which the bed line makes with the springing line in an oblique semicircular arch, in particular cases, $=\frac{\cot\ \theta}{\frac{1}{2}\pi}$ and when it has this value, then CO $=\frac{\cot^2\theta}{\frac{1}{2}\pi}$ $(r+e)$. But because, in practice, this value of the intradosal angle ought sometimes to be departed from, then the distance CO may be obtained by either of the two before-mentioned general expressions.

Again, at page 8 of the "Essay," treating of segmental arches, the tangent of the intradosal angle is given $=\frac{c}{a}\cot\theta$; and in this case CO $=\frac{c\ \cot^2\theta}{a}$ $(r+e)$. But here, again, as before in practice, this value of the intradosal angle ought not to be always adhered to (it requires adjustment to the particular case, as fully explained in the work), and then the distance CO is to be found by one of the two general formulæ before referred to.

Mr. Nicholson's concluding sentence of his "History" is in the following words:—"One thing which we consider defective in Mr. Bucks' 'Essay on Oblique Arches' is, that his instructions are not enunciated under regular heads, so as to call the attention of the reader; he gives no reasons for his rules, nor does he show the principles upon which his formulæ depend. The height of the point CO, Fig. 7, will depend upon the breadth of the bed."

I am really at a loss to conceive what could have induced Mr. Nicholson to make the several incorrect assertions contained in this short paragraph; and to which I shall reply in their order.

First, as to my intentions not being enunciated under regular heads: the table of contents, consisting of the *heads* of the seven chapter into which the work is divided, affords a sufficient refutation to this charge.

Secondly. "He gives no reasons for his rules, nor does he show the principles upon which his formulæ depend." To this it is only necessary to add, that by reference to the work itself it will be evident that the reasons which are geometrical and mathematical, flow naturally from the first principles and contain their own demonstration—the best of all reasons.

Thirdly. "The height of the point 0, figure 7, will depend upon the breadth of the beds." Very profound, indeed! inasmuch as the formula informed him of it, because e in that expression denotes the breadth of the beds.

Mr. Nicholson, at the same page, in speaking of my "Essay," says somewhat affectedly, "*as far as we have had leisure to examine it.*" Surely before any one can be competent to criticise a work he must read it, otherwise he will naturally and inevitably fall into such mistakes as Mr. Nicholson has here been guilty of.

It is not my wish or intention to be drawn into a review of Mr. Nicholson's book, but I think it right to make the following few remarks. In problem 9, referring to plates 28 and 29, he gives directions for radiating the joints of the face of the arch in two different ways. By his first method the joints are to be at right angles to a tangent to the elliptic curve; by the second method they will radiate to the points of convergence, which I have denominated the focus; this latter method is that given by me, and which Mr. Nicholson has here adopted. Now, if the voussoirs be worked in spiral beds, *according to his own rules*, they must necessarily radiate in this way; and consequently they cannot be made to radiate as described in his first method, *unless the beds are worked in some other way, the directions for which he has not given.* This dilemma leads me to infer that Mr. Nicholson is not practically familiar with the subject on which he has written. I have confined myself to the points referred to by Mr. Nicholson's strictures, or I might have added more on the subject.

Here I take the opportunity of saying that after making the discovery of the mutual convergence of the chords of the curves of the face of the arch, and after obtaining the formulæ applicable thereto, I long sought in vain for a *demonstration* of the generality of this property. On applying to my mathematical friends, both in London and Cambridge, I was equally unsuccessful. Under these circumstances, being experimentally quite certain of the existence of this property, I assumed it as a postulate in the "Essay," and the whole of the investigation contained in the 7th, or concluding chapter (*the only part of the work which I consider theoretical,*) is based upon it. The publisher, Mr. Weale, well knows how anxious I was to have given a demonstration in the work, and that I was finally under the necessity of publishing it without, although no one appears to have noticed this deficiency.

However, I have now the gratification of adding that about four months back my highly scientific friend and assistant, Mr. W. H. Barlow, son of Professor Barlow, of Woolwich, has accomplished a beautiful geometrical demonstration, which, in the event of another addition being called for shall, with his permission be given therein, together with some further practical information and additional investigations which I have recently made.

I am, Sir, your's truly,

George W. Buck.

Ardwick, Manchester, January 21, 1840.

MR. BARLOW IN REPLY TO MR. NICHOLSON.

Sir—I perceive in your last number a communication from Mr. Nicholson purporting to be a reply to Mr. Buck, and to the remarks signed W. H. B., which appeared in your Journal for May last. Being the writer of those remarks, I trust you will allow me to say a few words respecting that part of Mr. Nicholson's communication which refers to them.

Mr. Nicholson's observations are chiefly confined to the problem for finding "the curved bevels for cutting the quoin heads of an oblique arch," relative to which I stated that there was considerable obscurity as to what species of joints it referred. He replies, "Now, Sir, I assert that W. H. B. must either have been very inattentive or very stupid not to have observed to what species of joints the problem referred, since every page in which I treat of the oblique arch, has the words 'on the oblique arch with spiral joints,' placed in capitals over it."

Now Sir, I assert that the application of a problem is not determined by the capitals placed over it, but by the principles on which the construction is founded, and this problem is based on the following assumptions, namely, that "the bed and joint lines on the face are perpendicular to the curve which is the intersection of the cylindric surface and the plane of the face," (I quote Mr. Nicholson's own words). Also that the joint lines in the face are straight lines, and that they divide the curve of intersection into equal parts: all of which assumptions are incorrect, and not even an approximation to the truth in an arch of much obliquity, that is to say, with *spiral joints*, while three of them hold good for an arch with *plane joints*, namely, that the joint lines in the face are straight lines, that they are perpendicular to the curve of intersection, and that they divide the curve of intersection into equal parts. I think therefore it will be admitted that there *was* some difficulty in guessing what sort of arch the author wished it to be understood he was referring to. One point, however, the reader may rest quite assured of, namely, that whatever species of oblique arch the problem was intended for, it is about as near the truth for one sort as it is for another, which is an advantage in the construction the public will no doubt appreciate. The fact is, it is only correct for a *square arch*, and the more the arch differs from the square or the greater the obliquity, the greater will be the error in the construction. Mr. Nicholson gives it as a "near approximation," and says that "its simplicity is ample compensation for its introduction;" but if he really is practically familiar with the subject on which he has written, he must be aware that in cases of much obliquity, particularly in arches which are semicircles on the square section, this construction would lead to very great error, and could not be made use of.

The other discrepancies I pointed out in his book, with the exception of two to which he confesses, are only answered by personalities, which may go for what they are worth; it is not my intention to return them in kind, and I can only regret that Mr. Nicholson's resources suggested no other way in which he could reply to my remarks.

I am, Sir, your obedient servant,

WILLIAM H. BARLOW.

Manchester, July 17, 1840.

YORK MINSTER.

SIR,—As no account of York Cathedral has appeared in your valuable Journal since the late lamentable fire, probably your readers may feel interested in the following short notice of its present state, which I am enabled to give from personal inspection. The newspaper accounts have led many to suppose, that the last caused little less destruction than the former fire: but though the damage has been most appalling, this has been by no means the case. The fire did not extend eastward of the central tower, which, together with the transepts, remain entirely uninjured; these portions are now walled off from the nave, ready for the commencement of repairs in that part of the structure. On first catching sight of the exterior, it would hardly be perceived that any fire had ocurred, since the only parts to be observed wanting are the roof of the nave, and the mullions of the top windows in the south-west tower, that in which the fire commenced. The tower has sustained considerable damage, there being, I am given to understand, several large cracks in the masonry; but as the blocks in ancient works are united with a tenacity unknown (?) in modern erections, it can hardly be necessary or expedient to rebuild entirely this part of the edifice. The side aisles are untouched, but the roof of the nave is open to the sky its whole length. Though the heat of the burning timbers must have been excessive, the clerestory windows are perfect, and their stained glass is, I am happy to say, but little broken. The beautiful west window, the glory of its date, remains as before, but the wooden door beneath it was destroyed. The columns and capitals have received less injury than might be supposed, though not one has entirely escaped. The restoration will be attended with little difficulty should the requisite funds be obtained, and it is a matter of surprise that more vigorous exertions, in furtherance of this object, have not been made by the profession, who should look upon the cathedral as their own property. Viewing it in this light, I felt much chagrined at being refused by the dean, though in a very polite manner, the free range of the edifice, having visited York Minster with the express intention of studying closely its decorative and constructive beauties. All true lovers of our noble art must ardently hope the day may soon arrive, when no fee will be required for the inspection of any national monument. Since the former fire, all the screens in the choir have been glazed with plate glass, and the most happy effect in the reflection of the *stained* glass is caused. At Beverley the artist meets with no impediment to the prosecution of his studies, and is allowed to wander about at his will, without the payment of any fee. Perhaps too little care is taken to prevent plunder, and it would be better if a few attendants were stationed about the Minster, who should not, as at Hampton Court, be allowed on any account to exact money. But at York, and indeed at other cathedrals, the choir is kept locked, and you are admitted by the verger; so that sketching, unless you happen to be personally known to the dean, is out of the question. If you think the foregoing remarks worth notice, I shall feel obliged by their insertion,

And am, Sir,

Your very obedient servant,

A LOVER OF THE BEAUTIFUL.

47, *Lower Stamford Street*,
July 20th, 1840.

[The Institute and the Society should endeavour to remove such obstacles as our correspondent complains of, and obtain permission for members of the profession to take sketches and drawings of cathedrals and public buildings.—EDITOR.]

MR. GODWIN'S PAPER ON STAINED GLASS.

SIR—Mr. Godwin has entered with such warmth and energy on the advocacy of the claims which the art of painting on glass has upon us for protection and encouragement, that it is to be hoped he will not allow his efforts to stop where they have begun, but that he will continue to call public attention to the present languishing state of the art, until it appear to be in some degree roused.

There is a further reason for supervision just now, if it be true, as stated in your last number, that the Dean and Chapter of Westminster are about to glaze some of the windows in the Abbey with stained glass. Unless the old method be pursued in the design and execution of them, they may as well put up a few painted blinds, and save the money the glass would cost.

A LOVER OF ART.

REVIEWS.

Second Series of Railway Practice, a collection of Working Plans of Public Works. By S. C. BREES, C. E. London: Williams, 1840.

The success of the first series of Mr. Brees's work called Railway Practice has produced the present continuation, which, although under the same title, is extended to engineering works in general. The present volume is calculated to be of great use, as the author has profited by the experience gained in his former essay, and successfully catered for the wants of the public. Most of the illustrations are from recent works, with the exception of two or three of works by Telford and others, and include, besides railways, the Southampton and Croydon locomotive engines by the Rennies, the swing-bridges at St. Katharine's and the London Docks, and Grand Western Canal, locks on the Forth and Cart Canal, and River Cam, Quay Wall and Cofferdam of Sunderland Harbour, pile-driving machine at the new Houses of Parliament, &c. The plates are well executed, and exhibit very learly all the minute portions of the work. Appended to the workf there are several specifications, which form a valuable portion o the volume. The work is one which we can with justice recommend to our readers.

Glossary of Terms in Civil Engineering. By S. C. BREE, C. E.

A dictionary of engineering terms was one much wanted by the student and the public. The architects have had dictionaries for some time, and it was certainly required that the other profession should be as well provided. Mr. Brees's work seems carefully compiled, and is extensively illustrated; as it is not yet in its complete form, and we have had merely the proof sheets submitted to us, we shall defer the farther consideration of it until next month.

Architectural Remains of the reigns of Elizabeth and James 1st. By CHARLES JAMES RICHARDSON, Architect, F.S.A., M.I.R.A. Part 2.

This second part is decidedly an improvement on the former one, it contains some very excellent specimens of the style, and will prove to the lover of Elizabethan architecture a rich treat to peruse. We are compelled to defer our remarks until next month, when we shall examine into the merits of the work more minutely. We shall here do no more than remark that the perspective views are treated more tastefully and more pictorially than in the first part. The mansions of Burghley, Kirby, and Agnes Burton, furnish the principal subjects; and whichever opinion may be entertained in regard to their style, several of them are fine specimens of it, and eminently picturesque as compositions.

Treatise on the Theory and Practice of Naval Architecture. By AUGUSTIN B. CREWZE, Member of the late School of Naval Architecture, &c. Edinburgh: Black. 1840.

THIS is a reprint of the article Ship Building, from the Encyclopedia Britannica, and a work well calculated both from that circumstance and its own intrinsic merits to become a popular treatise. Such a form necessarily restricted the author within certain limits, and forced on him the option of neglecting either the theory of his subject, or the constructive portion, and as the latter has been the subject of numerous works, it is less perhaps to be regretted that Mr. Crewze should have chosen to elucidate the general principles of the art, with which he is so fully conversant. The theoretical portion derived from the best authorities, foreign and native, and illustrated from original sources, is perhaps one of the best works to which the student can be referred. The practical part good as far as it goes, is confined in itself, and in the view it takes of the subject, very little being said of steam navigation, and no general account of iron ship-building, steam ship-building, &c. This is to be regretted, for these departments are certainly neither of themselves, nor considered with regard to the future, as the least important branches of naval architecture.

The history of ship-building is sound and good, and is as useful as it is interesting, we cannot however make any extracts from it. The author's observations on the present state of his art, we are also obliged to dismiss thus cursorily, although the subject is one imperatively requiring public attention, and to which the notice of our readers should be directed. This work will doubtless go a great way towards dispelling the ignorance and prejudice which exist on this subject, and towards a reform so much demanded in the scientific department of the dockyards. We think with Mr. Crewze that the tonnage laws and legislative restrictions are the true root of the evil, for otherwise we feel convinced, and we think the history of the art shows it, that our countrymen are not so far deficient but what, as in every other case, they would have distanced their competitors. We are favourable to a restoration of the Naval College, but then it must be an open institution, not a jobbery for a score of cadets, but an establishment where the merchant ship-builder and the artisan may obtain instruction on fair terms. As Mr. Crewze has well demonstrated, nothing has been gained by exclusiveness, and nothing will be gained, so that the sooner the last traces of "the mysterie of shippe buildinge" are got rid of the better. The character of the pupils of the late institution Mr. Crewze has best defended by the proofs he has given in this work of their capacity and attainments; their contributions to the Papers on Naval Architecture, and to the present treatise, would do honour to any profession.

Although this is an elementary treatise, it contains so much valuable matter that we should, if our space permitted, make copious extracts from it; most of the tables for instance are very valuable. Perhaps one of the best specimens will be the following comparison of the technical differences between French and English ship-building, derived from Mr. Crewze's own observations, we are obliged however to omit the illustrations.

We shall now proceed to notice some of the peculiarities observable in the French practice of ship-building. The characteristic difference in their system from our own, which would strike an observer accustomed to English ship-building, would evidently be a less expenditure of material.

The French have retained the old system of frames and filling timbers. Frequently the frames are close jointed throughout their height, and the filling frames put up as single timbers. The filling timbers are also frequently of fir. Both frames and filling timbers are chain-bolted. There is no shelf under the beams, only a thick clamp, and a wide chock worked upon the short stuff, and up to the beam. There are generally three side binding strakes faced one inch on, and scored one inch over the beams, and bolted together by in and out bolts passing through the water-way, which is also faced and scored in the same manner. These bolts are secured with nuts and screws at the points, on the outside plank.

The water-way is not always scored over the beams, but is sometimes brought plain on their ends. The bolts of the binding strakes, which are then also merely brought on to the beams, secure its lower edge; and in both cases it has in and out bolts through the ship's side, to secure its upper edge.

The method of connecting the beam-ends with the ship's side, which appears to be most generally adopted in the French ships at present, consists of a chock under the beam, securely bolted through the ship's side, the points of the bolts being set up with a nut and screw. The beam-end hooks over the head of this chock. A plate-knee similar in shape to that known in the English service as Roberts' knee is brought on each side against the chock and beam; but these knees, instead of having a short arm against the ship's side for taking in and out fastenings, themselves form the bolt, each knee having an arm which is driven through the side by means of a shoulder worked in the knee, similar to the shoulder of a dog-bolt. The outer end is secured by a nut and screw. The security of the plate-knees to the beam and chock consists only of three screws in each arm, and one screw in the diagonal brace. These screws are not above five inches long. Thus the security of either knee is completely unconnected with that on the opposite side of the beam.

The wales, diminishing stuff, and plank of the bottom, are all treenail-fastened, the buts are secured with two bolt-nails in the timber on which the but is placed, and a through-bolt is driven in the timber next the but. In some instances the plank is nail-fastened, but whether with nails or treenails it is double fastened. The treenails are not caulked on the ceiling, but wedged with conical wedges. Most of the principal bolts, as those of the water-ways and chocks, under the beams, are set up outside with a nut and screw; and great care is taken to omit the fastening of the wales and outside planking, wherever these bolts can be advantageously made to answer as fastenings for them.

There is no regular system observed in shifting the buts of the plank, as there is in the English service; but the planks are worked to their full length, without reference to the shift: the only rule which appears to be observed is, that there shall be about two feet shift between the buts of following strakes.

Rather an interesting experiment as to the possibility of diminishing the scantling of the timber, to any great extent, which is used for building large ships, is in progress in the French navy. The Surveillante, a large frigate, was built wholly of small timber, about ten years ago, and as yet the reports on the system are favourable.

The following is an outline of the plan on which she was built.

The keel, stem, and stern-post are formed of various pieces of timber combined.

The several lengths of the centre piece, or core, are scarphed together, while the side or strengthening pieces only but with plain buts; care being taken that the buts and scarphs give good shift to each other.

There are in this system no other frames than those which form the sides of ports, and the timbers composing these frames are bolted together, without leaving any opening between them, that is, close jointed. The spaces between the frames are filled in with single timbers, or rather with a frame work of timber fitted together.

The cant-bodies are framed as in the ordinary method, the after-body timbered round to the post without transoms or fashion-pieces.

From the main-deck upwards the scantlings of the frames are not different from those of a ship of a similar size built in the usual manner; but below this line there is a very considerable reduction. This reduction commences at the lower edge of the gun-deck clamps, and there a couple of thick strakes are worked up to the lower edge of these gun-deck clamps, to form an abutment for a series of internal timbers, brought on the inner surface of the timbers of the frame, and crossing them at an angle of 45°, the upper ends being placed forward in the fore-body, and aft in the after-body. These timbers but at their heels on the heads of a series of internal floor-timbers, brought on the upper surfaces of the floors of the frame. These internal floors are laid athwartships. The openings between the timbers of this internal diagonal frame are filled in with wedge-fillings, so that the whole hold presents one smooth surface for stowage.

Wherever there is an athwartship bulk-head, there is a system of riders worked on the inner surface of this diagonal frame, but taking a vertical direction. The timbers of these bends of riders are not wrought side by side, but one series of timbers is worked on the inner surface of the other, and the bolts pass in and out through both, and through the bottom. These riders run up to the lower deck, and a beam is so disposed with respect to each bend of riders, as to be secured to their heads, and form a part of the system. The bulk-heads which necessarily fill in the space between the beam and the riders run diagonally up on either side the middle from a midship pillar to the beam and riders. Each bulk-head is water-tight.

It is lamentably true, we fear, that the French are superior to us in many departments of naval architecture, and it is therefore incumbent on all classes interested in the national prosperity to exert themselves to remove the legislative obstacles, which interfere with our progress, seriously injure us at present, and menace ruin for the future. Englishmen only want to be allowed to go in the right way, and not to be forced into the wrong way.

GILDING OF METALS BY ELECTRO-CHEMICAL ACTION.—M. de la Rive has succeeded in gilding metals by means of this powerful action. His method is as follows: he pours a solution of chloride of gold, (obtained by dissolving gold in a mixture of nitric and muriatic acid,) as neutral as possible and very dilute, into a cylindrical bag made of bladder; he then plunges the bag into a glass vessel containing very slightly acidulated water, the metal to be gilded is immersed in the solution of gold, and communicates by means of metallic wire with a plate of zinc, which is placed in the acidulated water. The process may be varied, if the operator pleases, by placing the acidulated water and zinc in the bag, and the solution of gold with the metal to be gilded on the glass vessel. In the course of about a minute, the metal may be withdrawn, and wiped with a piece of linen; when rubbed briskly with the cloth it will be found to be slightly gilded; after two or three similar immersions the gilding will be sufficiently thick to enable the operator to terminate the process.—*Athenæum.*

MR. PARRIS'S DECORATIONS.

A visit to a series of paintings by Mr. E. T. Parris for the decoration of the drawing-rooms at Redbourne Hall, the seat of the Duke of St. Albans, has afforded us more pleasure than we can well express: not simply by the beauty of the paintings themselves and the mind which shines in all, (of which more anon,) but as an indication that decorative art will yet be made to take its proper place in England, and that we may even now triumphantly refute the statement which has been made more than once, that if we need able artists in this department, we *must* resort to the continent for them. England is capable of the highest efforts of art in every branch, if opportunity for the exercise of talent be given, and fair play be but afforded the possessors of it, and we cry shame on those amongst us who would attempt to gainsay it. We shall have occasion hereafter to speak more fully on this head in connexion with fresco paintings, with which it is proposed to decorate the new Houses of Parliament, but at present must confine ourselves to the pictures which have given rise to these remarks. They consist of six large paintings in panels, and a variety of smaller groups and compositions, to fill surrounding compartments. Paintings *à la Watteau*, were the task prescribed to Mr. Parris, and a few rustic beauties and attendant swains beneath wide-spreading trees were all that would have been needed to comply with the terms. With a proper feeling of a painter, however, Mr. Parris has disdained his models, and boldly taken his own path: he has abandoned the constantly repeated nothings of that school, and in their stead, although of course at much greater cost of mind, has produced a series of pictures which all tell a long story of love, poetry, and thought, and are in themselves most elegant and graceful. The subjects are English, French, Indian, Italian, Swiss, and Grecian habits and feelings, each picture being appropriated to a different country, and the manner in which the artist has contrived to convey these is worthy of the greatest admiration and praise. In the panel appropriated to Italy, for example, we have in the foreground of a delicious landscape, music and painting suggested to the mind by a group representing Raphaelle sketching, and the Fornarina, with her guitar, gazing with rapture upon the production of his pencil, while, passing down a ravine at the side, is a peasant woman with a basket of fruit upon her head, in whom is recognized the model of one of the most beautiful works of the divine master. In the Grecian painting we have the sun setting on decaying monuments of the mental energy of her sons when Greece *was* "living Greece" while a modern Greek soldier is listlessly reclining at a well, and inquiring his path of the peasants. We cannot afford space to particularize the whole of the paintings, although each is eminently worthy of a detailed examination; nor can we now venture to add any further remark than that they reflect the highest credit on Mr. Parris as a decorative artist, and will serve to implant a taste and teach to think.

RAILWAY REPORT.

Fourth Report from the Select Committee on Railway Communication.

The select committee appointed to inquire into the state of communication by railways, to whom several petitions were referred; and who were empowered to report their opinion and observations, together with the minutes of evidence taken before them, from time to time, to the house, have further considered the matters to them referred, and have agreed to the following report:—

A considerable number of petitions have been referred to your committee, suggesting the justice and expediency of altering the present system on which railway passengers are taxed.

Much evidence upon this subject was collected by the committee on railways during the last session of Parliament, and your committee have also entered fully into the same inquiry; from both which inquiries your committee are satisfied that this question is of great importance to the public at large, and especially to the poorer classes of the community; and that, in proportion as railway communication is extended through the country, the unequal pressure of this tax will be more severely felt, inasmuch as it will be found to limit the accommodation which railways might otherwise beneficially afford to the labouring classes.

The great advantage which would result to these classes from the establishment of railway communication was repeatedly urged as an argument in favour of these undertakings. To convey the labourer cheaply and rapidly to that spot where his labour might be most highly remunerated, was frequently stated to be one great benefit which would be derived from opening these new channels of intercourse, while it was added that the health and enjoyment of the mechanics, artizans, and poor inhabitants of the large towns would be promoted, by the facility with which they would be enabled to remove themselves or their families into healthier districts and less crowded habitations. Your committee believe that Parliament would deeply regret to find that the tax imposed on railway passengers had a tendency to deprive the labouring classes of these promised advantages, and especially when it is seen that in those parts of the country where the pressure of this tax is most severely felt, the revenue derived from it is insignificant in amount.

The income derived from the duty on railway passengers during the last six years has been, in the years ending

5th January 1835	£ 6,852
1836	8,693
1837	10,296
1838	16,892
1839	39,570
1840	72,716

A reference to the Appendix will show, that of the sum of £72,000 derived from this tax during the last year, £53,000 was received from the five following lines, namely, the Grand Junction, Great Western, Liverpool and Manchester, London and Birmingham, London and Southampton; so that those railways in Scotland and in the North of England which derive their income, as connected with the conveyance of passengers, chiefly from the poorer classes of society, and which suffer most from the present tax, contribute in a very small proportion to the revenue.

The effects of the present system of taxation are very clearly pointed out by witnesses practically conversant with railway communication.

The present duty on railway passengers is fixed by the act 2 & 3 Will. 4, c. 120, which states that "the Proprietor or Company of Proprietors of every railway, along which any passengers shall be conveyed for hire, shall pay for all such passengers at the rate of one halfpenny per mile for every four passengers so conveyed."

Every passenger, therefore, whatever may be his fare, is taxed to the amount of one-eighth of a penny per mile. It is obvious, that while the tax is the same on each passenger, the proportion which it bears to the fares of different classes of passengers must vary considerably. The operation of this tax is well illustrated in the observations of Mr. Smith, the assessor of stage-coach duties: "Suppose a line of 120 miles, and three classes of carriages; suppose the first class fare to be 3d. per mile or 30s., the second class to be 20s., the third class to be 10s., the duty on each passenger would be 15d." This is a large proportion on the lowest fare, and its effect must be to prevent railway Directors reducing their charges for the accommodation of the poorest class of passengers. A comparison of the mileage duty with the fares of different railways will be found in the Appendix, from which it will be seen that the proportion of the mileage duty to the fares on the London and Birmingham is 1-22nd, while on some of the Scotch railways it amounts to 1-10th, and in one case even to 1-6th.

By examining the fares actually paid on different railways, it will be found that, while, in some cases, the first class passenger pays a tax of only 3¼ per cent. on his fare, the third-class passenger is taxed 12, and in some cases 15 per cent.

This inequality of taxation tends materially to diminish the profits arising from the third class passengers, and thereby operates as a discouragement to Railway Companies giving that accommodation which the labouring class might otherwise derive from railways. The real hardship of this result deserves the greater attention on the part of the Legislature, because railway communication has superseded, and in many cases destroyed the conveyance by means of waggons, vans, and carts, which afforded a cheap though dilatory mode of travelling to the labourer and his family. How much the poorest members of society are interested in some alteration of the present duty may be seen by referring to the evidence of Captain Lawes, in regard to the hand-loom weavers, and also in the answers of Mr. Lindsay Carnegie, and other gentlemen connected with the Scotch railways, from whose statements it appears that the tax will, on some of these lines, almost put an end to the passenger traffic, inasmuch as the Railway Directors must raise their fares to an amount which will exclude the chief part of the present passengers from the line. The pressure of this tax is now for the first time felt on many lines of railway; because, in former years, the Lords of the treasury have exercised a power given to them by the act 2 & 3 Will. 4, c. 120, and have allowed many of the Scotch and some of the English railways to pay an annual composition in lieu of this tax; this indulgence, however, which was a great accommodation to Companies opening railway communications in the poorer districts of the country, is now no longer granted, and your committee see many objections to the future exercise of such a power by the treasury.

In considering the question of railway taxation, Parliament ought not to overlook the facts which were elicited by the inquiries of the committee of last session, and which tend materially to increase the objections to a continuance of the present system. It was stated by the chairman and deputy chairman of the Leeds and Selby Railway that, in the year 1836 they raised the fares on that line to an amount which diminished greatly the number of passengers; but they added, that by this increase of fare, although they lessened their number of passengers by 12,000 in the year, yet they augmented their profits by £1,300. Evidence to the same effect has also been given by the chairman of the Bolton and Bury Railway; and a reference to the returns of some of the railways, contained in the Appendix, will further prove the same fact.

Wherever the interests of Railway Proprietors and of the public are at variance, it is probable that the community will be in some degree restricted from the benefits which railway communication is capable of affording; your committee, therefore, believe it to be inexpedient to continue a system of taxation which tends to separate the interests of the Railway Companies and of the public, and which will gradually exclude a great number of persons from the benefit of cheap conveyance.

Two modes of altering the present system of taxation have been proposed, by which the inconvenience above mentioned would be removed.

One suggestion is, to substitute a per-centage on the gross receipts derived from passengers, in lieu of the present tax. The assessor of stage-coach duties, an officer in the department of stamps and taxes, has stated that five per cent. on the gross receipts derived from passengers, would produce about the same amount of revenue as is raised under the present system. This would relieve railways from that inequality of which many complain; and several of the petitions referred to your committee recommend this as the best course which could be adopted.

Another suggestion has, however, been offered to your committe, which would be much more favourable to the interests of the public, namely, to establish a graduated scale of taxation, by which the amount of the tax should be made immediately dependant on the amount of the fare: the great advantage such a system would be that it would act as a check on high fares, and would hold out an inducement to Railway Companies to accommodate every portion of the community.

A scale of graduation has been submitted to your committee by Captain Lawes, which will serve to illustrate this plan. Many Railway Companies are limited by Act of Parliament to a maximum charge of 3½d. per mile for a passenger. Captain Lawes proposes that on all fares exceeding 70 per cent. of the maximum allowed by the act, a duty of 10 per cent. should be levied; on all fares exceeding 40 and under 70 per cent., a duty of five per cent. should be levied; on all fares below 40 per cent. a duty of two and a half per cent. should be levied.

Mr. Wickham, the chairman of the stamps and taxes, stated his objection to the plan to arise from a belief that such a graduated scale would be evaded, and that the revenue would suffer a loss, or at least would not receive the increase which may be expected from a continuance of the present system.

According to the calculation made by Mr. Smith, upon the accounts rendered to your committee by several Railway Companies, it appears that there would be a considerable increase of duty by the adoption of the proposed scale.

Your committee have examined into the different objections urged against a graduated scale, which are, the danger of fraud, by which the revenue might suffer, and the difficulty of collecting duties varying in proportion to the fare.

It is the interest of every Company that all its accounts should be kept in a clear and intelligible form, and in this respect the interests of the Company and of the Government are identical; under a proper system of accounts it does not appear to your committee that frauds could be practised without detection: and the mode of issuing tickets adduced by Mr. Edmonstone, or some similar method, would afford considerable facility for the introduction of a graduated scale of duty.

Your committee do not recommend that the scale proposed by Captain Lawes should be adopted, because they think that the duty of 10 per cent. would be too high; but they would recommend, that wherever no maximum has been fixed by Act of Parliament, 3½d. per mile should be considered to be the maximum, for the purpose of this graduated taxation; and that on all fares exceeding 70 per cent. of this maximum, a duty of 7½ per cent. should be levied: on all fares exceeding 40 and under 70 per cent., a duty of 5 per cent. should be levied; and on all fares below 40 per cent. a duty of 2½ per cent. should be levied. They believe that a scale thus graduated would be found more just than the present system, and that while it would not diminish the revenue, it would afford relief and continued accommodation to the poorer classes of the community.

Your committee would further suggest, that if it be expedient that such an alteration should be made, it is desirable that it should be carried into effect with as little delay as possible, because every alteration in the principle of a tax becomes more difficult in proportion to the extension of the traffic to which it applies; the traffic itself is thereby more deranged, and especially in this case it is expedient that in those districts where railways have been allowed to compound for the existing tax, a substitution to the graduated scale should enable them still to afford accommodation to the labouring class, before they have been induced to abandon their present system of cheap conveyance.

Two other subjects have been incidentally brought under the notice of your committee, on which they are desirous of offering a few observations to the House.

The rapid conveyance of troops from one part of the country to another is occasionally an object of great national importance; and, for this purpose, provision is annually made in the Mutiny Act, whereby in cases of emergency "all justices are required within their several jurisdictions to issue their warrants for the provision not only of waggons, wains, carts and cars, kept by or belonging to any person, and for any use whatsoever; but also of saddle-horses, coaches, post-chaises, chaises and other four-wheeled carriages kept for hire, and also of boats, barges, and other vessels used for the transport of any commodities whatsoever upon any canal or navigable river." Your committee recommend that similar powers should be taken with regard to railway conveyance, on payment of a reasonable sum in consideration of the accommodation required.

It appears that on the Great Western Railway experiments have been made to a considerable extent, with a view of ascertaining the best means of conveying intelligence through the medium of electricity. There is no necessary connexion between railways and this new mode of communication, except that a railway possesses continuity of property between two distant places; and, also, that the numerous servants of an established railway are available to protect the machinery required for the purposes of this communication.

Mr. Wheatstone, Professor of Experimental Philosophy in King's College, has for some years turned his attention to this subject, and has, in conjunction with Mr. Cooke, obtained patents for his inventions. From his evidence, which is especially deserving of notice, it appears that there is no difficulty in conveying intelligence to any part of the island, with an almost instantaneous rapidity, by means of a few copper wires, and small galvanic batteries. There is great ingenuity in the various modes in which Mr. Wheatstone has applied the power of electricity to alphabetical communications, and your committee believe that in a short time further improvements in this mode of intercourse will simplify the machinery, and render the correspondence between distant parts of the island more speedy and certain than by means of such telegraphs as have been usually employed.

Mr. Saunders, the secretary of the Great Western Railway, states the expense of constructing the electrical telegraph on the line of that railway to have been from £250 to £300 a mile. This description of telegraph, however, when once constructed, is worked at a very trifling expense, whereas the telegraph now in use between London and Portsmouth, independent of the original outlay, costs about £3,300 a year, and the lines of telegraphic communication to Plymouth, to Yarmouth, and to Deal, were abandoned in the year 1816, on account of the expenditure required for their maintenance.

Whenever a telegraph shall have been laid down between London and the other ports and mercantile cities of the island, it will give to its proprietors great advantages in obtaining and transmitting information, which must be attended with most important results. For the purposes of the railway itself this telegraph may also be frequently used to prevent the risk of accidents and to obviate delay and inconvenience.

Your committee are of opinion that circumstances may arise in which it may be very inconvenient to leave in the hands of a private company, or possibly of an individual, the exclusive means of intelligence which this telegraph will afford; and it cannot fail to be of paramount importance that the government should be furnished with similar means of procuring and transmitting intelligence, and they believe that no Railway Company will object on fair terms to give every facility to the government for establishing a line of electrical communication over the whole length of their railway.

Your committee are aware that they have not fully developed the great and increasing importance of this subject, which perhaps does not fall strictly within the terms of the subject-matter referred to them, but they are most anxious to fix the attention of the House and of the public on a discovery which is no less susceptible of useful than of dangerous application.

July 2, 1840.

ADCOCK'S PATENT FOR RAISING WATER FROM MINES.

At the last quarterly meeting of the Manchester Geological Society, Mr. Adcock, C.E., read a paper on his invention for the raising of water from mines and other deep places, and illustrated his subject by numerous diagrams and cards of data, which excited much attention. This invention is unusually novel; it is wholly unlike every thing that has preceded it; and should it answer as well in practice, in the large way, as it appears to have answered in the experiments that have been conducted upon it, it must be regarded as one of the most important and extraordinary inventions of the day, and effect a revolution, as extensive as desirable, in mining affairs. It can be put down, even in the deepest pits, at comparatively little cost, for there are no pumps, no pump rods, no clacks, no valves, but simply one pipe extending to the bottom of the mine or to the sump, and another pipe united with it extending from the bottom of the mine to the top. These pipes are made of sheet zinc, or sheet copper, of the thinnest gauge; and the cost, therefore, when compared with the heavy pump trees now employed, is but of small amount. Wear and tear, comparatively speaking, there is none. We will, however, let Mr. Adcock describe his invention in his own words. He stated that, encouraged by the successes he had experienced in some former attempts to improve pump work, by which he had been enabled to make one valve perform the duty of four clacks, he was emboldened to attempt still further improvements, and eventually proposed to himself the question—"Is it possible, in the raising of water from mines and other deep places, to do without clacks or valves altogether?" He stated he knew this desirable effect could not be produced if the water had to be raised from the mine in a compact or solid state, as in pump work. For in a pit of 1,000 feet in depth, the column of water being also 1,000 feet, the pressure of water against the sides of the pipe at the bottom of the mine would be about 440 lbs. on each square inch, and no pipe that could be conveniently applied in practice could resist that pressure. He, therefore, in the next place, questioned within himself whether the water could not be brought up from the mine in a divided state; and the obvious reply to that question was, if the water be brought up in a divided state, it must be in the state of vapour or of rain. The chain of reasoning, thus far continued, led him, he states, to investigate the descending velocities of drops of rain compared with what those velocities should be by the laws of gravitation; and he found that, by the laws of gravitation, the rain ought to descend towards the earth with a speed constantly accelerating; so that if the cloud were high from which it fell, it ought by its velocity, and consequently its *momentum*, to inflict evils of a serious nature on all animal and vegetable life. Then how is it that such effect is not produced? Simply by the resistance of the air. Each drop of rain, while in the cloud, may be considered to be in a quiescent state. It begins to descend from a state of rest, with a motion constantly accelerating, and thus it continues until it acquires a certain amount of speed; from which time forth the motion of its descent is uniform. This uniformity of motion, Mr. Adcock stated, is produced by the resistance of the air; by its not being able to flow from beneath the drop beyond certain rates of speed under certain amounts of pressure, and the ultimate amount of pressure is determined by the weight of the drop. Hence the drop descends with an accelerating speed at first, compressing the air more and more immediately beneath it until the resistance and the compression become equal to the weight of the drop; thenceforward its motion is uniform. Mr. Adcock stated that he then proceeded to investigate the greatest descending velocities of drops of rain, and he found that, under ordinary circumstances, they were from eight to twelve feet in a second; from which time the remaining portion of the reasoning was to him clear and decisive, viz., if water, in globules of a certain size and weight, like drops of rain, cannot, under ordinary circumstances, and in consequence of the resistance which they meet with in the air, descend with a greater speed than twelve feet in a second, then it is certain that if those drops were in a quiescent state, and a current of air were made to move upwards, at a greater speed than twelve feet in a second, those drops would flow upwards, instead of downwards, and that too, whatever the height. Hence the invention was perfected. He had only to try the experiment in secret. It far surpassed all that he had expected from it, and he forthwith secured the patents. Mr. Adcock, therefore, does not raise water in solid mass as in pump work, but in a divided state like drops of rain. His apparatus consists of a fan, which is driven the required number of revolutions by steam or water power, and two pipes, as we have before remarked—the one to convey the air from the fan to the bottom of the mine, and the other to return the air back to the surface, together with the water with which it is accompanied. With a 20-inch fan, 6 inches wide, he has driven up 63 gallons of water in a minute, 40 feet in height; and by a 3-feet fan, 1 foot wide, erected at the works of Messrs. Milne, Travis, and Milne, at Shaw, near Manchester, he states he has driven up 130 gallons of water per minute 120 feet in height. His experiments having been seen by numerous miners and practical men, a highly respectable body of them have subscribed a certain sum each, that its merits, so important to them, may be at once fully tested; and it gives us much pleasure to add that the machinery, now being made for that purpose, will be put down at the Pemberton Colliery, in the neighbourhood of Wigan, which is under the management of Mr. R. Daglish. The depth of the pit is 100 yards; and from that depth Mr. Adcock proposes to bring up 300 gallons of water per minute. The fan, now making, will be 6 feet diameter and 18 inches wide.—*Mining Journal.*

NEW RAILWAY LOCOMOTIVE.

Invented and constructed by Mr. Walter Hancock, of Stratford, Essex, and now on trial on the Eastern Counties' Railway.

One of the principal advantages of this locomotive is presented in the boiler, by which steam of greater power is generated with far greater certainty of continued supply, and more perfect safety, than by the boilers now in use, either in railway, marine, or stationary engines. This boiler is constructed of a number of distinct chambers, each chamber composed of several tubes. Each chamber, or rank of tubes, connects with two general cylinders or reservoirs—one at the bottom for the supply of water, and the other at the top for the reception and passage of steam. The communications from each chamber to the water, steam pipes or reservoirs, have self-acting valves. When any leakage occurs, from wear, rents, or other causes, to any one chamber, the valves belonging to it close, and are kept to their seats by the pressure of the water and steam contained in the neighbouring sound chambers, and the boiler remains as effective as before, excepting that the surface of that one chamber, is thrown out of use, without stopping the engines, and perhaps it would not be observed by the engine driver until the end of the trip, when the pressure being reduced by withdrawing the fire, the valve would fall from its seat, and point out the defective chamber by the discharge of water. In half an hour a new chamber could be attached in its stead. In the ordinary locomotive boiler, when any one of its tubes become defective, the whole is rendered inoperative by reason of the unchecked communication of all the parts with each other, and so it remains until the defective tube is repaired, replaced, or plugged, which generally occupies three or four hours, and is attended besides with the inconvenience of stopping the train until another engine is procured from the next station.

By adopting the improved boiler no such delay would occur, and the expense both in fuel and wages, of keeping a number of engines with their fires up ready to meet such casualties, would be avoided, as well as the risk when a train stops out of time, and having another train brought in collision with it, and the lives of passengers and attendants endangered.

The great heating surface obtained in a comparatively small space, is likewise a recommendation to this boiler. It is intended to attach a reciprocating set of fire bars to it, by which a clean floor of bars can be introduced without lowering the fire. The small weight of this boiler in comparison to its generating power, is another material point in its favour, for it leaves room for giving sufficient strength to all other parts, without exceeding the present total weight of a locomotive.

Having given a general description of the power—the engines and machinery come next under consideration.

The engines of the present locomotives are placed horizontally, and are thereby very much confined and difficult of access, but in this one they are vertical, and therefore the whole of the machinery, pumps, &c., are open to view, can be readily oiled, and speedily detached for repairs; or any portion may be put right and secured whilst the engines are working.

The engines of this locomotive give motion to a separate crank shaft, and this communicates the progressive motion to the wheel axle by an endless chain, working over a pulley fixed on each, and which two pullies may be either of equal or different diameters, so that advantage may be obtained either for speed or power, whichever may be required. This arrangement not only allows the wheel axle to be straight instead of cranked, but it also possesses the advantages of a moderate accommodation or play, by which all sudden jerks or concussions of the machinery, &c., are avoided.

The friction is reduced to above one-half, from such large eccentrics, crank-bearings, &c., not being required, in consequence of the weight of the machinery, boiler, &c., being on straight instead of cranked axles.

This arrangement allows the work to be immediately thrown out, so that the engines will work the injection pumps, and get up the fire, without working the driving wheels. By running locomotives about to effect these purposes, much of unnecessary wear and tear is incurred, besides running on the rails in the way of trains, &c. The present locomotive need not stir from the spot until the train is attached—the clutch then thrown in, it immediately starts upon its trip.—*Correspondent of the Railway Times.*

STEAM LOCOMOTION ON COMMON ROADS.

An experimental trip of Sir J. Anderson's steam-drag for common roads, took place yesterday on the Howth road, and fully answered the anticipations of all concerned. It ran for about two hours, backing and turning in every direction—the object being chiefly to try the various parts in detail. It repeatedly turned the corners of the avenues at a speed of about twelves miles an hour, and at a pressure of only about 16 or 18 pounds upon the square inch. No smoke whatever was emitted, and very little steam was observed, while even these, it is alleged, will be removed, when running publicly on the roads. The whole machinery is ornamentally boxed in, which prevents the nervousness so often experienced in railway carriages, when the movements of the different parts are exposed to view; neither do horses show any alarm when it passes them.

The directors of the English company formed for the purpose of working out Sir James Anderson's patent, are about to assemble at Manchester, in order to witness a trial of the carriages constructed there; and it is expected that the noblemen and gentlemen forming the company will afterwards come to Dublin; it being the intention of the patentees to form a company, in conjunction with that of England, for establishing communications by means of these drags, between the principal towns in Ireland, as soon as a few of the carriages now constructing, and in a forward state, are completed. It is proposed that the English company should, in the first instance, in conjunction with the railway trains from London, run from Birmingham to Holyhead; the passengers to be thence conveyed by steam vessels to Dublin twice a day; from Dublin to Galway by the steam drags, and thence by steam vessels to New York, touching at Halifax. Thus making Ireland the stepping-stone between England, Nova Scotia, and the United States, and avoiding the delay and danger of beating up the channel, the most arduous and annoying part of the present route. The whole distance between London and New York will be accomplished, it is expected, in ten days.—*Dublin paper, June 30.*

Daguerreotype Engraving.—We have received from Dr. Mackenzie, still at Vienna, some further particulars of the interesting process by which Dr. Berres fixes and engraves the Daguerreotype pictures, and also two impressions from such engravings. These impressions are shadowy and very indistinct, but the design is sufficiently made out to justify the hope that further experiments and practice will render the discovery practically available. Respecting the process, Dr. Mackenzie observes, "The proportions are now fixed as follow:—Seven parts of acidum nitricum, of forty degrees of strength, to eight parts of distilled water. With gum arabic the operation is a little longer in being finished, but the picture is much handsomer; without gum it is quicker, but it requires much more care and attention to produce a good engraving. When it happens that the nitric acid produces a precipitate upon the silver plate, *ammonia* must be poured upon the plate, and it will instantly disappear. From time to time it is desirable to take the plate out of the acid and wave it about; thus drying it you perceive better the progress made in the engraving. When the acid becomes muddy it is necessary to change it."—*Athenæum.*

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

ROYAL SOCIETY.

May 14.—Major Sabine, R.A., V.P., in the Chair.

The following papers were read:—

"*Tables of the Variation, through a cycle of nine years, of the mean height of the Barometer, mean Temperature, and depth of Rain, as connected with the prevailing Winds, influenced in their direction by the occurrence of the Lunar Apsides, with some concluding observations on the result.*" By Luke Howard, Esq.

From the tables here given, the author draws the following conclusions: 1st, the barometer is higher under the lunar apogee, than under the perigee; the mean height in the former case being 29·84517, and in the latter, 29,75542. 2nd, the mean temperature is lower under the apogee than under the perigee; the mean height in the former case being 48°·7126, and of the latter, 49°·0356. The mean of the whole year was 48°·7126. 3rd. The rain of the weeks following the apsis exceeds that under the perigee; but with two striking exceptions in the annual result of nine years, the one in the wettest, and the other in the driest year of the cycle. With regard to the winds, the author remarks that those from the north, north-east, and east, prevailed under the apogee on thirty-eight days, under the perigee on twenty-one days; and those from the south, south-west, and west, prevailed under the apogee on twenty days, under the perigee on thirty-eight days. It appears, therefore, that in the climate of London, the moon in her perigee brings over us the southern atmosphere, which tends to lower the density and raise the temperature of the air, occasioning also a larger precipitation of rain. In the apogee, on the contrary, there is a freer influx of air from the northward, a higher barometer, a lower temperature, and less rain; subject, however, to a large addition of rain under this apsis twice in a cycle of nine years, at the times when also the extremes of wet and dry take place on the whole amount of the year.

May 21.—The Marquis of Northampton, President, in the Chair.

His Royal Highness Prince Albert, of Saxe-Coburg and Gotha, attended the meeting, signed his name in the charter-book, and was admitted a Fellow of the Society. William Burge, Esq., Walter Ewer, Esq., T. T. Grant, Esq., and Henry Lawson, Esq., were balloted for, and duly elected.

The following papers were read:—

"*Remarks on the Meteorological Observations made at Alten, Finmarken*, by Mr. S. H. Thomas, *in the years* 1837, 1838, *and* 1839. By Major Sabine, R.A., and Lieut.-Col. Sykes; *being a Report from the Committee of Physics to the Council.*"

These observations, made at Alten, in lat. 69° 58′ 3″ north, and 23° 43′ 10″ east of Paris, would seem to have a claim to the attention of the Royal Society, as they offer the *experimentum crucis* of Professor Forbes's empirical formula respecting the gradual diminution of the daily oscillations of the barometer, within certain limit hours, from the equator to the poles. Professor Forbes has laid down an assumed curve, in which the diurnal oscillation amounts to ·1190 at the equator and 0 in lat. 64° 8′ N., and *beyond that latitute* the tide should occur *with a contrary sign*, plus becoming minus. Now, Alten being nearly in lat. 70°, if Professor Forbes's law hold good, the maxima of the diurnal oscillations should occur at the hour for the minima at the equator, and a similar inversion should take place with respect to the minima. Mr. Thomas has himself however modified the value his observations would otherwise have had, by adopting 2 p.m., instead of 3 p.m., for the hour of his observations for the fall; and he has adapted his barometrical observations to a mean temperature of 50° Fahr., instead of 32°. The first year's observations commence on the 1st October, 1837, and terminate on the 30th of September, 1838. The barometer stood sixty-six feet five inches above low-water mark, and the thermometer hung at six feet above the ground; but care was not always taken to prevent the sun shining on it. The mean height of the barometer for the year was 29°.771, and the mean of the thermometer at the freezing point was 32°·017. The maximum height of the barometer was 30°·89 in January, and the minimum 28°·71 in October. The mean of the barometer at 9 a.m. was 29°·764, therm. 33°·455; at 2 p.m. 29°·765, therm. 33°·327; and at 9 p.m. 29°·784, therm. 29°·270. The diurnal observations would seem to support Professor Forbes's theory; but the 9 p.m. observations are entirely opposed to it, as they appear with the same maximum sign as at the equator, whereas the sign ought to have been the reverse; indeed, with respect to the diurnal observations, the mean of five months of the year at 9 a.m. gives a plus sign, although the mean of the year at 9 p.m. only gives the trifling quantity of ·001 plus. There is one remarkable feature in these observations that cannot fail to strike the meteorologist. M. Arago, from nine years' observations at Paris, reduced to the level of the sea, makes the annual mean height 29°.9516; twenty-one years' observations at Madras make it 29°·958; and three years' observations at Calcutta, by Mr. James Prinsep, make it 29°·764; and Mr. Thomas brings out 29°·771. That there should be this coincidence between the observations at Calcutta and Alten is curious. Neither Mr. Thomas nor Mr. Prinsep state whether or not their means are reduced to the level of the sea. It is to be suspected they are not For the next year, that is to say, from October 1838 to September 1839, both inclusive. Mr. Thomas uses a French barometer and French measurements, with centigrade thermometer attached to the barometer, and Fahrenheit's for the detached thermometer. He changes his time of observation from 9 a.m. to 8 a.m., 2 p.m., and 8 p.m., and he reduces his barometrical observations to 0 centigrades. The results of the year are as follows:—mean annual pressures 29°·627; English thermometer, Fahr. 33°·36; greatest pressure in April, least in January!! The mean of 8 a.m. is 29°·620; therm. 33°·75. The mean of 2 p.m. is 29°·631; therm. 34°·73. And at 8 p.m. 29°·631; therm. 30°·75. The diurnal observations assist to support Professor Forbes's theory; but, as in the preceding year, the p.m. observation is at fault; and if the hour had been 9 o'clock instead of 8 o'clock, it would probably have been more so than it appears. The low annual mean state of the barometer for the 1837-8 is even increased in the last year's observations: and as fresh instruments* apparently have been used, there appears some ground to believe that the fact is associated with the locality, and it may be desirable not only to record in the Proceedings of the Royal Society the data already supplied, but to recommend to Mr. Thomas more particular inquiry on the subject. The phenomena of the Aurora Borealis appear to have been observed by Mr. Thomas with great assiduity, and recorded with great care. On examining the register, with reference to M. Erman's important remark, that "in Siberia two kinds of aurora are distinguished, one having its centre in the west, and the other in the east, the latter being the more brilliant." I find that twenty-two nights occur in the course of the two winters, in which the formation of arches of the aurora is noticed and their direction recorded; of these, *ten* are to the *west*, having their centres rather to the southward of west, the arches extending from N.W. to S.S.E. and S.E.; *seven* are to the *east*, or more precisely to the southward of east, the arches extending from N.E. to S.E. and S.W. Of the five others, *four* are said to be from east to west across the zenith, and cannot therefore be classed with either of the preceding, and *one* is noticed generally as being to the north. The facts here recorded appear to afford an evidence of the same nature as those mentioned by M. Erman, as far as regards their being two centres of the phenomena. In respect to the relative brilliancy of the eastern and western aurora, nothing very decided can be inferred from the register. If, as M. Erman supposes, that they may be referred respectively to "les deux foyers magnétiques de l'hemisphère boreal," it is proper to notice that the position of Alten is nearly midway between those localities. There can be no doubt that the frequent appearance of the aurora, and the peculiarities of the phenomena observed there, render it a most desirable quarter for a magnetical and meteorological observatory.

Edward Sabine.
W. H. Sykes.

"*Second Letter on the Electrolysis of Secondary Compounds, addressed to Michael Faraday, Esq.*" By J. F. Daniell, Esq.

The author, in this letter, prosecutes the inquiry he had commenced in the former one, into the mode in which the chemical elements group themselves together to constitute *radicles*, or proximate principles. He considers his experiments as establishing the principle that, considered as electrolytes, the inorganic oxy-acid salts must be regarded as compounds of metals, or of that extraordinary compound of nitrogen and four equivalents of hydrogen to which Berzelius has given the name of *ammonium*, and compound anions, chlorine, iodine, &c., of the Haloide salts; and as showing that this evidence goes far to establish experimentally the hypothesis originally brought forward by Davy, of the general analogy in the constitution of all salts, whether derived from oxy-acids or hydro-acids. Some remarks are made on the subject of nomenclature, and the rest of the paper is occupied with the details of the experiments, all bearing on the important subject which he has undertaken to investigate.

May 28.—Francis Baily, Esq., V.P., in the Chair.

The following papers were read:—

"*Meteorological Register kept at Port Arthur, Van Diemen's Land, during the year* 1838, *and Register of Tides at Port Arthur, from August* 1838 *to July* 1839, *both inclusive.*" By Deputy-Assistant-Com.-Gen. Lempriere. Communicated by Sir John Franklin, R.N.

"*Notice relative to the form of the Blood-particles of the Ornithorhynchus hystrix.*" By John Davy.

A portion of the blood of the *Ornithorhynchus hystrix*, mixed when fresh with a strong solution of common salt, being examined by the author, exhibited a few globules of irregular shape. Another portion, preserved in syrup, contained numerous globules, most of which had an irregular form, but many were circular; none, however, were elliptical, like those of birds. Hence the author concludes, that in form they accord more with those of mammalia.

"*Researches on Electro-Chemical Equivalents, and on a supposed discrepancy between some of them and the Atomic Weight of the same bodies, as deduced from the theory of Isomorphism.*" By Lieut.-Col. P. Yorke.

The author describes various experiments made with a view to determine the electro-chemical equivalents of sodium and potassium. Three experiments gave, respectively, 22·3, 22·9, and 25, as the equivalent of the former; and two other experiments gave, respectively, 45 and 41·7 as the equivalent of the latter of these substances. He then inquires what would be the result of

* It appears that the barometer was compared before leaving France, and subsequently to its being taken back to that country.

the [illegible] of soda and potash, on the hypothesis of [illegible] composed of two equivalents, or atoms, of metal, and one of oxygen. To determine this question he employs a solution of dichloride of copper in muriatic acid, as being a substance composed of two atoms of metal, and one of an electro-negative element. Its electrolysis gave as the equivalent of copper, 52·8, 59·4, and 61·6, numbers approximating closely to 63·2, or double the atomic weight of copper. After a long train of investigation, he concludes that there is no reason deducible from the theory of isomorphism for doubting the correctness of the received atomic weights of silver, sodium, &c., but that the difficulty, or anomaly, if it may be so called, should be considered as attaching itself to the di-compounds of copper: and that Faraday's propositions on this subject remain unimpeached.

"*On the Solubility of Silica by Steam: with an account of an experiment on the subject, conducted in the East Indies.*" By Julius Jeffreys, late of the Hon. East India Company's Medical Establishment.

The inner surfaces of a flue built of siliceous bricks appeared to be deeply eroded by the passage over it of steam at a very high temperature, and fragments of siliceous materials laid in the course of the current were partially consumed. A siliceous crust was deposited on several vessels of stone ware, coated with a micaceous glaze, placed in the upper part of the furnace, and this crust was re-dissolved when the vessels were removed to a hotter situation in the same furnace. The author notices the experiments of Dr. Turner and others, which failed in showing the solubility of silica by steam, in consequence, as he conceives, of the heat having not been sufficiently great to effect the solution.

INSTITUTION OF CIVIL ENGINEERS.

Feb. 4.—The President in the Chair.

On Steam Engines.

The abstract of Mr. Parkes's communication (*Journal*, No. 31, p. 136,) having been read, Mr. Enys remarked, that Mr. Parkes had adopted a different unit of power to the one he was accustomed to employ; but that was a point on which he was not disposed to insist, and he was prepared rather to yield to Mr. Parkes's opinion where they differed. Agreement on terms was very important, and he wished to see more accuracy introduced in the use of certain terms relating to engines; he would confine the term "duty" to the net work, and the gross work he would call "effect." In speaking of a locomotive engine, he conceived the goods carried to constitute the duty—the whole mass moved, the effect. The duty in Cornwall is a theoretical term, being the water which ought to be raised according to the column displaced, but the whole of which did not reach the surface; and the whole mass of pump work, water, &c., set in motion is the effect. The duty is not commensurate with the effect, as it is independent of friction and other expenditure of power. The pit-work is not always well executed, and is not under the care of the engineer. Duty in Cornwall is, in fact, entirely a commercial question, it having been instituted as a check between the adventurers and the engineer who originally undertook to perform the work of pumping for a certain share of the saving of fuel to be made. There were three distinct causes of improvement in Cornwall, viz., in the boilers, in the application of highly expansive steam, and in the pit work.

Mr. Wicksteed, in reply to a question as to the work now being performed by the engine at Old Ford, stated the general result to be, that with small Newcastle coals of inferior quality, and of such a size as to pass through a screen of three-quarter inch mesh, the duty amounted to 71 millions raised one foot high with 94 lb. of coal. He had experienced great difficulty in procuring good Welsh coal, but with some Merthyr coal he had recently tried, the duty immediately increased to 91 millions.

In the Old Ford engine, the steam is cut off at one-third of the stroke, and the water is raised by the weight of a mass of iron acting on the water at the return stroke. With the ordinary valves there is a loss of about one-tenth, but with the valves invented by Messrs. Harvey and West, used in the Old Ford engine, there is no loss, and no perceptible blow from the water on the valves closing, although no air is admitted beneath.

The speed of this engine varies from one stroke to ten per minute, according to the demand for water. In Cornwall, it is thought that at slow speed there is a considerable saving of fuel, but he is of opinion that there is no difference in duty at a fast or slow speed, provided there is sufficient time for opening and shutting the valves.

As to the term duty, although it is important to know what is the absolute quantity of water raised, yet that is not the whole effect. The engine raises a certain weight of rods, which is its load, and this weight should, in the return stroke, produce a certain given effect in water brought to the surface; but, owing to bad valves, leaks in the pumps, and other causes, the quantity of water raised is not equal to the calculated amount. We cannot say that an engine has not done its duty because a portion of the water is lost. Two engines, equally good and of identical power, may not produce equal results; because one may be raising water close beneath the beam, another, up a shaft at some considerable distance, by means of a series of long horizontal-motioned pump rods; the latter, again, may be doing a duty of 20 millions in working the pump rods only.

It was his intention shortly to present to the Institution a complete report of the work done by his engine, with drawings of every part: but he was waiting to have the opportunity of ascertaining the evaporation from the Cornish boilers, as well as from those of a pumping engine of Boulton and Watt's, also in use at Old Ford, so as to determine, at the same time, the respective duty and consumption of steam by the two engines.

Mr. Field insisted on the importance of distinguishing between the duty and effect, by using the former term for the water actually raised, and the latter for the real power expended. He understood these terms to be so applied to engines for water works in London, and that effect included the friction of the water in the pipes, and all other causes of diminution of duty. The real effect should be ascertained from the pressure of the water at the pump, as determined by a mercurial gauge. It is generally understood that, in speaking of the real comparative effects of the water works engines in London, it would be unfair to take the water raised, as the same power would in one case be expended in raising water 100 feet, as is expended in another case in raising water 200 feet. The pressure of the water at the pumps is the proper standard of comparison.

Mr. Parkes stated, that in his paper he had used the term duty as distinguished from the absolute power of the engine. The same Cornish pumping engine at different periods performs very different amounts of duty, although the absolute power exerted by the steam is the same. This arises from additions to the friction by new pump rods, and from other causes. The Cornish result is below the real duty done by the engine, taking the term in their acceptation of it, and using their mode of calculation for that which is by them considered a purely commercial question. The only correct manner of ascertaining the absolute power exerted by pumping engines, so as to compare them with rotative engines, is to take the pressure on the piston, and the value of the vacuum on the other side at the same time. The term duty expresses the true, useful, or commercial performance of the engine, but is no measure of the absolute power of the steam, which has to overcome the friction of the engine, pumps, rods, &c., in addition.

Mr. Enys, in reply to a question from Mr. Gordon as to the speed at which an engine is worked with the greatest economy, stated the general opinion in Cornwall to be in favour of about 9 strokes per minute; if there was a pause of half a second between each stroke, the Cornish engineers were perfectly satisfied. The indoor stroke is usually at the rate of from 250 to 260 feet per minute, and the outdoor stroke about 140 feet. When the number of strokes exceeds 9, the balance requires to be altered; the engine then runs out quicker, but requires a greater expenditure of steam to bring it in again. In answer to a question relative to Woolfe's engines, he believed they had never had a fair trial, as all the boilers originally adapted to them were much too small, and the tubes soon got full of oxide and mud; if the present system of Cornish boilers had been in use at the time, he thought they would have acted much better. Some engineers are so much impressed in their favour, that they are desirous of giving them a trial again with all the recent improvements.

Mr. Cottam mentioned an engine on Woolfe's principle which had worked perfectly well for several years. It is now grinding a bushel of corn with a fraction less than 4 lb. of coal. The pressure of the steam in the boiler is from 22 to 25 lb.

Mr. Cottam, in reference to the above discussion, at a subsequent evening (Feb. 18) alluded to the pumping engine at Hammersmith, which forces the water through five miles of pipes, and then through a vast number of smaller pipes, and was subject to great variations of service, and inquired how the duty could be ascertained with any tolerable accuracy, as the variable expenditure of steam under different circumstances must lead to considerable errors. If a boiler, as in the Cornish engines, is adapted to raise the bob 7 times per minute, and, owing to some cause, as the water not being able to get away, the bob is raised only 5 times per minute, there is two-sevenths in favour of the boiler; or if an engine adapted for 30 strokes per minute makes only 25 occasionally, there is great difficulty in comparing it with other engines.

Mr. Donkin urged the necessity of keeping the quality of the engine and its commercial effect perfectly distinct; if a given weight be raised to a given height, it must produce a given effect minus the friction; in water-works engines the resistance opposed by the friction is very considerable, and being very variable, it must not be allowed to interfere with the consideration of the intrinsic quality of the engine; of two engines having equal power, one may discharge, owing to these circumstances, more water than the other, but if both be of the same construction and raise a given weight, whether the water be discharged perpendicularly or forced through any length of horizontal pipes, there can be no mistake as to the amount of the effect produced, or, in other words, of duty performed, as that would be determined by the weight raised if in a Cornish engine, or by the resistance overcome if in an ordinary pumping engine.

Mr. Wicksteed observed, that there was no difficulty in instituting a comparison between the duty of a Cornish engine and of an ordinary water-works engine, because by the former the water was raised through a perpendicular shaft, and by the latter forced through several miles of pipes, of varying length and resistance. He had for several years ascertained, by means of a mercurial syphon gauge, the pressure at the pump piston, and this gave, with perfect accuracy, the resistance overcome by the engine, whether arising from the pressure of water raised to a given or varying height, or from the friction in a great length of pipes. This was easily proved at Old Ford, where the water was raised into a perpendicular column or stand pipe, in which the level of the water would be that necessary for overcoming the resistance opposed by the pressure and friction. In making comparisons between the common water-works engine and the Cornish, this was the mode he had adopted, and he believed it to be the only fair one. He had proved the accuracy of the mercurial gauges by the measurement of the column of water supported. The Cornish engine at Old Ford acts by raising a weight of metal, which, upon its return, raises the water. This is the only engine in London of the kind, and to establish a comparison between it and any other pumping engine, it is only requisite to apply a mercurial gauge as just described to the pump of each, and whether the water is lifted direct or forced through any length of pipes, the resistance or load against which the steam acts will be shown. Previously to his Cornish engine being set to work, the beam and plunger were balanced with the greatest accuracy, and their preponderance ascertained before the steam piston and plunger were packed. The weight afterwards added to the pump end was also carefully ascertained. The weight raised at each stroke of the engine is thus accurately known. The number of strokes performed in a given time is registered by the counter. The coals are carefully weighed. By ordinary attention, the boilers are so managed with regard to the work to be done, that no steam is allowed to blow away, whether the engine be making 3 or 9 strokes per minute; and in calculating the duty done by the quantity of coal consumed, no deduction is made for stoppages. Thus, a certain number of strokes being made, a known weight has been raised to a given height a given number of times by the consumption of a known weight of coals. This engine worked under the pressure of a column of water from 110 to 116 feet in height, and the water was forced through 300 miles of pipe, varying from 42 inches to 3 inches in diameter. The load at the pump in the common pumping engine is ascertained by the same means, and no error can exist in determining the duty performed by each.

Mr. Parkes observed, that the term duty did not seem to be quite understood; duty was not the weight of water raised 1 foot in height, but that weight divided by a bushel or other measure or weight of coals also; that the time in which the water was raised did not enter into the computation of duty, though it did into the determination of horse power. He would again call attention to the fact, that coal was no measure of power or of the quality of an engine; that one engine might be doing more duty than another, because it had better coal or better boilers; and that the only standard of perfection between different engines was the relative consumption of water as steam for equal effects.

Feb. 11.—The President in the Chair.

The following were balloted for and duly elected:—John Green, John Hartley, as Members; Joseph Woods, Frederick Rumble, as Graduates; Oliver Lang, John Grantham, Capt. George Smith, R.N., Lieut. E. N. Kendall, R.N., as Associates.

"*A Description of the Coffre Dam at the site for the new Houses of Parliament.*" By Grant S. Dalrymple.

The works described are those which necessarily precede the erection of the main building. They consist of the coffre dam, river wall, and the foundations of the river front—according to the designs, and under the direction of the engineers (Messrs. Walker and Burges) and Mr. Barry, the architect; the whole being executed by Messrs. Lee, the contractors.

The mud at the site of the works varied much in depth and in consistency, but beneath it is a bed of red gravel and sharp sand, averaging 14 feet in thickness, laying over a stratum of stiff clay, into which the piles are driven to a depth of 2 feet. To facilitate the driving of the piles, a curved trench, 27 feet wide by 8 feet deep, was dredged in the line of the dam. The main piles of Memel fir, 36 feet long by 1 foot square, were then driven, leaving their tops $4\frac{1}{2}$ feet above the Trinity high-water mark of ordinary spring tides. The waling pieces were then attached, and the outer sheet piles of whole timber, 36 feet long by 13 inches square, sawn square on all sides, so as to ensure the joints being close when driven and bolted to the waling. The inner sheet piles of half timber were then driven to the same depth as the others; the space above them was made up with horizontal pieces, bedded down to them, and secured with bolts to the furring pieces inserted above the waling at each gauge pile. The whole length of the dam was secured by diagonal braces, extending back to the old river wall, against which they were abutted. The outer and inner rows of piles were secured together by three rows of wrought iron bolts, the lower being $2\frac{1}{2}$ inches diameter, and the two upper rows 2 inches diameter. The whole of the piles being driven, the space between was cleared out down to the clay substratum, and then filled up with stiff clay mixed with a portion of gravel; a portion of the excavated matter was then laid on both sides of the dam to protect the piling from injury.

The first pile was driven on the 1st of September, 1837, and the dam was closed on the 24th of December, 1838. The extreme length of the coffre dam along the river face is 920 feet, and the ends return at an angle until they meet with and enter the old river wall, at a distance of about 200 feet from the face of the dam.

The excavations for the foundation of the river wall were got out in lengths of 50 feet, levelled to receive the footing courses, which were laid on a bed of concrete of a thickness varying from 1 foot at the north end to between 5 and 6 feet in the centre and south corner, where the substratum was loose and spongy. The concrete was composed of 6 measures of gravel and sand to 1 of ground lime from the lower stratum of the chalk formation. Along the face of the wall was driven a row of elm sheet piles, from 8 to 12 feet long by 5 inches thick, square sawed, so as to drive close, spiked to an oak wale, and the whole secured to the front by 1-inch wrought iron bolts, placed at distances of 4 feet apart, stretching back 6 feet into the wall, and fixed by cast iron washers bedded between the footing courses. The two bottom or footing courses of the wall are 11 feet wide, of York landing, 6 inches thick; on these are two courses of Bramley-fall stone, each 1 foot 3 inches thick, from which rises the stone facing of the wall, of Aberdeen and Cornish granite, in courses varying in thickness from 2 feet 2 inches at the bottom to 1 foot 7 inches at the top. The front is built to a curve of 100 feet radius, and is backed with brickwork, making the total thickness of the wall 7 feet 6 inches at the bottom, and 5 feet at the top. Counterforts, projecting 3 feet $4\frac{1}{2}$ inches by 3 feet 9 inches wide, occur at intervals of 20 feet along the whole length. At a distance of 28 feet 9 inches from the back of the river wall is the foundation of the front wall of the main body of the building, the space between the two walls being filled up with concrete, composed of 10 parts of gravel to 1 part of ground lime. The total length of the river wall, at the present level of 2 feet 3 inches above the Trinity standard of high-water mark, is 876 feet 6 inches. The wings at each end, projecting 2 feet 3 inches before the face of the centre part, are 101 feet 6 inches long each, leaving a clear terrace walk, 673 feet 6 inches long by 32 feet wide, between the wings and fronting the river. The height of the wall from the bottom of the footing courses is 25 feet 9 inches.

The excavation for the wall was commenced on the 1st of January, 1839, and the building of it was commenced in March of the same year. The amount of the estimate for the dam and wall was £74,373.

"*On Browne's Patent Hydraulic Level.*" By A. T. Hemming.

This instrument, designed for ascertaining the relative heights of points not visible from each other, consists of lengths of water-tight flexible tubing, attached to each other by brass joints, and having glass vessels at each end. The vessels and tubing being nearly filled with water, the level of the water, as seen in these vessels at two points whose relative heights are to be compared, will serve to indicate their positions, whatever may be the inflexions of the tubing betwixt the two vessels. Graduated rods are placed perpendicularly at the points of observation, and the lower vessel is raised, and the higher lowered, until the level of the fluid therein intersects the graduation of the rods. It is conceived that this level may be peculiarly useful in mines and excavations, and in fixing complicated machinery.

Light for Light-houses.

Captain Basil Hall briefly explained his views as to obtaining for light-houses all the advantages of a fixed light by means of refracting lenses in revolution.

The difference between a fixed and a revolving light is much in favour of the revolving light, as the light can be concentrated and great brilliancy obtained on any particular point at each succeeding flash;—by a fixed light being meant one in which the light is visible on every side; and by a revolving light, one in which the light appears in periodical flashes. Fresnel's fixed light has only one-sixth the brilliancy of his revolving light. Fresnel's system consists in having a large central lamp with four concentric wicks, surrounded by eight lenses, each three feet diameter. The light is thus concentrated and thrown off in eight pencils, which, as they strike the eye successively, have very brilliant effect, and are visible at a great distance.

Captain Basil Hall's inquiries have been directed to ascertain whether the well-known superior brilliancy of a revolving light could not be obtained for a fixed or continuous light; that is, for one equally visible in all directions at the same moment. His idea was, that by giving a certain velocity of revolution to a series of lenses round a fixed light, as in Fresnel's arrangement, a continuity of illuminating power, equal almost in brilliancy to that of a slowly revolving light, might be produced. This, he expected, would prove true, provided no intensity were then lost. He had erected some apparatus at the Tower, and determined the effect by experiment. The apparatus consisted of a fixed central light with a series of eight lenses, 1 foot diameter and 3 feet focal distance, so arranged as to revolve at any velocity up to 60 revolutions per minute. The light from the central lamp being concentrated by refraction through the eight lenses into eight pencils, having a divergence of about 8° each, illuminated not quite 50° of the horizon when at rest; but when this same system of lenses was put into rapid motion, every degree of the 360° of the horizon became illumined, and to spectators placed all round the horizon, the light would appear continuous and equally brilliant in every direction. The only question would be, whether or not this continuous light is essentially less intense than the light seen through the lenses at intervals when in slow motion. The fact is, that two distinct effects are produced in this experiment—a physical effect in diminishing the brilliancy of the light exactly in proportion to the ratio of the dark portion of the horizon compared to that of the enlightened portion, viz. as 310° to 50°; and a physiological effect (suggested by Professor Wheatstone), by which the sensibility of the retina might be so excited by a succession of bright flashes, that not only a continuity of light might be produced, but a light not much, if at all, inferior in intensity to that caused by the lenses at rest. When first set in motion, the effect is that of a series of brilliant but trembling flashes; as the system of lenses is accelerated in velocity, the steadiness of the light increases with scarcely any apparent diminution of brilliancy. At 44 revolutions per minute absolute continuity is produced, and at 60 revolutions nearly the steadiness of a fixed light. When viewed from the distance of half a mile, the effect is nearly that of continuity, very much resembling that of a fixed star of the first magnitude. The only difference in the quality of the light is, that the lenses being in motion, it resembles a star twinkling violently; and when at rest, it resembles a planet. The difference of intensity had been measured by examining the light through a number of plates of stained glass. Some eyes had seen the light through 13 glasses, the lenses being at rest—and through 12, the lenses being in motion; other eyes with other glasses had seen it through 10, the lenses being at rest—and 8, the lenses being in motion. He had seen it through 9, the lenses being in motion, and through 10 at rest. He did not pretend to say whether mechanical difficulties might not prevent the adoption of the system; what he aimed at was to establish the principle, that by putting a system of lights into a rapid rotary motion, a continuous light visible in all directions would be the result, without any essential diminution of brilliancy, as compared to that of the same lights when viewed at rest. If this principle should prove correct, its application to practice might afterwards be thought of, and left to the ingenuity of the engineer; but if the principle should not be correct, and there was a great loss of light by the rotary motion, then it would be useless to go on.

At the subsequent meeting, Feb. 18, Mr. Parkes observed, that he could entirely confirm the account of the experiments with revolving lenses given by Captain Basil Hall on a preceding evening. It appeared to him, that when the lenses made 32 revolutions, the light was not quite continuous; but at 40 revolutions it was perfectly so, although the general effect was twinkling. The central spot was very distinct; he saw the light equally as distinctly through 10 coloured glasses, the lenses being in motion, and through 11, the lenses being at rest. He would suggest, whether the tremulous appearance of the light might not be in part accounted for by the slightness of the revolving frame, which, at the required velocity, vibrates considerably. In the temporary apparatus erected at the Tower, one man could maintain about 40 revolutions per minute.

Mr. Alexander Gordon remarked the coincidence of the experiments of Captain Basil Hall with a law of light as laid down by writers on optics,—viz. that if a luminous body pass the eye eight times in one second, the impressions are blended so as to produce the appearance of continuity, or that the duration of an impression on the retina may be taken at about eight seconds. Now, in the apparatus erected by Captain Basil Hall, there are eight lenses, and continuity of light is produced when the frame makes 60 revolutions a minute. Thus, eight lenses flash across the eye in one second, and the observed result is a remarkable confirmation of the law alluded to.

Mr. Hawkins thought the light was better and steadier at 40 revolutions than at any other speed. When observing the reflection of the light on the features of the by-standers, he saw them very distinctly, the lenses being at rest; but from the moment of commencement of motion, there was a visible diminution in the intensity of the light, which increased with the speed. He saw the light, the lenses being at rest, through 10 coloured glasses, and through 9 when in motion.

Mr. Macneill thought the light was steadier at 60 than at 40 revolutions. The shadow was less intermittent. He did not conceive the mode of examining the intensity of the light through coloured glasses to be so correct as by observing the depth of the shadow, as the eye was capable of judging more correctly of the relative intensity of shadows than of lights. When the lenses were in rapid motion, there appeared a dark spot in the centre of a luminous disc.

Professor Keating, of Philadelphia, stated that the dark spot in the centre appeared as if he saw the wick of the lamp. The lenses being at rest, the light was uniform; but on their acquiring a certain degree of velocity, its whiteness diminished; until at 40 revolutions a decided orange tint appeared, and at 60 revolutions both the orange hue and the centre dark spot increased.

Mr. Lowe inquired whether the quantity or intensity of light was most required for lighthouses. The conflicting opinions of experimenters on the intensity of light, as ascertained by the photometers now in use, show that some better test or means of comparison is wanted. He should conceive that pieces of coloured glass could not afford any accurate measurement of the space-penetrating power of light at so small a distance as 345 feet, which he understood was the length of the room in which these experiments were tried. The depth of shadows also furnished no adequate measure of the intensity of light, for shadows were differently coloured for different lights. Perhaps the photogenic paper might furnish the tests and means of comparison now so much wanted.

The President remarked on the advantages of the revolving lights, as apart from the greater brilliancy, in that they are peculiarly useful as being easily distinguished from land and other lights, which tend to mislead mariners. There may be peculiar advantage in the tremulous character of Captain Basil Hall's light, as enabling it to be more easily distinguished among others. It is not simply the quantity of light which is diffused over the horizon which is valuable, but the intensity of the ray in a certain direction, which, falling on the eye, rivets immediate attention.

Feb. 25.—The President in the Chair.

The following were balloted for and elected:—William Reed, Captain Andrew Henderson, Edward Oliver Manby, William Johnson, Alfred King, and Gustave Holtze, as Associates.

"On the Improvement of Navigable Rivers, with a Description of a self-acting Wasteboard at Naburn Lock, on the River Ouse." By Henry Renton, Grad. Inst. C. E.

Previously to the year 1834, the navigation of the River Ouse from Selby up to Boroughbridge, a distance of 39 miles, was much impeded by a number of shoals or "huts," some of them of considerable extent—all vessels drawing more than 5 feet water being compelled to await until the spring tides set in, so as to afford them sufficient depth of water. Mr. Rhodes was consulted as to the best mode of obviating this difficulty. He recommended the employment of a steam dredging-machine to deepen the bed, by removing the shoals, and the construction of a self-acting wasteboard on the dam, so as to give an additional height of water between Naburn and Linton Locks, as it was found that no injury could occur in the adjacent lands from the level of the river being raised 18 inches.

The greater part of the shoals consisted of compact blue clay, with a mixture of gravel and large boulder stones, and, in a few instances, of oak trees, such as are found near the bottom of bogs.

To use the dredging-machine in the most advantageous manner, the principle of the sliding tool in a turning lathe was adopted, by running the machine across the face of the shoal from side to side of the river, without altering the position of the lower tumbler. This method produced a perfectly even horizontal surface of the bed, and prevented subsequent accumulation. The whole of the shoals were thus removed, so that sea-borne vessels and steamers, drawing from 11 to 12 feet water, could at all periods navigate to York, a distance of 80 miles from the Humber. It was still necessary to raise the height of the water at least 18 inches between Naburn and Linton Locks, to enable vessels drawing 7 feet water to pass at all seasons from York up to Boroughbridge, a farther distance of 20 miles. To accomplish this, the self-acting wasteboard was constructed.

It is composed of two distinct boards of Memel timber, each 76 feet long, 18 inches high, and 4 inches thick, placed on the top of the angular face of the dam. It is fixed by means of strong wrought-iron hinges, leaded into the stone work at intervals of 10 feet. Over the hinges are fixed wrought-iron bolts, 1 inch diameter, connected by flat chains with the plummer blocks on a line of shafts extending behind each board on the face of the dam; on the ends of these shafts are fixed spur-wheels working into pinions which drive pulleys, over which run the chains supporting the balance weights, which are hung on the face of the wing walls. When the balance weights are at the bottom of the walls, the wasteboard will be in an upright position, which occurs when the surface of the water does not rise 6 inches above the top of the boards or 2 feet above the dam; but when, on a sudden increase of the volume of water, there is a considerable pressure on the face of the wasteboard, it more than counterbalances the weights, and causes the boards to incline towards a horizontal position, at the same time raising the balance weights and allowing a free passage for the water. When the pressure diminishes, the weights descend and the boards resume their vertical position.

The time occupied in dredging the river and constructing the wasteboards was two years, and the cost of the latter, which was made by Messrs J. and W. Lailder, of York, was £300.

The result of these alterations has been most satisfactory, as, since their completion, not a vessel has been detained in the upper level, and the registers of the heights of the water at Linton and Naburn Locks and York show, that the winter floods have not risen to such a height, or continued for so long a period, as previously to the improvements being carried into effect.

"On the autogenous uniting of Lead and other metals." By M. Delbruick.

The term "autogenous" is employed by the inventor, M. de Richemont, of the method now described, to designate the union of pieces of metal of the same kind with one another, without the intervention of the ordinary alloys of tin or other connecting medium. This is effected by directing, by means of a fine beak, the flame of a jet of hydrogen on the parts to be united. A complete fusion of the metal is thus effected, and the parts are united in one homogeneous mass, the metal at the points of junction being in the same state chemically as at the parts untouched. Plates of any thickness, whatever the direction of the edges to be joined, may thus be perfectly united, and the lines of junction made as strong as the rest of the mass. Many circumstances contribute to render the joints made with common solder objectionable. The rates of expansion and contraction on changes of temperature for lead and its alloys with tin are different; some chemical agents act much more on alloys of lead and tin than on lead alone. The alloys also are fragile, and the solder may not perfectly attach itself, without the imperfection being observed. In addition to obviating these objections, M. de Richemont conceives that his new method or union possesses the farther advantages of economy, in saving of solder and in avoiding seams and overlappings; in permitting the use of thinner lead and the use of lead where it is now inadmissible, and in rendering practicable the repairs of vessels which are now impracticable.

M. de Richemont also applies this jet of flame to heating the common soldering irons used by tinmen and plumbers. The jet is permitted to play upon the tool, which, in a few seconds, is brought to the requisite heat, and maintained at that heat without any injury to the tool. The heat can be regulated to the greatest nicety by diminishing or increasing the jet. The author conceives that the sulphate of zinc produced in the manufacture of the gas will be found of such value as greatly to diminish the cost of this process.

ROYAL INSTITUTE OF BRITISH ARCHITECTS.

The closing meeting of the Session of the Institute of British Architects was held on Monday evening, the 13th of July. The chair was taken by the President, Earl de Grey, who was supported by a numerous attendance of the Members of the Society and their visitors.

The proceedings of the meeting derived a peculiar interest from the presence of Mr. Morrison, of Dublin, Vice President of the lately established Institute of Irish Architects, who was announced as the representative of that body; Mr. Morrison is also a Fellow of the Institute of London, and the present occasion being the first on which he had attended since his election, he was admitted in due form by his Lordship, who then addressed him as follows :—

Mr. Morrison, I assure you that I am extremely happy at being able to attend here to night as President of this Society, to receive you as the representative of the Royal Institute of Architects of Ireland. We have the same feelings and views as yourself and your colleagues: namely, to promote the arts essential to the profession, and at the same time to elevate the character of the Professors themselves.

It will be remembered by many of those who hear me, that your Society when first projected, was intended to form a branch of our own. The wording of our charter, or some technicality, combined with the distance by which we are separated, rendered it impracticable to effect that union. But though we were thus forced to adopt separate names, we coincide and unite in one common feeling; and I do not hesitate to say that by co-operation we can always mutually be of service to each other.

The utility of such an institution is I think obvious. The benefit resulting to the profession is not confined to any particular portion of it: the juniors as well as the seniors profit by it; for at the same time that the junior members are thereby furnished with opportunities of hearing the opinion, and acquiring information from those who are of longer standing than themselves, it is by no means devoid of utility to the seniors by inducing them to communicate amongst one another the result of their more extended experience. The Association of the Honorary Member is not without its utility. It affords to us, who were not educated for the profession, an opportunity of becoming acquainted with many of the most eminent men in the various branches of it, whilst, we in return, may occasionally have it in our power to assist them, by affording a facility of meeting with persons, and assembling at places which they might not otherwise have an opportunity of doing. With this feeling I accepted with readiness and pleasure the complimentary offer from the Irish Institute, of electing me an honorary Fellow, and I hailed with satisfaction the appointment of a very intimate friend, Lord Fitzgerald, as its President. He, like myself, was not brought up to the profession with which he has thus been associated; but, with the talent which he possesses, I have no doubt that his friends and colleagues will derive much advantage from his connection with their Society.

I look upon this, and our sister Institute in Ireland as one; though separated by St. George's Channel, we have but one and the same object in view, and are pursuing the same road for its attainment. In my double capacity therefore of member of both Institutes, I beg leave again to repeat the pleasure I experience in seeing you, Sir, (to whose exertions I believe I may say our sister Society, is very mainly indebted for its present position, and whose own private and professional character is so deservedly eminent,) now present to take your seat amongst us, as one of our own members. And I feel confident that I express the unanimous sentiments of every one who hears me, in offering to you, and through you, to the Royal Irish Institute our most cordial wishes for continued prosperity.

Mr. Morrison said,—In rising to return thanks for the kind reception I have met, on the occasion of this my first visit to your Institute, and for the obliging expressions which your Lordship has addressed to me, while I feel that I am indebted for both to the position which I hold with relation to he sister Institute in Ireland, I am not less proud of the honour done me, or less grateful for the manner in which it is conferred.

It is, indeed, my Lord, to me a most gratifying circumstance to find, that the efforts I have made to establish, on a proper footing, an Institute of Architects in Ireland, are appreciated by your Lordship and by a Society such as this; and that the success which has crowned my exertions is hailed by a body of gentlemen so qualified to judge of its importance. It assures me, my Lord, not only that the unnatural state of depression, in which for so long a period the professors of our art have been placed in the sister kingdom, was deplored with the sympathy of generous feeling, by our professional brethren in this country, but that by those whose judgment on such a matter must be decisive, it was *felt*, as it is pronounced to be, *undeserved*.

I have never, my Lord, for a moment, mistaken the claims of the architects of Ireland, to hold the position and to participate in the honours which in this and in other countries, are conceded to the instructed professors of our beautiful art. In literature, in science, and in the display of poetic taste and feeling, Irish genius has not been behind that of other lands, in earning for itself " a station and a name ;" and in our art, which demands the union of both taste and knowledge, its Irish professors, as far as opportunities have been afforded them, have (I trust I may say) shewn themselves not unendowed with the admitted talent of their country. I have, then, ever felt, that it has been owing to other unhappy causes, and not to want of ability amongst us, that in Ireland architectural science has been depressed, as it has been undervalued. The dark cloud which, from whatever cause, has hung over the destinies of that country, has discouraged the efforts, as it has depressed the spirits of her children; but still, amidst her darkness, beautiful structures have sprung up from time to time, to testify that architectural taste and ability were there, which under happier auspices, would shed a lustre on the land where they were protected; and record, with enduring monuments, the history of her reviving prosperity and social peace.

It was with this feeling that, while I regretted the past depression in Ireland of the art I loved, and with the cultivation of which I associated the brightest visions of my country's happiness, I felt encouraged, under the awakening aspect of Irish prosperity, in making an effort to exalt my profession in Ireland, by vindicating the true dignity of its educated members. I do not wish to dwell upon a subject which would, by implication, attach discredit to those, who from their station in society, should be the natural protectors of native talent; suffice it to say, what alas! is too well understood, the architects of Ireland have not been valued or encouraged by the wealthy and educated classes of their own countrymen; and they have now sought to win the favour, and the respect, which have been unjustly and unwisely withheld from them, by showing that they understand their own proper merits, and that they have learned to respect and to do justice to themselves.

Such, my Lord, has been the origin of the Royal Institute of Architects in Ireland, to which your noble Society has generously held out the right hand of fellowship, and of friendship; declaring that you esteem us " as a branch of your own Institute in every thing except the name."

For myself, then, and for the Members of the Irish Institute, which has been so honoured and encouraged by this approbation, allow me, my Lord, to return my sincere and grateful thanks. We feel, indeed, that in encouraging and promoting the success of the Irish branch of our profession, they have consulted our common interests, by vindicating the dignity of an art, which we, in common venerate: but while their conduct towards us, has been wise, as it has been generous, we are not from our sense of its prudence, on that account the less grateful for its manifestations.

To all and to each of the members of this Society, I return the respectful and earnest thanks of the body over which I have the honour professionally to preside. Where there are so many who have honoured us, and from whom approval and encouragement are, indeed, so flattering, it is difficult to name individuals to whom we would in particular, be desirous to render our acknowledgments. I may, however, venture to mention *one* whose approbation is no less valuable from his acknowledged attainments, than from his rank; and whose esteem is equally flattering, as, emanating from his good feeling or from his good taste. I need scarcely say, I allude to the noble President of this Institute, one of the first in this country who hailed the establishment of the Institute of Irish Architects, and of whose support and patronage, extended to a scientific association such as ours, it may truly be said, " Auctor preciosa facit."

To Earl de Grey then, the Vice Presidents, and the Members of the Royal Institute of British Architects, I return the warmest acknowledgments I can express, from myself, and from the body which I represent.

Letters were read, from Mr. C. H. Smith, accompanied by a specimen of white marble from America, imported for the first time.—From Mr. Chantrell, of Leeds, on a remarkable case of decay in oak timber, and several other communications from the members and correspondents of the Institute.

Mr. Fowler read a paper on the mode of warming and ventilating the Custom House on Dr. Arnott's principle, which elicited a well merited compliment to Dr. Arnott for the liberality with which he has placed his scientific inventions at the disposal of the public at large.

The noble President then congratulated the Society on the success which had attended the proceedings of the session. The accession of ten Fellows, nine associates, one honorary member, and two foreign members, sufficiently attested the estimation in which the Institute was held by all classes connected with architecture. With regard especially to the interest taken in the proceedings of the Institute by foreign architects, his Lordship adverted to the valuable paper on Greco-Russian ecclesiastical architecture, contributed to the literary funds of the Society by Herr Hallmann, which had been acknowledged by the presentation of a medal to that gentleman. It was further to be observed with reference to the manner in which the Institute had been supported in this respect during the session, that no lectures had been delivered in the rooms—and however desirable the delivery of lectures might be, in bringing before the members in a condensed form, much information on subjects for the study of which they could not otherwise afford time, yet it was undoubtedly to be noted as a proof of the increasing prosperity of the Institute, that the influx of communications on professional subjects had been such as to occupy the meetings during the whole session, and leave no opportunity for hearing lectures. Of the value of the papers read it was not necessary to speak, but of the advantages resulting from the mere circumstance of professional men uniting together, an instance had been afforded during the present evening, when in consequence of a conversation which had occurred at a former meeting on the subject of the remarkable arch between the Western towers of Lincoln Cathedral, one gentleman had produced a drawing of the arch, and another, a resident at Lincoln, had explained its construction; and thus, said his Lordship, information is elicited and science promoted. His Lordship then adverted to the volume which had been announced of the Transactions of the Institute. The question had sometimes been put to him, " what were the Institute doing?" The former volume of the Transactions had sufficiently answered that question at the time it was produced, and it was not to be doubted that another would equally vindicate their proceedings though a longer delay than might be desirable had intervened between the two.

In conclusion his Lordship expressed his warmest wishes for the continued prosperity of the Institute, and his determination to contribute to it by every means in his power.

To all who knew how greatly the Institute are indebted to the support of their noble President, this assurance cannot fail to be gratifying in the highest degree.

NOTES OF THE MONTH.

Blenheim Palace is likely to be repaired at the public expence; a bill is now before Parliament for providing the necessary funds.

Blackfriar's Bridge was closed on the 21st ult. against all horse-conveyances, for the purpose of completing the repairs and paving the roadway, which are expected to be finished and the bridge again opened by the 1st of next month.

At Brighton, Sir Samuel Brown is engaged in making a survey and taking soundings of the coast, for the purpose of ascertaining whether it is practicable to construct an asylum harbour by means of an extensive breakwater.

We perceive by the daily papers, that Mr. Barry has had several interviews with the Commissioners of Woods, &c. on the subject of laying the foundation-stone of the new Houses of Parliament; we were in hopes from the rapid progress that is being made in the erection, that this mummery was likely to be done away with—we hope so still; it is quite a farce, to call it the foundation-stone, now that the building has considerably advanced in height above the ground.

The houses lately built by Mr. Cubitt, in Lowndes Square, near Belgrave Square, in the combined styles of the Elizabethan and Venetian, are deserving of a survey by the architect.

We are happy to hear that Government has determined to have engraved, at the public expence, the elaborate drawings of St. Stephen's Chapel, which have been made with great care by Mackenzie.

The design for the Oxford memorial to the martyrs, is decided in favour of Mr. Scott; we understand that it is in the style of Waltham Cross.

The Duke of Devonshire's grand picture gallery at Chatsworth, which was commenced under the superintendance of the late Sir Jeffry Wyatville, has been just completed. Many of the gems of art at Chiswick and Devonshire House it is said, will be transferred to this gallery.

The sum of £5,000. has been voted by Parliament for the improvement of Trafalgar Square. This amount appears to us very inadequate to do all the work stated in the report given in the last months' Journal. A Committee of the House of Commons has, for some time been sitting, to consider whether it would not be prejudicial to the effect of Trafalgar Square and the adjoining buildings, particularly the National Gallery. The following queries have been put to Sir Richard Westmacott and Messrs. Barry, Deering, Donaldson, Burton, Sydney Smirke and others, with the view of eliciting the opinions of those artists on the subject. When the report of the evidence has been published, it will be interesting to see how these gentlemen have treated the matter, and the reasons they may adduce for their various opinions:—What effect, in your opinion, will a column, of which the pedestal, including the steps is 43 feet high, and the height altogether 170, have upon the National Gallery? What effect, in your opinion, will the said column have as an ornamental object, in combination with the surrounding buildings? What effect will the column have on the National Gallery as you approach it from Whitehall? How far do you consider that position a favourable position for the column itself? The answers, we think, cannot be doubtful. The plans, &c. can be seen by application at the Committee Clerk's office.

Mr. Bielefeld, with considerable ingenuity, has applied Papier Maché to a new purpose, that is for delineating the map of a country, by the aid of which, he is enabled to shew all the eminencies in relief, and at one view the comparative height of the mountains, and a general character of the country. The model which Mr. Bielefeld has lately completed of the Pyrenees, is now exhibiting at his manufactory; it was made from the elaborate model of Sir T. L. Mitchell, who devoted very considerable labour to it in marking out the seat of the Peninsular warfare, together with the principal rivers, mountains, vallies, villages, towns, and forests, which are all laid down to a scale with great accuracy.

At the distribution of prizes at the King's College on the 1st ult., Professor Moseley read a statement of the progress of the department of Civil Engineering and Architecture; it was replete with information, and of such a gratifying character, that we regret we cannot publish it in our present months' Journal as was our intention. The mode of instruction is very excellent, as laying the foundation of an intuitive education, and renders a youth capable of appreciating the value of the profession of which he is to become a member, as well as prepares him to apply the knowledge he has obtained to practical objects in the office of the engineer or architect.

DREDGE'S PATENT SUSPENSION BRIDGE.

Sir,—I noticed a letter in your last Journal from Mr. Curtis, on suspension bridges, and am sorry, on his account, that he should have so strangely attempted to mislead the public on so important a branch of mechanics. He has there stated, that in 1838 he submitted his invention to the British Association at Newcastle, that mine was introduced to their notice last year 1839, that there is an identity of principle in the two inventions, &c. Now unfortunately for his claim to priority, I patented my invention early in 1836, and carried it into practice successfully the same year, in the Victoria Bridge at Bath. *I was* at Newcastle in August, 1838, and there submitted it to the British Association, who unanimously acknowledged its merits (see the *Journal*, vol. i. p. 350,) the particulars of which were published in No. 794 of the Mechanic's Magazine.

At Birmingham, in 1839, I read a paper on Bridge Architecture, and no one disputed the position I assumed. Mr. Curtis must be well aware of these facts, for I believe he was present at both meetings, but why he has found it convenient to forget the former, I must leave for him to explain. I am, however, most astonished that he should so imprudently assert that there is an identity in our plans; it is an assertion that he cannot prove, and it is impossible for the most ordinary observer to look at them, without detecting that difference which he pretends not to see. I would here ask him, was his important discovery acknowledged by the British Association to be new and correct? and if so, has it ever been carried out in practice? I would thank him to answer these questions, and also to state the difference between the bridge of which he says, he is the original inventor, and that proposed by M. Poyet, 40 years ago, and the one at King's Meadows across the Tweed, constructed in 1817.*

It now remains to be observed, that Mr. Curtis, as an inventor, has no reason to complain, as his invention is very different, is undoubtedly of later date, and is in his own opinion, the best of all suspension bridges. If you will insert, in your useful Journal, the above, you will oblige, Sir, your humble servant,

James Dredge.

Bath, July 9, 1840.

* Drewry in his work on suspension bridges, has given particulars and drawings of these bridges.

STEAM PASSAGE TO INDIA.

The Prospectus of the proposed Company for carrying into effect the long dormant plan of traversing, by means of steam, the distance between this country and our Oriental possessions, has been extensively circulated during the present month; and from the vast importance of the subject which it embraces, as well as from its intrinsic merit, and the solidity of the basis upon which the scheme therein set forth stands, it merits a more elaborate notice than we have hitherto been able to give it.

Since the year 1830, two Select Committees of the House of Commons, and one Private Committee, composed of men of the highest character for honour, intelligence, and wealth in the city of London, have sat at intervals of from two to four years, and have thoroughly sifted the question of Steam Communication to India. The labours of these three committees are embodied in as many volumes of evidence, published respectively in 1834, 1837, and 1839; and it is upon the unanimous, and almost undivided opinions and judgment of such men as the Honourable Mountstuart Elphinstone, Lord W. Bentinck, Sir Pulteney Malcolm, Captain Sir David Dunn, Messrs. Maudslay and Field, and other eminent engineers, and a host of other authorities, equally valuable and weighty in their respective departments, that the present undertaking has been determined upon.

The line of route adopted by the Company, is the one so ably and so successfully advocated by Captain Barber in his pamphlet on the subject, namely, by sea from the English port of embarkation to Alexandria, thence over the Isthmus to Suez, and thence again down the Red Sea to Galle, and along the Coromandel coast to Madras and Calcutta. The other routes, as is well known, are the Cape line, the Syrian and Euphrates line, and variation of the Alexandrian line, by crossing the territory of France from Dieppe or Calais to Marseilles; but the objections to all these lines are so incontestibly strong, when compared with the simple and continuous route determined upon by the Company, that it needs only to place a few of the leading points before our readers to induce them to coincide in the decided opinion which we have formed as to the respective merits of the different lines. A glance at the table of relative distances, set forth in the Map appended to Mr. Curtis's temperate and manly exposure of "The state of the question of Indian Steam Communication," will show that the number of miles between Calcutta and England by the Cape route is 11,750, being 3,430 miles greater than that by Suez and the Red Sea, consequently lengthening the voyage, and materially enhancing its risks and annoyances, not to say its expenses, beyond those which will attend the line chosen. It must however be fairly stated, that even the Cape line, with all its inconveniences and additional delays, would be far preferable to the chimerical and impracticable scheme for converting the Euphrates and Tigris into English canals, and for taming the wild Nomadians of the Syrian and Mesopotamian deserts down into well-behaved honest rovers. Nay, we find amongst the minutes of evidence taken before the Private Committee, of which Mr. Curtis was the chairman, that Captain Barber, who is incomparably the best-informed, and the most sagacious and far-seeing of the Steam Company's agents, has expressly taken into his calculation the possibilities of a future war with some of the Continental Powers, or a change in the Egyptian Dynasty, shutting up the Suez line of route, in which case the Cape line would be adopted as a *pis aller*; and Captain Barber, very wisely in our opinion, grounds his reasons for advocating the adoption of the largest class of vessels (2000 tons and 600-horse power) upon the distant contingency of such a war arising, and compelling the Company to send their boats round the African Promontory, in which case the size and consequent speed of the vessels would add to their security, and diminish the duration of the voyage.

Few of our readers would credit the statement, if unfortunately too flagrant proofs could not be adduced of its exactitude, that the state of the communications by sea, between the three Presidencies of Bombay, Madras, and Calcutta are at this moment very little better than they were in the days of Clive or Macartney: there are certain periods of the year during which the Monsoon rages alternately on the Malabar and Coromandel coasts, and during the continuance of these winds, which may truly be styled the *approbrium mercatorum*, the intercourse by sea between the different civil and military stations is almost closed. The steamers plying between the Presidencies, including those established on the line from Bombay to Suez, are totally unequal to the effort of contending with the south-west Monsoon; consequently, the ports are, so to speak, shut up, and the communications take place by the tedious and precarious foot-post or dâk, which runs between Madras and Bombay, and Calcutta and Bombay and Madras, and which is shown by the evidence of Mr. Elliott and others, before the Select Committee of 1837, to be wholly inadequate to the effort of carrying communication as rapidly as might be done between the three Governments, in cases of emergency which are liable to arise from day to day. We have asserted that the steamers now employed by the East Indian Government as mail-boats between Bombay and Suez, are not equal to the effort of facing and mastering the Monsoon during the four months of its duration, from May to September. This assertion is borne out by the fact, that the Atalanta was compelled to put back to Bombay in April 1839, and the Berenice broke her beam in an unsuccessful struggle to make the passage against the Monsoon; and the powers of these two vessels afford a very fair criterion of the capabilities of the remainder, which the East India Company has declared it to be its determination not to alter or increase. Under these circumstances it becomes a matter of vital importance to Madras and Calcutta, but more especially to the latter city, which is the emporium of the East, to set on foot such a means of constant and continuous communication as will supply the glaring deficiencies of the Company's establishment; and after the most mature deliberation, aided by the experience and inventive capacities of some of the most eminent men in the respective departments of the Royal and the Commercial Navy, Civil Engineering, and other Scientific Professionist, to whose testimony is added the unerring and triumphant evidence afforded by the successful experiment tried by the Atlantic Steam Company, as to the capability of steam to overcome the obstacles of wind and weather, the Indian Steam Directors have determined upon building vessels of a tonnage equal to the mastery of the Monsoon gales, consisting of boats of two thousand tons and of six hundred horse power. Of these boats there are to be seven, namely, four in the Indian seas, and three on the European side, which number will, it is confidently anticipated, be fully equal to maintain the monthly communication with the three Presidencies, which it is the object of the patriotic and public spirited gentlemen forming the present nucleus of the Company to achieve, and whose efforts deserve the grateful co-operation of every right-thinking man in the British empire.

There is one topic which we have yet to touch upon as connected with the subject before us, and that is the question raised by the East India Company, as to the expediency of confiding the transport of the Indian mails to a Private Company. * * Appended to Mr. Curtis's pamphlet on the State of the Steam Question is a pertinent document, furnished by the East India Company itself, which ought to convince every holder of India Bonds, that the sooner the conveyance of the mails is made over to a competent, well-arranged Company, the better is his chance of continuing to secure his present ample dividend. The document referred to is entitled, "A Return of the present Annual Cost to the East India Company of *maintaining* (?) the communication between Bombay and Suez." This return extends only to the period of eight and a half months; but an approximate calculation has been formed on its figures, extending it to an entire year, from which it is shown that the total expense of maintaining the four steamers now employed (including an allowance of fifteen per cent. on the prime cost of the vessels, £162,000, for wear and tear,) amounts to £182,828. The receipts, according to the same approximate estimate, were, for passengers £9,534, and the British Government allowed the sum of £50,000 for the transport of the mails: thus a dead loss of £123,294 has been incurred in one year on the present incomplete and inadequate establishment, which cannot perform what it purports to do during four months out of the twelve; and if the number of boats were to be increased, and the establishment extended, the loss would be proportionably greater. The only means of diminishing this loss, or of turning the scale the other way, is by the *conveyance of passengers*.

Having thus, at a considerable, but we trust not an useless, expense of time and labour, endeavoured to demonstrate the physical and commercial advantages of the proposed plan for reducing the distance between Great Britain and her Indian territory, let us turn for a moment to the consideration of the incalculable, the inestimable blessings which must inevitably follow in the immediate train of such increased facilities for intercourse. We have laid it down above, as an axiom, that civilization and benefits of all classes flow naturally from the establishment of a continuous stream of transit; and if this be true with respect to the deserts of Arabia, how much more applicable is it to the fat and fertile plains of Bengal, and of the Payen Ghauts, and the millions who cultivate them? To the philosopher, the poet, the philanthropist, the Christian, the mighty results which may be anticipated from rendering the access to the shores of India safe and easy, are at once exhilirating and overpowering; nor is the gradual and insensible amelioration which must of necessity take place in the minds and religious feelings of the peaceful and tractable Hindoos, by the mere progress of events, independently of the efforts of the Christian missionaries and others, amongst the least of the blessings which British domination and British communication will bestow upon the natives of India. What a field will there not be opened up for encouraging and creating fresh agricultural enterprizes! what schemes for reconstructing the gigantic machinery which formerly existed in the Carnatic and Mysore countries, for the irrigation of the thirsty, though productive soil, may not be expected to be formed, as soon as the capabilities of the country are developed by the discerning eye of the practical engineer! Who can estimate the increased consumption which will ensue of British manufactures, as soon as the natives discover that they can employ themselves more profitably in raising agricultural produce for barter or sale, than in wielding the shuttle and beam? If even manufactured cottons to the amount of two fanams a head, (1*s*. 3*d*.) were to be taken by the populations of the Carnatic, Canara, Bengal, and Orissa, the annual increase in the export value of calicoes would be more than £3,000,000, and surely this is a consideration worth the attention of our manufacturing classes.—*Abridged from a Morning Paper.*

STEAM NAVIGATION.

Steam Tug.—On the 9th July, 1840, a trial satisfactory in its results was made of the new steam tug boat, which has been built for the River Clyde Trustees, by Messrs. Hedderwick & Rankin. The engines by Messrs. Smith & Rodgers, under the personal superintendence and specifications of William Bald, engineer of the Clyde. This small steamer has been built for the purpose of drawing the punts which carry the material dredged up in deepening the river. She is about 140 tons. Her dimensions are, keel 82 feet long, with fore rake 86 feet; breadth between paddles 18 feet, depth 9 feet, and draws 5 feet 8 inches of water. She carries two engines, each about 30 horses power. Diameter of cylinder 30 inches; length of stroke 3 feet 6 inches. The diameter of the paddle-wheels are 12 feet, and float-boards 5 feet 8 inches by 1 foot 2 inches. If the engines make 34 strokes in a minute, the velocity of the wheel per hour will be 4·58 miles. This little steamer has been constructed in the most solid and substantial manner, only for the purpose of drawing heavy loaded punts, and not for speed; yet upon her first trial, and against a strong breeze of wind, she steamed from Glasgow to Port Glasgow, a distance of eighteen miles, in one hour and fifty-nine minutes; and there can be no doubt that her speed will exceed ten miles an hour when everything shall have been put into proper working order, for she has run from Glasgow to Renfrew, a distance of five miles in 32 minutes.

Pacific Steam Navigation Company.—On Tuesday, the 4th ultimo, the Peru, one of the vessels belonging to the Pacific Steam Navigation Company, started from her moorings at Blackwall on an experimental trip down the river and back to Blackwall. She is a very splendid steamer; her engines are of 90 horse power each, and her burden 700 tons. Over her paddles are placed safety boats of a large size, and capable of affording means of escape for the crew and passengers, in the event of fire or any other accident to which long voyages are exposed, but which precaution, there is every reason to think, from the excellent arrangements of this steamer, will be superfluous. Nevertheless, it is a matter of congratulation to those who are about to traverse the immense space of water which divides England from South America, that such contrivances have been adopted for their security, and great praise is due to Captain G. Smith, the inventor and adapter of these safety boats. Their appearance adds to the elegance of the steamer, they take up less room than the paddle-boxes which in general cover the paddles, and, as they are more snug, so they hold less wind, and consequently occasion less impediment to the speed and management of the vessel. This ada tation has been made use of in the royal navy, and has been found to answer all the purposes intended by the inventor, but it has never been employed in me cantile steamers until on board the Chili (which belongs to this company) and the Peru. A model of the invention has been exhibited at the Polytechnic Institution, and the results exhibited in miniature have been satisfactory. The Peru and the Chili were both built in the yards of Messrs. Curling and Young; their engines are from the manufactory of Messrs. Miller and Ravenhill. In these vessels coal will not be used during the voyages, but the prepared fuel of Mr. Oran will be substituted. The Chili started about a fortnight previously. Both she and the Peru will touch at Rio, and proceed through the Straits of Magellan to the Pacific Ocean. The arrival of these vessels in the Pacific will be an era in the history of navigation. They will create a communication between localities which cannot be attained by sailing vessels under two months in the short space of a fortnight, and will help in no little degree to civilize the inhabitants and restore good good government.—a desideratum too long wanted in the regions to which their operations are destined. It [illegible] Blakey [illegible] the efficacy of [illegible] survived [illegible] have [illegible] the water no less [illegible] conveyed by one of them to the shore. Each [illegible] boats will contain upwards of 100 persons. They are in length 27 [illegible] 2 inches in the beam.

The Steamer Brigand.—A remarkably fine iron built steamer, called the *Brigand*, arrived here on Thursday, 9th ult., from Liverpool, *via* Wexford, being her first voyage. She is fitted up in a superb style; the saloon and cabins are elegantly furnished; the panels of the former are painted in a similar style to those of the *Great Western*, and in the latter sixty beds are made up. Her engines, we are informed, are 180 horse power each. She only draws seven feet of water. The vessel is said to have cost £23,000.—*Bristol Mirror.*

PUBLIC BUILDINGS, AND IMPROVEMENTS.

The Neale Monument.—The decision for the design for the testimonial to the late Admiral Sir Harry Burrard Neale, Bart., advertised in the May Journal, has been given in favour of Mr. Draper, of Chichester, and is, forthwith, to be carried into effect under his superintendence. Mr. Draper was also the architect to the military column at West Park, in the neighbourhood of Lymington, and to the Goodwood Race-stand, for his Grace the Duke of Richmond.

Norwich.—On Tuesday, 23rd of June, was laid by the Dean of Norwich the first stone of a church for the Hamlet of New Catton, on a site situated about a quarter of a mile northward of the walls of this ancient city. The building which has been designed by Mr. John Brown, the Surveyor to the County of Norfolk, will be cruciform, consisting of a nave, two transepts, and a chancel. At the west end will be placed a campanile or bell turret, 60 feet in height, so that although the church will not possess a regular tower, there will be an object of sufficient eminence to mark, after the usual manner, the sacred character of the edifice. The style adopted, is the early English, the exterior being wrought with flint-work, white brick quoins, and stone dressings, producing much the same effect as that of the Ladye Chapel at Southwark. The church is to be completed for the sum of £2,400., and will be capable of containing 750 persons, with the means of increasing the accommodation by the future erection of galleries. It is a fact somewhat remarkable, that this is the first church erected in or near Norwich since the Reformation. It must be remembered, however, that within the walls of the city, there exist no less than 35 churches, built in the olden time—a few of these possess some good architectural features, but the majority of them are of an exceedingly common-place character; still, in those cases where the innovations of the Goths of the Batty Langley school are not visible, they are distinguished by a quality but seldom attained in our modern attempts—viz. the *picturesque*.

Bedford.—A new church is nearly completed, for the parish of St. Paul, from the designs and under the superintendance of Mr. John Brown, of Norwich. The first pointed, or "early English" style has been adopted throughout. The plan of the building is perfectly regular and uniform, and at the west end is placed a massive square tower, the pinnacles on the summit of which, reach to the height of 100 feet. In the interior, galleries are placed on three sides of the church; the ceiling, which is in one span, is divided longitudinally, by main ribs, springing from corbels, into compartments corresponding with the external bays, and these principal compartments are sub-divided into panels. Some portion of the area of the building has been excavated, and a crypt formed. The walls throughout, are built of the rough lime-stone, from the neighbouring quarries at Bromham, stuccoed on the external surface, the dressings are executed in Whitby stone. The contract for the building was taken by Messrs. Rollett and Son, of Gainsborough, for £3,338., but the crypt, which was not originally intended, has cost £500. in addition.

New Church at Lee, Kent.—In the notice of this church in our 29th number, we omitted to state that Mr. John Brown, of Norwich, was the architect, and that the contract was undertaken by a Mr. Butler, of Atherstone, in Warwickshire, for £7,446.

The River Shannon.—Our readers will perceive by the list of advertisements that very considerable works are immediately to be contracted for and commenced for the Shannon Commission, under the directions of Mr. Rhodes the engineer.

PROGRESS OF RAILWAYS.

RAILWAYS IN BELGIUM.

A Report has been presented to the Legislative Chambers of Belgium, containing the details relating to this branch of the public works. It appears that the law providing for the construction of the first railways was enacted on the 1st of May, 1834, by which the Government was authorized to construct 397,106 metres, or about 250 miles of railway, starting from a common centre established at Mechlin, and forming a sort of network for connecting different parts of the country. Four lines were thus designed—the eastern line terminating on the frontiers [illegible] by Louvain, Liege, and Verviers, with an extent of 136,323 metres; the northern line to [illegible] with a branch towards the Scheldt, of 25,500; the western line [illegible] Ostend by Ghent and Bruges, of 127,111; the southern line to the frontiers of France, by Soignies and Mons, of 108,152. By the law of the 26th of May, 1837, three new lines were added, viz. one from Ghent to the French frontier; and to Tournay by Courtray, 73,100 metres; the line of Namur, 66,074; the line of Limburg, 10,802; making in the whole, 151,976 metres additional, and the total of all 549,082 metres of railway. The proportion actually opened for traffic was 309,291 metres; that in course of execution 13,453; that remaining for execution, 126,338 metres. Upon the 309,291 metres of lines completed, three-fourths are established with a single line of rails or road; the other fourth, or 82,000 metres, on two lines, comprehending the sections from Brussels to Antwerp, from Mechlin to Ghent, and from Mechlin to Louvain. The outlay incurred to the 30th of September last for the lines completed, and those in course of construction, the railroad, buildings, and materials inclusive, amounted to 55,264,211f., or about 2,200,000*l.* On the enactment of the last law for the construction of additional lines, the experience derived from working out the first lines enabled the Government to arrive at a more exact estimate of the presumed cost. The differences betwixt the estimates for the first lines and the actual expenditure, however interesting as comparative data, will not surprise those in this country conversant with, and interested in, the details of railway enterprise; thus,—

	Estimate. Francs.		Cost. Francs.
The first works, cuttings, embankments, &c.	16,512,000	..	24,177,648
Fixed stations - - - -	741,100	..	2,100,549
Land - - - - -	3,074,900	..	7,321,852
Material (steam-engines, carriages, &c.) -	2,000,000	..	8,300,135
Surveys, &c. - - - -	502,250	..	1,394,175
Total - - - -	22,830,330	..	43,294,359

Thus the cost has been nearly double the total amount of estimates. It is equal to 33 per cent. increase upon the first works of the railways; 138 per cent. upon the estimated value of the land; 182 per cent. upon the stations, work-shops, &c.; and 315 per cent. upon the material of transport, &c. Considering the natural advantages possessed by Belgium for the formation of railroads, in the general absence of hills or unequal ground, in the abundance and cheapness of iron and coal, and in the low comparative price and plenty of labour, these discrepancies between the original estimates and the ascertained cost may, perhaps, be regarded as too considerable not to appear extraordinary. The lines, moreover, had the advantage of being all combined upon one uniform plan, of parting from one common centre, and of being executed under the same superintendence, which must have tended greatly to simplify details, as well as to prevent waste. But it must not be forgotten that in all enterprises where there can be no experience to guide, all previous calculations will, to a great extent, be found fallacious in the end. The progression of the *materiel* on the Belgian railway presents these results:—On the 1st of May, 1835, the number of locomotive engines was 3; of carriages, 40; of waggons for merchandise, &c., 5. On the 1st of May, 1836, the number of the first was 8; of the second, 62; of the third, 6. On January 1, 1837, the first stood at 12; the second, 102; the third, 47. On January 1, 1838, the first at 29; the second, 181; the third, 55. On January 1, 1839, the first at 52; the second, 344; the third, 114. On the 1st of November, 1839, the number of locomotives was 82; of carriages for passengers, 392; of waggons, 163. The prodigious increase of waggons serves to show to what a large extent railway carriage has been made available for merchandise. The full complement of 41 locomotives more had still to be made up, so that the number would be 123; and as they are of greater steam power, the expense under that head would be surcharged more than 50 per cent. The increased means of transport were the natural consequence of the increased pressure of traffic, both in respect of passengers and merchandise. The progressive augmentation of travellers is thus stated:—For the eight months of 1835, the first section of railways alone opened, 421,439 passengers; 1836, two sections, 871,307; 1837, (three sections during eight months, and six during 4 months), 1,384,577; 1838, (six sections during three months, eight for four months, and ten for five months), 2,238,303; ten months of 1839 (ten sections for nine months, and 13 for one month), 1,694,019. Thus in the space of something more than four years 6,609,615 persons have paid as passengers on the Belgian railroads. The fares in the first instance were fixed too low, and of course afforded no fair return for capital sunk. Last year the rates were advanced from the mean price of 1f. 13c. per head in 1838 to 2f. 6c., and the total product of the passenger traffic, which for the month of September, 1838, was 412,542f. ascended in the same month of 1839 to 461,359f. The total receipts from 1835 to the first nine months of 1839 inclusive, amount to 8,759,946f.; the expenses to 6,422,071f.; nett product, 2,337,875f. It may be remarked, that the single line of Brussels to Antwerp, which alone was open in 1836, yielded a larger net return than the clear produce of the whole of 1838, when ten sections were opened. The nett result, after payment of all charges, of the first was 403,997f.; of the second only 364,665f.; from which it may be inferred, as indeed is the fact, that several Belgian lines do not defray the charges of working, and were probably only decided upon in deference to local interests, which could not conveniently, and for political reasons, be denied. The carriage of merchandise commenced only with 1838, the product of which year was 58,591f., and in ten months of 1839, 351,747f. The regular progress during the last year month by month was remarkable, the amount of receipts for January under this head being 7,713f., and for October, 74,790f. The Belgian Minister declared that a stock of 400 waggons for the transport of merchandise was far from being adequate to the wants of trade. In the first instance the directors of railroads commenced with letting out empty waggons to the common carriers, and confining themselves to the mere service of forwarding them with the trains. But this method not proving satisfactory to all interested, a charge is now made according to tonnage, that is, one rate of price for all under 1,000 kilogrammes, and another for all above. The tariff for the first is 40 cents. per ton, or 4 cents per kilometre, or per 100 kilogrammes; for the second, or all above 1,000 kilogrammes, the invariable charge for all kinds, whether by measure or weight, is $13\frac{1}{2}$ cents. per ton. There is a difference, however, in regard of the location of the waggons, which may be supposed to be optional with the carriers, and is charged in that case 18 cents. per ton. These rates are provisional only, and are so headed in the list of charges, as "provisional tariffs for the carriage of merchandise." It is hoped that by improvements, savings in expense, and the increase of traffic, these rates may yet come to be reduced.

It is singular that in the face of this extraordinary increase of railway traffic, the travelling and carriage on common roads in Belgium should not only not have diminished, but progressively been on the increase. The contrary was universally anticipated there, as here, where in many localities such a result has been verified. The following statement of the produce of the *peage des barrieres*, answering to our turnpike tolls, will show how the case has worked in Belgium:—The produce of the *peage* tolls let to the highest tender in 1831 was 2,390,882 francs; in 1832, 2,195,343f.; in 1833, 2,360,161f.; in 1834, 2,415,769f.; in 1835, 2,385,430f.; in 1836, 2,447,985f.; in 1837, 2,584,791f.; in 1838, 2,759,548f.; in 1839, 2,749,301f.

M. Nothomb, the Belgian Minister, gives as the result of his calculations the following comparative analysis of the advantages resulting to the public in time and money between the ancient mode of travelling by diligence and the railroad system, at the least increase of rates by the tariff of 1839. The mean result is stated to amount to a "saving of one half in time, and of 33 per cent. upon fares." The saving in price is thus subdivided: by diligence or first class carriages, 15 per cent.; by open carriages, 30 per cent.; by waggons, 60 per cent. The more humble orders of society profit, therefore, most largely, as ought to be the case everywhere, by the establishment of railroads. In Belgium, where the railroads were undertaken directly by the state, a consummation so desirable was, of course, more easy to carry into effect at any time. But the fact may suffice to show, that here it should have been the business of the legislature to introduce stipulations into all railway bills which would have secured the same proportionate advantages in favour of the lower classes.—*Times*, July 6.

Edinburgh and Glasgow Railway.—The following particulars respecting this important undertaking are abridged from the *Glasgow Constitutional* of Saturday, the 4th ult.—The works on the line from Edinburgh to the Almond Valley, a distance of about eight miles, have recently been commenced, but they are neither of a difficult nor of an expensive character. The line will be carried across the valley by means of a viaduct of 36 arches, of 70 feet span, and vary from 60 to 85 feet high. Near this point it has been found, on levelling some of the embankments formed last year, that the subsidence was only three inches, although the earth had been raised so as to allow 14 inches to subside. This arises from the mixed character of the materials used (stones, blaze, &c.,) and will prove a great saving in the future maintenance of the line. Onwards to the west, the line passes through the Winchburgh Whinstone Ridge, and here is a tunnel of 360 yards, of which 250 yards are completed. This important work is proceeding rapidly. The Avon and the valley through which it runs are crossed by a stone viaduct of 20 arches, some of them upwards of 90 feet high. This will be a beautiful piece of masonry, and will give increased effect to the picturesque views of the Avon valley. The approach to Falkirk presents many fine views of the Carse and the Frith of Forth. The high ground immediately behind Falkirk is crossed by a tunnel of 880 yards, of which 270 are completed, and the drift mines greatly advanced. The view, on emerging from the west end of the tunnel, bursts on the eye, with the panoramic effect of a splendid landscape—the foreground—the rich valley of the Forth, with Stirling Castle in the centre—Benledi and the Ochil Hills, marking out the margin of the plain, and Benlomond and the Grampians filling up the picture in the distance—the whole forming an assemblage of objects of surpassing natural beauty. The line, after crossing the Union Canal which it does on a magnificent arch of 130 feet span, continues nearly level for some miles, is of easy execution, and is partly finished, and possesses no feature of engineering interest, until it reaches the neighbourhood of Castlecary, where it crosses the Cumbernauld road, and a deep ravine, by a viaduct of eight arches, nearly 100 feet high—the one end terminating on an embankment, and the other resting on the remains of a Roman camp. Here will be the station for Stirling and towns to the north of the Forth. The line beyond Castlecary commands an extensive view of the valley. Croymill is the summit of the line, and here there is an excavation of a ridge of whinstone and freestone of considerable depth, presenting no difficulty, however, but what time may overcome. At Cowlairs, near Glasgow, will be erected the engine establishment; and here the fixed engines will be placed to work the tunnel to Queen Street. The incline will be about 2,000 yards, consisting of open cut and a tunnel, divided by eyes into three portions of 550, 300, and 298 yards. From the head of this incline to Edinburgh, the ruling gradient is 1 in 880; presenting, in the facility and cheapness of working it, almost all the advantages of a level line, of which two-thirds are nearly level. The distance being 46 miles, the mail trains will easily run it in one hour and a half. Upwards of 400 yards of the tunnel are completed, and upwards of 200 yards of Guide Mine is carried forward. The contract are all let to be completed by the 1st of August, 1841, and the engineer is directing his energies to realise the opening of this great national undertaking by that time. Much work is done, and this has been greatly advanced by the late fine weather, but a great deal is still to do. There are employed on the line, however, upwards of 8,000 men, horses to correspond, and ten or twelve fixed engines; and, if the weather prove auspicious, this force is adequate to the work.

Hull and Selby Railway.—The importance of this railway, of the opening of which more detailed notice will be found in another part of the Journal, justifies a few remarks of our own. It is comparatively but little known in London or in the share market, partly from the shares being held chiefly by parties in and near Hull, and partly from one of the termini, Selby, being a small town upon the banks of the Humber, or more correctly the Ouse, and many thinking that this is a branch from a main line terminating at Selby. To correct this impression, the name "of Hull and Leeds Junction" has lately been added in the Director's reports, which gives a better idea of the object of the line, although it is less correct, as the Leeds and Selby connects the Hull and Selby line with Leeds, Selby being an intermediate station. The Hull and Selby may, indeed, with equal truth be called the Hull and York, or the Hull and Liverpool, or even the Hull and London, as the Hull and Leeds, because, with the intervention of other railways, it connects Hull with the metropolis and the other places we have named. In this remark on the name we by no means intend to undervalue the importance of this railway, and the very properties we have named of so many lines being connected into one or diverging from it, is proof of our opinion that it ought to be and will be better known to the public than it hitherto has been. In the more extended sense, it forms the eastern link of the chain of railways which, when the Manchester and Leeds is opened, will join the Irish Sea, and the Atlantic with the German Ocean and the North of Europe. With the exception of the bridge over the Ouse, constructed so as to allow ships to pass through, some other bridges, and a long embankment upon the Humber, there has been but little of expensive engineering works to contend with. This railway is 31 miles long, is practically straight and level, excepting the short lengths at the bridges, and to these unusual facilities are, we suppose, in a great measure, to be ascribed the rather unusual facts, that both the ways of this line have been completed without a second application to Parliament for additional power to borrow money, or otherwise, and that the Directors have been enabled to complete both the ways before they opened any part to the public.

The American Engines on the Birmingham and Gloucester Railway.—(Copy.) To W. Gwynn, Esq.—Sir,—In reply to your request, I now briefly give you the results of our trials with the *Philadelphia* engine (manufactured by Mr. Norris, of Philadelphia, U. S.) and the following are the facts up to the present time. 76 chains in the incline of 1 in $37\frac{1}{2}$ have been made ready with a single way, and 3 chains nearly level have been laid temporarily to rest upon before starting. The road is quite new, and consequently not firm nor well gauged, and the works going on close at hand occasionally cover the rails with dirt. The waggons used are of a large class, like those on the Manchester and Leeds Line, and weigh, when empty, rather more than $2\frac{1}{2}$ tons, but having been sent fresh from the shops a few days ago, they work very stiffly. They are loaded with 4 tons, and generally weigh, including persons upon them, about $6\frac{1}{2}$ tons. The *Philadelphia* weighs (as she works) 12 tons 3 cwt., and her tender weighs nearly 7 tons, being in all 19 tons. She has $12\frac{1}{2}$ inch cylinders, 20 inch stroke, 4 feet wheel, not coupled. The weight on her driving wheels is $6\frac{1}{2}$ tons, (as I weighed her at Liverpool,) without water. The usual loads she takes in the present state of the plane are—eight waggons, engine, and tender, with persons equal to 74 tons, gross weight, in ten minutes, or nearly 6 miles per hour; the last quarter of a mile being at the rate of $9\frac{3}{4}$ miles per hour. Seven waggons, &c., equal to $67\frac{1}{4}$ tons, gross weight, in about 9 minutes, or $6\frac{1}{2}$ miles per hour mean speed. Six waggons, &c., equal to 61 tons, gross weight, in sometimes $5\frac{1}{4}$ and sometimes $6\frac{1}{2}$ minutes, say in 6 minutes average, or 9 miles per hour mean speed; the last quarter of a mile usually giving a speed of nearly 11 miles per hour. Five waggons, equal to about 53 tons gross, are usually taken at a speed of 13 miles per hour for the last half mile up. The foregoing results have generally occurred during fine weather, but sometimes the rails have been partially wet, and this has occasioned a difference of speed in the ascent of from half a minute to a minute and a half. The worst day we have had was the 19th instant, when drizzling showers, and the men walking over the rails with marl on their boots, rendered the way very greasy and slippery. On this day, also, the lower part of the plane had been formed only a few hours, and was very soft and badly gauged. Under these circumstances, the *Philadelphia* took five waggons and self and tender, being a gross weight, including persons, of about 53 tons, up at a mean rate of rather more than 5 miles per hour, and the last quarter of a mile was passed at the rate of 8 miles per hour. We then took two waggons off, and the *Philadelphia* took the remaining three waggons, self and tender, being a gross weight, including persons, of 40 tons, up at a mean rate of 12 miles nearly per hour, her maximum speed being nearly 16 miles per hour. I am now making trials to determine the actual pull required by these new and large waggons, and I must beg you to excuse the rough form of this paper, as I am much pressed for time.

Believe me faithfully yours,

Worcester, June 22, 1840. W. S. Moorsom.

P.S.—I ought to add that the pressure of steam in the boiler has been from 55 to 62 per square inch.—W. S. M.

Opening of the North Midland Railway.—The North Midland Railway, which was opened on Tuesday, 30th June, not only completes the communication between this county and London, but also for several miles forms the line by which the Manchester and Leeds, and the York and North Midland Railways enter Leeds. When the Great North of England Railway shall be opened from York to Darlington, (which it will be in October,) and the Manchester and Leeds shall be opened throughout, (as it will be in December,) Leeds will, as it were, stretch out its arms to the German Ocean on one side, and the Irish Sea on the other—to the seat of government and the great emporium of the world southwards, and the county of Durham northwards. Of late years Yorkshire has been considerably behind Lancashire in commercial activity and general enterprise, in the accumulation of wealth and the progress of improvement. But is not this in part to be ascribed to the earlier connexion of the towns of Lancashire among themselves and with London by railways? We think it is; and when Yorkshire has the advantage of the same means of rapid, cheap, safe, and agreeable transit that Lancashire has had, we anticipate that her great manufacturing and commercial resources will be brought out in fuller development, and that she will advance in the race of improvement at the same or nearly the same speed as the sister county. Yorkshire is the seat of several of our most important [illegible] the woollen, the worsted, the linen, and the cutlery, besides [illegible] of iron, leather, pottery, &c.; and it has also the [illegible] with the north of Europe. Hull, and the first corn [illegible] in the north of England. Will be, by the railway now completed, [illegible] population will have their [illegible], Lincolnshire, and their [illegible], Leicestershire, almost at their doors. All raw materials for [illegible] will be more accessible, and the goods manufactured will [illegible] to their home or foreign markets. For health or recreation, its inhabitants will be able in two or three hours to reach either the shores of the sea or the romantic valleys of Derbyshire, or many of the most interesting objects and places of resort in our own county. The agriculturists will also be able to procure more easily the necessary articles, manure, lime, building materials, and implements, and to bring their produce more cheaply and expeditiously to market. And all of every class whom business or taste call to the metropolis will be able, in the short space of ten hours, and ere long perhaps in eight hours, to glide from the heart of Yorkshire to the banks of the "royal-towered Thames."—*Leeds Mercury.*

Opening of the York and North Midland Railway.—This line, the length of which, from York to its junction with the North Midland Railway near Altofts, is 23½ miles, (exclusive of the short branches to Methley, and of two branches to bring it upon the level of the Leeds and Selby Railway,) has been opened in distinct portions at three several times. The portion from York to the Leeds and Selby Railway, near South Milford, being a distance of 13½ miles, was opened on the 29th of May, 1839. A second portion, of about three miles in length, from Milford to Burton Salmon, was opened on the 11th of May, in the present year. And the third portion, about seven miles in length, completing the connexion between York and the North Midland Railway, near Altofts, was opened on Tuesday, June 30, when a party of directors and friends came from York, and joined the immense train from Leeds, by which the North Midland was formally opened. The York and North Midland Railway, together with the Leeds and Selby, and Hull and Selby Railways, completes the communication between York and Hull; and with the North Midland Railway, completes the communication from York to Leeds, Sheffield, and London. The York and North Midland Railway has the advantage of running on almost a dead level through its entire length, with no heavy works, except a tunnel of two hundred yards long at Fairburn, and two fine bridges over the rivers Aire and Calder. One of these bridges was erected with unprecedented despatch, only six weeks having elapsed between laying the foundation of the last pier and completing the bridge. The line has been as economical in the construction as almost any railway in the country, and promises to be productive to the shareholders. It gives great advantages to the city of York, which is thus made very easy of access to all the populous parts of the county, and is placed on the line of railway from the English to the Scotch metropolis. The engineer of this line was George Stephenson, Esq.—The York and North Midland Railway, though completed as far as regards the communication between York and London, is not quite complete as far as regards the communication by *that* line with Leeds. It joins the North Midland Railway at two points, namely, near Altofts for carriages to and from the south, and at Methley for carriages to and from Leeds: the latter branch, from one to two miles in length, is not quite finished, but will be so in a few weeks, after which passengers between Leeds and York will, we understand, be conveyed by the North Midland and York and North Midland lines.—*Leeds Mercury.*

Opening of the Hull and Selby Railway.—This railway, which is 30¾ miles in length, was formally opened by the directors and their friends, on Wednesday, July 1, preparatory to its being opened to the public on the following day. It had been previously arranged that the opening should be signalized by a grand procession. Lord Wenlock (as lord lieutenant of the East Riding), Lord Wharncliffe, the chairman of the board of directors of the Manchester and Sheffield Railway, Sir Thomas Clifford Constable, high sheriff of the county, the members of the borough of Hull, and of other places; the Mayor, Recorder, and Sheriff of Hull; the Mayor of Beverley, the Chairman of the Hull Dock Company, Chamber of Commerce, Trinity House, and other corporations and institutions, were to go in procession through the town to the railway station. But all these intentions were abandoned in consequence of the heavy rain that fell during the morning, and the directors, shareholders, and their friends, instead of starting at ten o'clock, remained at the station till noon. Indeed, it was twenty minutes past twelve when they started, in five trains, (comprising 40 carriages and about 1,000 passengers,) the first of which reached Selby at a quarter past two. The Hull and Selby and Leeds and Selby lines run into each other at the crossing of the road from Selby to Bawtry; and we understand that passengers from Hull, for Leeds or York, go through in the same carriages. The numerous party remained there, inspecting the terminus, the station, &c., till half-past four, when they started on the return trip. They reached Hessle Cliff, about five miles from the Hull station, at half-past five, at the rate of twenty-five miles an hour; but between Hessle and Hull a slight hitch occurred to the engine of the first train, which delayed it and those in the rear for a short time. However, the whole distance was performed in less than an hour and three-quarters. Great crowds were collected at Hull, Selby, and other populous places on the line. All went off well; the railway police exerted themselves to keep order; and not one accident, causing the slightest personal injury, occurred during the whole day. The directors and their friends dined together on their return to Hull in the evening. The effect of this opening is beneficial on the shares, which, it is said, have consequently risen to par.—*Leeds Intelligencer.*

Eastern Counties Railway—opening from Shoreditch to Brentwood.—About twelve o'clock on Wednesday, July 1st, the Directors, accompanied by the engineer, manager, secretary, &c., left the station at Shoreditch, and proceeded down the line to Brentwood, preparatory to the opening to the public in the afternoon; the journey, including stoppages, was performed in 45 minutes, and on their return in 35 minutes. At two o'clock the line was opened to the public, and a train, heavily laden with passengers desirous of availing themselves of the earliest moment to make the trip, left the station at that hour; and other trains, which left in the course of the afternoon, were all full. The extended opening created a great sensation in the neighbourhood of Shoreditch, Bethnal Green, &c., and it is estimated that upwards of 20,000 persons were collected on the occasion; every window, with a view of the line, was crowded, and in some instances the roofs of the houses were removed to admit of a sight.—*Essex Standard.*

The London and Blackwall Railway.—This line was opened to the public on Monday, the 6th ult. A description of the railway was given in the Journal for June last.

The Glasgow and Paisley Joint Railway, extending to 7 miles, was opened by the Directors on Monday, the 13th ult.

The Maryport and Carlisle Railway.—The first portion of this line from Carlisle has been opened. The road is a single line of rails excepting at the ends, and the work has been throughout completed in a most substantial and satisfactory manner. There are no heavy embankments on the line, but the cuttings have been severe, and in one or two places several feet of freestone rock are gone through, which must have been both difficult and expensive. The line passes down the beautiful vale of the Ellen, and crosses the river of that name three or four times. The terminus at present is at Arkleby Coal Pit, near Oughterside, a distance of about seven miles from Maryport.

Lancaster and Preston Junction Railway.—On Saturday, 11th ult., the above railway, which joins the North Union Line at Preston, and thus forms a continuous line from London to the county town, was opened to the public for the conveyance of passengers, &c.

Preston and Wyre Railway—opening throughout.—This railway, which is about 19½ miles in length, and places the rising town and port of Fleetwood on Wyre in connexion with Preston, the manufacturing districts, and the metropolis, was finally opened on Wednesday, 15th ult., by the Directors and proprietors.

The Great Western Railway—further opening.—On Monday, 20th ult., the line of the Great Western Railway was further opened from Steventon to the Farringdon Road, a distance of sixty-three miles from London.—The Great Western Railway works at the Old Bridge, Bath, are proceeding with extraordinary vigour, and greatly excite the interest of the inhabitants and passengers. The arches for the oblique bridge are in part erected, and every day supplies fresh proofs of the exertions of the contractors and the progress of the undertaking. It is expected that the Railway will be open as far as Bridgewater early in 1841, if not during the present year, a distance of 150 miles from London, which will then be accomplished by mail trains in four hours and a half. The Railway will, it is confidently expected, be extended to Swindon, 76 miles from London, in September, and the road from Bath to Bristol (12 miles) will be perfected at the same time; the entire distance between London and Bristol, by the assistance of coaches in the intermediate road, may be then performed in six hours.—*Bristol Times.*

Manchester and Birmingham Railway.—A viaduct over the valley of the river Dane, of dimensions nearly as gigantic as the one over the valleys on each side of the river Mersey, in this town, is about to be contracted for on the line of the Manchester and Birmingham Railway, between Winslow and Crewe. It will have 24 arches of 63 feet span each, at an elevation of about 80 feet, and will be upwards of 1,700 feet in length. There will be but little difference between the one here and that over the Dane, except that the former has 26 arches, and the latter 24, with an altitude of several feet less. We suppose the cost will be much the same; the one here being, we believe, £80,000.—*Stockport Advertiser.*

MISCELLANEA.

The Electrotype.—This important discovery of multiplying copperplate engravings, medals, &c., by precipitating copper from its solutions through the agency of galvanism, is fast progressing in this country. Joseph Saxton and Mr. Peale of the Philadelphia Mint, and Messrs. Chilton, Mapes, and Connor of this city, have made many improvements on the English process. Dr. Chilton has caused copper to be precipitated on non-metallic bodies even, by covering the paper with nitrate of silver, and thus obtaining a copperplate engraving from a mere print on paper. The *savans* of England will see that we are not behind them in science.—*New York Morning Herald.*

Electrotype.—At a recent meeting of the Academy, M. Arago exhibited to the members an impression of a copperplate, taken by M. Jacobi, by means of a galvanic current. But in England this process is already and extensively in practical use. We have now before us a copy from E. Finden's engraving of Dr. James, Bishop of Calcutta, and a copy from an electrotype plate of the same, published by Mr. Palmer, of Newgate Street, and it appears to us impossible to distinguish the one from the other; but as both are for sale, the curious may examine and decide for themselves.—*Athenæum.*

Brass Mouldings patented by Cuerton.—These mouldings are a great improvement upon those made by the ordinary method of casting in brass and then filing and polishing them with considerable labour, which, after all, are never turned out true. By the patent method the moulding is first made in wood, a thin plate of sheet brass is then drawn over the surface by machinery, which is made to fit it very accurately. The patentees are enabled to offer their mouldings at a very low figure in comparison with the former prices for brass mouldings. Patterns may be seen at Messrs. Bunnet & Corpe's, in Lombard Street.

Dampier's Patent Geometric Balance.—We much regret that want of space has hitherto prevented us giving this machine the attention it is fairly entitled to. Of the many improvements in the means of weighing none have appeared so important as the simple machine now before us, indeed, it bids fair to supersede every other method now in use. The great advantage of this machine is, that so far from requiring the usual number of weights, *one* only is wanted; and this weight, from its never requiring removal, or the slightest alteration, ensures accuracy for an almost interminable period. In appearance, it is much like the "Spring Dial," and possesses all the portability and readiness of action with that machine, at the same time being entirely free from those well-grounded objections, which have kept that instrument from being generally adopted. The *mathematical* principle on which Mr. Dampier's balance is founded, renders it equally applicable for light or heavy weights, and one purpose for which it is admirably adapted, is that of a letter balance, in which form, its elegant appearance and beautiful design, render it a necessary appendage for the library.

Blowing up of Cannon-mills Bridge.—On Friday, June 26, a vast multitude of persons assembled to witness the blowing up of these mills. About six o'clock, the trains communicating with 12 charges of gunpowder of 4 lbs. each, inserted at each base of the arch, to the depth of about four feet, were set fire to; hardly had the men time to make good their escape, before seven tremendous explosions took place, carrying away the chief of the fronts of the base of each arch. Much incidental damage was done, but still the bridge remained standing. After clearing away the foundation, however, of the bridge, at 11 o'clock it fell with a terrific crush, but with no damage to any person.—*Caledonian Mercury.*

Painting on Lime, &c.—M. Heideloff, a professor at Nuremburgh, has succeeded, after many investigations and numerous experiments, in fixing paintings unalterably, and at little cost, upon lime, gypsum, and stone. The application of this process has been successfully tried in the cathedral at Bomberg. The process is extremely simple. The size, for binding the lime, is formed only of milk, and the preservation of the painting from heat, cold, and damp, is solely attributable to the method of preparing this mixture. This invention has also the additional advantage that the paintings done in this manner may be washed with water without losing any of the freshness of their colours. It may be added also, that lime receives the colours better than fresco.—*Inventor's Advocate.* [Is there anything new in this?—EDITOR C. E. & A. JOUR.]

Kalsomine, a new paint.—A new and inodorous sort of paint, the invention of Miss Fanny Corbeaux, has been lately introduced to public notice. The materials of which it is composed, are at first soluble in water; and while in this state admit of the design being effaced, or a portion of the colouring of a wall or ceiling being removed, if necessary; a subsequent operation renders the paint insoluble, by a chemical change of the properties of the material, which fixes the colour durably. It is free from any offensive smell, dries in a few hours, is not acted upon injuriously by atmospheric influences, and is said to be more durable than oil paint, as well as more agreeable to the eye, and not at all prejudicial to the health; indeed, a room painted with it one day, may be inhabited the next. It may also be made applicable to easel painting also. We have seen a little landscape painted with this material, which combined something of the depth and solidity of oil with the transparency of water-colour; and a specimen of broad flower painting, for a room, was shewn us, which had resisted the rude action of the scrubbing-brush. The effect of the white as a ground for gilding, is extremely clear without being dazzling; and we can well understand that it possesses the property ascribed to it of "softening and diffusing light."—*Athenæum.*

Novel Wind Engine.—We have been much gratified this week, in examining a wind engine for fen drainage, upon a very improved construction. The object of the inventor (Thomas Brighty, Esq., of Ramsey), seems to have been to produce a machine that shall not be affected by the head thrown against it, to render the least motion of the air available to raise a corresponding weight of water, which may be increased exactly in proportion to the strength of the wind, and (what is intirely a new feature in the above machine) it may safely be left "to take care of itself," requiring only occasional attendance: it clothes itself when the water is high, and when low, unclothes and stops; and let the wind be never so strong, it cannot stir until the water has again risen to a certain pitch; then, if the wind is sufficiently strong, it clothes and sets itself in motion, and continues going until the water is reduced to a certain level, when it at once unclothes and stops. The machinery is extremely simple, and not subject soon to get out of repair.—*Cambridge Independent.*

Soundings at Sea.—At a meeting of the Royal Geographical Society, a letter was read from Captain James Ross, of her Majesty's ship Œdipus, giving an account of some extraordinary deep soundings taken by him at sea. One of these, 900 miles west of the Island of St. Helena, extended to the depth of 5,000 fathoms, the weight employed amounting to 450 lb. Another made in the latitude of 33 deg. S., and longitude 9 deg. W., about 300 miles from the Cape of Good Hope, occupied 49½ minutes, in which time 2,266 fathoms were sounded. These facts were thought clearly to disprove the common opinions, that soundings could not be obtained at very great depths.

Inland Navigation.—A project is on foot for improving the navigation of the river Nen, from the sea to Peterborough, so as to render that place an inland seaport, connecting itself with the towns of Northampton, Leicester, Market Harborough, Stamford, &c.; and, at the same time, to drain 50,000 acres of fens, to lay dry Whittlesea Mere, and to carry lines of road through the drained country, so as to diminish the distance between London and Hull, ten miles and upwards.—*Gloucestershire Chronicle.*

A new manufacture of Tissue.—We have had an opportunity of inspecting the process for manufacturing an entirely new species of tissue and tapestry, which was originally invented or discovered by M. E. Parry, and which, we understand, has been secured by patent, and which, as the material is produced in our own colonies, promises to become an article of great commercial value. In particular, we would refer to some coverings of chairs and tapestry, which have been especially ordered by her Majesty for the palace. It bears so strong a resemblance to silk of the best kind, that it is difficult, without a minute examination, to discover the difference. The material of which it is composed, is the fibre of the banana, aloe, and other trees and plants which are plentifully found in our West India islands, and by very accurate experiments, made by order of the French Government, they have been found on an average to exceed the strength of hemp by one-fourth. The experiments were made at Toulon, upon cordage which had been six months exposed to the air, and an equal time immersed in the sea. We understand that the French Minister of Marine has introduced ropes and cables made of this material, into the Royal Navy, and as it is so much superior to hemp, we see no reason why it might not be advantageously employed in the cordage of the military and commercial navy of this country.—*Post.*

New Planing Machine.—We lately had the pleasure of seeing in operation a new and very curious, as well as effective machine for planing iron, invented and constructed by Mr. Reynoldson, of South Shields. The advantage obtained in this machine over others which we have seen, is that it cuts over the whole of the surface of the metal at once, whether it be one inch or 12 inches in breadth, with great ease; by which process, a very great saving in time is, beyond doubt, effected. It is extremely difficult to convey a correct idea of the manner in which this is effected without the assistance of diagrams. We can state thus far, however: the principal feature in which it is superior to others, is in the chisels or cutters, which are firmly imbedded in an iron roller about fourteen inches in length, and about three and a half inches in diameter. There are eight chisels in the circumference of this roller which extends rather more than half the length. The other end is furnished with an equal number, which likewise extend over a little more than half the length of the roller, and also intersect the position of the cutters in the opposite end, dividing the power which would be required to work it, if the cutters were as long as the roller itself. It is decidedly superior to the point for which a patent has been obtained, as it is calculated to do three times as much work, in a better style, in the same time.—*Tyne Mercury.*

Improved Sash and Table Fastening, &c.—By Thomas Hardeman Clarke, Birmingham, cabinet-maker, June 24.—In place of the ordinary spring bolt, the inventor adopts the use of a wedge formed bolt, which is urged backwards in the frame or socket attached to one window-sash, while the hasp or catch reaching from the other sash is held by this wedge-formed bolt. The same improvement may be applied to tables, but the position of the bolts must be varied, as circumstances may require.—*Inventor's Advocate.*

An improved apparatus for regulating the supply of water to steam-boilers, patented by James Knowles, Little Bolton, Lancaster.—Claims the use of a self-acting apparatus, the working parts of which are within the boiler, and communicate to the supply valve from without. A lever or rod is placed longitudinally on a fulcrum within the boiler, the longer end of which is an upright rod, with a float attached thereon, passing to the outside of the boiler; at the shorter end of the lever is another upright rod connected with the supply valve, working in a tube. As long as there is plenty of water in the boiler, the float will continue to press up the long end of the lever, and, consequently, cause the valve on the upright rod of the short end of the lever to press down on its bearing, and prevent the admission of water from the tank. But when the height of the water in the boiler diminishes, the float lowers with it, and thereby forces up the rod with the valve; thus admitting a further supply of water until the float again rises to close down the valve.—*Ibid.*

Improvements in reducing friction in wheels of carriages, which improvements are also applicable to bearings and journals of machinery, patented by Charles Greenway, of Douglas, in the Isle of Man, July 3.—The first claim consists in the method of forming a "cradle" for the reception of spheres or rollers, near to which, the arm of the axle is made to rotate, whereby a considerable friction is overcome, as the spheres or rollers do not require an axis, and the cradle is so formed as to keep them close to the axle.—In the description of the second improvement, the inventor states that to the carriage, on which the trunnions of a carronade are usually fixed, wheels are not used, in order to prevent recoiling. But in his improvement, wheels are put to the carriage, so as to facilitate the movement of the carronade towards the port-hole or embrasure; and before the act of firing, the carronade with its trunnion is moved by the action of a lever from the carriage on to the deck of a vessel to prevent recoiling, and is again restored to the carriage by the same lever, when preparing to reload.—*Ibid.*

Improved mode of applying water-power, patented by Capt. George Davey.—The inventor claims the application of air jackets or chambers to a column of water, and the method of applying the power obtained by the pressure of the said column of water, through the medium of the compressed air contained in the said air jacket, whereby so great a quantity of air is driven into the working cylinder as to effect a great saving of water, which, in cases requiring a reservoir at a high level, is very important. An upright tube leads from the reservoir to the full extent of the fall of water; at each thirty feet this tube is surrounded by an air jacket, and three or four fine holes are made at the bottom of the tube, within the space covered by it. The lower part of the tube has a lateral connection with a small cylinder, with a double piston or dead boxes working therein. At the opposite side of this cylinder, there is a lateral connection with the working cylinder, that moves, by its piston and rod, the pump or engine. The water, passing from the reservoir, down the tube, forces a quantity of air from the air jackets, with the water, through the small cylinder (that has its double piston open) into the large working cylinder, by which means the piston of this cylinder is forced up; and the tappets on the rod of this piston are so arranged as to strike a lever connected with the rod of the double piston, which admits and shuts off the supply of water from the tube to the working cylinder. The piston of this cylinder being now forced up, the tappet on the rod causes the lever to put the double piston in such a position as to cut off the supply of water, until the water that is below the large working cylinder flows out into the waste, or discharging level. The piston with the rod, in descending, by its gravity, causes another tappet to strike the lever, and put the double piston or dead boxes, [illegible] supply of compressed air and [illegible] is on [illegible] engine in motion, which com- [illegible] a pump or engine.

[illegible] steam-boat has just been completed by Messrs. [illegible] Napier, of Millwall, said to be decidedly the fastest [illegible] England. She has made several experimental trips up and down [illegible] her surprising speed and singular appearance (the engine [illegible] and the piston cross-head working above the deck) a report has [illegible] she is driven by high pressure steam. This, however, is in- [illegible] is propelled by one engine of 100 horse power, the cylinder is [illegible] inches diameter, with four feet stroke; she has a double bottom, which [illegible] strength and safety, and at the same time affords a large space wherein the steam is conveniently condensed, which keeps up a regular supply of fresh water to the boilers, saving nearly the entire power of working an air-pump. She has four separate boilers, any three of which are adequate to supply the engine; so that one may be repaired, &c., without causing any delay. The makers have met the report of "*high-pressure steam*" being used, by an offer to run the *Eclipse* against any steamer afloat, for any distance under 500 miles, with steam at a *lower pressure* than that of her opponent!—*Mech. Mag.*

New mode of propelling Steam Boats.—Falkirk, July 7.—An ingenious mechanic, residing at Grahamstone, has been for a long period engaged in constructing a small vessel to be propelled by means of pressure-pumps—the application of a principle quite new to the masters of this science. On Monday evening the boat was launched into the Forth and Clyde canal, at Bainsford-bridge, and proceeded beautifully along the reach at a rate of not less than 15 miles per hour, conducted alone by the inventor, who worked the pumps. This novel invention has produced much speculation among the members of the profession in this place, and it is now reported that he is so much satisfied with his first experiment, that another on a larger scale is forthwith to be undertaken, and a patent procured to protect the invention. He has no doubt that it will, at no distant era, entirely supersede the present mode of propulsion by means of paddle-wheels.—*Times.*

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 26TH JUNE TO 29TH JULY, 1840.

John William Nyren, of Bromley, Manufacturing Chemist, for "*improvements in the manufacture of oxalic acid.*"—Sealed June 26; six months for enrolment.

Thomas Spencer, of Manchester, Machine Maker, for "*a certain improvement or improvements in twisting machinery used for roving, spinning, and doubling cotton, wool, silk, flax, and other fibrous materials.*"—June 26; six months.

William Jefferies, of Holme Street, Mile End, Metal Refiner, for "*improvements in copper spelter and other metals from ores.*"—July 1; six months.

William McMurray, of Kenteith Mill, Edinburgh, Paper Maker, for "*certain improvements in the manufacture of paper.*"—July 1; six months.

John David Poole, of Holborn, Practical Chemist, for "*improvements in evaporating and distilling water and other fluids.*" Communicated by a foreigner residing abroad.—July 2; six months.

Charles May, of Ipswich, Engineer, for "*improvements in machinery cutting and preparing straw, hay, and other vegetable matters.*"—July 6; six months.

Edward Turner, of Leeds, in the County of York, Engineer, for "*certain improvements applicable to locomotive and other steam engines.*"—July 6; six months.

James Harvey, of Bazing Place, Waterloo Road, Gentleman, for "*improvements in extracting sulphur from pyrites and other substances containing the same.*"—July 8; six months.

Louis Leconte, of Paris, but now residing in Leicester Square, Gentleman, for "*improvements in constructing fire proof buildings.*"—July 9; six months.

Joshua Taylor Beale, of East Greenwich, Engineer, for "*certain improvements in steam engines.*"—July 10; six months.

George Barnett, of Jewin Street, Tailor, for "*improvements in fastenings for wearing apparel.*"—July 11; six months.

Joseph Getten, of Paul's Chain, London, Merchant, for "*improvements in preparing and purifying whale oil.*" Communicated by a foreigner residing abroad.—July 11; six months.

William Palmer, of Feltwell, Norfolk, Blacksmith, for "*certain improvements in ploughs.*"—July 11; six months.

Peter Fairbairn, of Leeds, Engineer, for "*certain improvements in machinery or apparatus for heckling, combing, preparing or dressing hemp, flax, and such other textile or fibrous materials.*" Communicated by a foreigner residing abroad.—July 13; six months.

Thomas Tassell Grant, Esq., and Officer in Her Majesty's Victualling Yard, of Gosport, for "*improvements in the manufacture of fuel.*"—July 13; six months.

Edward Travis, of Shaw Mills, near Oldham, Cotton Spinner, for "*certain improvements in machinery or apparatus for preparing cotton and other fibrous materials for spinning.*"—July 15; six months.

John Lambert, of Coventry Street, Saint James's, Gentleman, for "*certain improvements in the manufacture of soap.*" Communicated by a foreigner residing abroad.—July 15; six months.

James Jamieson Cordes, and Edward Locke, of Newport, Monmouth, for "*a new rotatory engine.*"—July 18; six months.

Moses Poole, of Lincoln's Inn, Gentlemen, for "*improvements in fire arms and in apparatus to be used therewith.*" Communicated by a foreigner residing abroad.—July 18; six months.

James Roberts, of Brewer Street, Somers Town, Ironmonger, for "*improved machinery or apparatus to be applied to the windows of houses or other buildings, for the purpose of preventing accidents to persons employed in cleaning or repairing the same, and also for facilitating the escape of persons from fire.*"—July 18; six months.

John George Bodmer, of Manchester, Engineer, an extension of a patent for the term of seven years granted to him for "*certain improvements in the machinery for cleaning, carding, drawing, roving and spinning of cotton and wool.*"—July 18; six months.

Robert Urwin, of South Shields, Engineer, for "*improvements in steam engines.*"—July 29; six months.

Alexander Angus Croll, Superintendant of the Chartered Gas Company's Works, in Brick Lane, for "*certain improvements in the manufacture of gas for the purpose of illumination, and for the preparation and manufacture of materials to be used in the purification of gas for the purposes of illumination.*"—July 29; four months.

Joseph Bennett, of Turnlee, near Glossop, in the County of Derby, for "*certain improvements in machinery for cutting rags, ropes, waste hay, straw, or other soft or fibrous substances usually subject to the operation of cutting or chopping, part of which improvements are applicable to the tearing, pulling in pieces, or opening of rags, ropes, or other tough materials.*"—July 29; six months.

John Swain Worth, of Manchester, Merchant, for "*improvements in machinery for cutting vegetable substances.*"—July 29; six months.

TO CORRESPONDENTS.

Books received:—Parts 2 and 3 of Ricauti's Rustic Architecture; Ibbetson on Turning, 3rd Edition, this work we before noticed as of one considerable interest to the amateur in Turning: Report on Steam Communication via the Red Sea, by W. D. Holmes, C. E.

Communications received from Pisiculus *on the Tides of the Ocean:* Mr. East; *and* Mr. Burstall *on his Locomotive and Marine Tubular Steam Boiler.*

An original Subscriber *will find in next months' Journal the information he requires on Wood Paving.*

A Comparison of the Rival "Screws" *will, if possible, be noticed next month.*

Mr. Pinkus *forwarded us a paper, which was too late for insertion, relative to our remarks on the Atmospheric Railway, given in the last months' Journal.*

"A Subscriber."—*We are happy to inform him, that as the Reform Club is approaching completion, we shall give engravings of the elevation, plans, sections, and a description of the building either in the next or following months' Journal.*

A constant Reader.—*We will endeavour at some future opportunity to obtain the information he suggests relative to Iron Sailing Vessels.*

A Student of Architecture.—*The work is not yet before us, we will when it is, attend to his suggestions.*

"Ajax, &c." *is mistaken.*

"A Student."—*We will enquire and announce next month, the regulation for obtaining admission to the Economic Museum, we believe it is not sufficiently advanced for its being opened to the public.*

"A Lover of Fair Play" *is unavoidably postponed.*

We have received a communication relative to the "Fire King" *challenge in last months' Journal; we very much regret, that in consequence of an overabundance of materials for this month's Journal, we have been obliged to postpone it: it contains an account of the run of its sister boat the* Glowworm *with the* Ruby, *wherein it appears that the glittering of the* Ruby *completely took the shine out of the* Glowworm.

W. B. C.—*We regret that the original copy of the article which appeared in the 29th number has been destroyed, as we feel satisfied that that part which he states was omitted in the Journal never appeared in the original, as we are always most desirous of giving the name of the architect of any public building, and also the amount of the contract.*

The communications relative to Herr Laves' Truss Beams, *will appear next month.*

Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," *No. 11, Parliament Street, Westminster.*

Books for review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

The First Volume may be had, bound in cloth and lettered in gold, Price 17s.

*** The Second Volume may also be had, Price 20s.

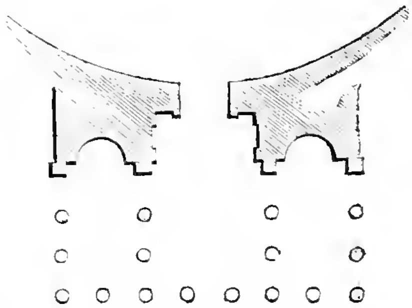
REMARKS ON ANTIENT AND MODERN PORTICOES.

Translation of some Remarks of Milizea, upon the Portico of the Pantheon at Rome, with general observations upon that feature in Architecture, including a notice of some of the Porticoes of London. By A. W. H.

To the uninitiated nothing may appear to be so easy as to compose a good portico; the fact, however, is exactly the reverse; the very simple and dignified character of its details, demanding consummate taste on the part of the architect to combine it with the peculiar style of the building to which it is to attach, and serve as chief ornament. The beauty which shines in the building should be still more apparent in the portico, which feature should become, as it were, the very focus of beauty, since, owing to its position in the edifice, it acts like the countenance in the human form, attracting the first glance, and recalling the last look of the observer; and, as the countenance reveals the mind, so this corresponding feature in a building, should bespeak *its* dignity and spirit; it is therefore manifest, that whatever difficulties may be overcome by taste in designing the body of a building, those difficulties become infinitely greater in the composition of its portico. Owing to the few parts of this architectural feature, and their striking character, it is necessary that the laws of harmony be rigidly observed; any, nay the least, infringement of those laws, leads in this instance to some glaring deformity. One must not, therefore, tamper with so difficult a subject, but recognise it as the legitimate patrimony of matured skill, as a feature which, whilst it spurns all crude attempts, affords, on the contrary, the finest opportunity for the display of real talent.

Besides, what charms in the associations, that sparkle from this gem of architecture! The sacred pageants of Greece and Rome, when seen arrayed within its precincts, appear in all their glory; from beneath the portico's grateful shelter, flowed with full effect the sources of ancient learning; from beneath its roof a Plato and a Tully spoke, and sages to debate, and crowds, thirsting for knowledge, flocked to the portico's genial shade;—seen, therefore, through the hallowed medium of the past, the *portico* rises to our view invested with all the charms of association, as the bewitching scenery which surrounded the ancient founts of wisdom.

Pantheon at Rome.



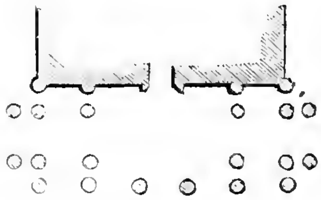
With so much, then, to give it effect, it is not too much to say that this feature demands the architect's chiefest care, and that every effort should be made to invest it with its wonted power, so that it may either strike with awe, attract through its richness and grandeur, be rendered imposing through dignified simplicity, or made captivating by its grace. Milizia, in speaking of the portico of the Pantheon, perhaps the finest specimen of the kind which has ever been erected, makes the following observations:—

"This portico," says that admirable critic, "all dingy as it is through the lapse of ages, its ornaments mutilated, the whole of the upper portion dismantled of its former richness, still expands the mind. It is simplicity itself." This last observation, upon a work which is abundantly rich, of the Corinthian order, and where the sculptor's mimic art appears to rival nature in the production of the luxuriant acanthus, recalls to mind the poet's invocation to that powerful attribute, when, addressing himself to simplicity, he says,

> "Though taste, though genius bless
> To some divine excess,
> Faint's the cold work till thou inspire the whole;
> What each, what all supply,
> May court, may charm the eye,
> Thou, only thou, canst raise the meeting soul."

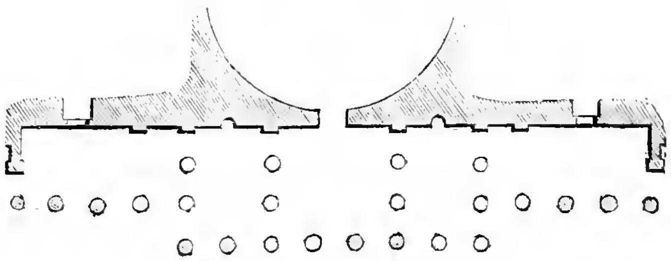
"A few columns merely, and a pediment, constitute this imposing mass, nothing more satisfactory than the straight forward character of its plan, so well adapted to the purpose for which it is designed, a passage to an entrance." It may here be observed, that viewed relatively to their position, the two internal ranges of columns gain great value in our estimation; they guide the visitor at once to the entrance of the sanctuary, who, but for them, might stray to the right or to the left of the immense area of the portico, and thus lose that high enjoyment now produced by the quick succession of strong and varied sensations, resulting from the contemplation of scenery at once so imposing and contrasting. It were in vain to attempt to describe the sensations produced by a visit to the Pantheon; those who have enjoyed so great a treat, will agree that such rapture must be experienced to be understood; such themes soar above mere prose, and, in attempting them, we feel that we are trenching upon the domain of the poet. The Roman critic continues thus; "the eye dwells with rapture on the justness of proportion of the various parts, those parts either taken separately, or in conjunction with one another. *Strength, richness, grandeur,* all the elements which constitute the beautiful, are here combined. Hence that possession which it takes of the mind! hence the universal admiration which it has ever excited among the intelligent! How inferior in their effect to this grand original are the porticoes of the Vatican, and many others attached to the basilicas of Rome, notwithstanding their artificial arrangement of plan, and prodigious efforts made to enrich them; but these lack the judgment which has presided over the distribution of the parts of the Pantheon portico. In this work the columns, though gigantic, appear of a proper size, whereas those of the Vatican always appear enormous; but in the Pantheon they are sensibly applied, inasmuch as they are admirably adapted to their office; to suppose the removal of one, would be annihilation to the whole design; whereas to remove almost all from many of our buildings (still referring to Rome), would be to rid these for the most part of some extravagant superfluity:" thus far our author. Nothing can prove more satisfactorily the merits of this portico, than the circumstance of the great Michael Angelo judging that no design could be conceived more appropriate for an approach to the first temple of modern times, and keenly must the lover of art regret that such an authority as the opinion of that great man should have been made to yield to the puerile conceit of a Carlo Maderno.

St. Geneviève at Paris.



While upon this subject, a feeling of regret also naturally suggests itself, that the architect of the Church of Ste. Geneviève at Paris, bearing, as he seems to have done, this fine portico in his mind, should most unaccountably have disdained to avail himself of its real merits, and by substituting a complicated arrangement of columns, thrown away the opportunity of producing a sublime effect, by aiming at the simplicity of this exquisite model. Nor can we compliment the architects (three in number) to the Capitol at Washington, upon the use which they have made of this grand Roman original; by what those architects have added and retrenched, they have come infinitely

Capitol at Washington.



short of the effect which they might have produced. The additional side columns by apparently bolstering up the portico, sadly impair its vigorous aspect, and quite destroy the effect of its profile. Whenever such adjuncts are deemed necessary, it is preferable to make use of a square ante instead of a column to unite them with that portion which is more properly the *portico;* this not only gives solidity where it is wanted, but causes an agreeable separation of the side columns from the main feature, giving to the eye an opportunity of dwelling upon the more striking portion of the front. The retrenching the depth, which leads from the centre portion of the portico to the interior of the building, must be considered as a great error, as it not only detracts from the solid appearance of the portico, but really weakens it, by lessening its hold upon the body of the building: this depth, too, is a source of much beauty in the composition, inasmuch as, by linking the portico with the chamber, to which the former is intended as an approach, it produces unity in the design, and gives to the portico the appearance of a feature of natural growth, just as in the human form we see the head shooting from the shoulders, connected with them, and gracefully supported by the neck. The architecture of the ancients is full of such propriety, doubtlessly owing to the enlarged and correct view which their highly instructed architects took of the subject,—and here it may not be amiss to touch upon the importance of the study of the human form to the architect, the necessity of which has been so strenuously advocated by the great professors of the art, the soundness of which advice we cannot but admit. The mind bent upon creating, cannot contemplate the wisdom displayed in the mechanism of the human frame, without imbibing lessons of the utmost value to its own productions; the treasures dug from so rich a mine of study by the architect, will go to teach him the importance of balancing the various parts of his design, and of blending them one with another in the plan, as well as in the elevations, so as to produce symmetry and proportion throughout, and to the end that his building may be solid in point of fact and in appearance, and that, numerous as the parts may be, they shall strike the beholder not so much as an accumulation of ideas, than as necessary features to the devellopment of one single thought, the which is so beautifully exemplified in all nature's works.

A glance of the porticoes which adorn our metropolis, may still afford pleasure and instruction, though the attention may have been recently directed to so exquisite a specimen as that of the Pantheon. They divide themselves into two classes; those which were erected at the period of the introduction of fine art into this country from Italy, and those which have been more recently built, and subsequently to the revival of the Greek taste. From its size, as well as from its merits, St. Martin's portico stands foremost amongst those which court attention. Its columns are massive and finely proportioned, and the capitals bold, and finely sculptured, and the detail generally evinces taste and study on the part of the architect; this portico recommends itself moreover, by its great projection from the face of the building, a requisite which should ever be a *sine quâ non* in the composition of this architectural feature. Its defects are, too great a distance between the columns, which gives it a straggling look, the which detracts very much from that vigorous effect which it would otherwise possess; its not extending the whole width of the building is not graceful, as on that account it seems not so much to grow out of it, as to be added to it; and the effect is also much impoverished through the wall immediately behind the columns not receding from the face of the two outer pilasters, and this wall or back part of the portico being crowded with parts, the which sadly interferes with the good effect of the columns; this is a defect which all the porticoes of that period partake of more or less. There is an adjunct to this portico which acts as a very great eye-sore, and the more so since present circumstances by no means sanction its continuance; the object alluded to, is the inhospitable iron railing, inserted between the columns through which the utility of the portico is wofully curtailed, inasmuch as the multitude, who pass to and fro, daily in that neighbourhood, are debarred the shelter which it would otherwise afford them, from the inclemency of the weather; the obtaining of which shelter should surely be the primary object in erecting a portico in a populous neighbourhood. It is possibly very true that at the time at which this railing was so placed, the neighbourhood of St. Martin's offered a very different scene from that which we now behold; and that without some such defence, the portico would have been exposed to injury, from the barbarous propensities of the rude frequenters of that quarter; but circumstances have changed, and the reason for the defence having vanished, the defence itself might also disappear. The feeling which protects such barriers to public comfort, is not a charitable one. Until lately the little portico of Vere-street Chapel, which possesses that important and useful requisite depth, was both an object of utility as well as of ornament, to its immediate neighbourhood; it offered moreover the additional attraction, of plants and flowers which a poor man used to sell, ranging his vases between the columns; the portico thus adorned became really a pleasing sight, it imparted cheerfulness to that portion of the street, which is itself quiet and retired; and offered a spectacle quite refreshing to the eye; besides the mind's eye being gratified by this picture of the church *sheltering*—not encouraging poverty. The charm has however been sacrificed, and the plants and their vendor have been driven from their sacred asylum, and, as a substitute, the inhabitants of that quarter, gaze upon an uncouth iron railing, introduced in a more barbarous manner, even than in the case with St. Martin's portico, since here, it is made to enclose the portico, steps and all, giving to that which looked free, and inviting, an imprisoned appearance.

A most peculiar portico, and one of a very striking character, and a great favourite with the Londoners, is that of St. Paul's, Covent Garden, the condemnatory terms even of a Quatremère de Quincy, avail not in shaking our admiration of a work, so very characteristic of the bold genius of its author,—the learned Frenchman when mentioning it, indulges in a snarl at the English, and attributes their approbation of this work to their little opportunity of judging: London being, according to that learned critic, so barren of porticoes; an observation which either prejudice, or want of local information must have prompted it, for where is the city of modern times, that can vie with our metropolis in the possession of numerous admirable specimens of this fascinating feature in architecture? The propriety of applying so plain an order as the Tuscan, to a building of so exalted a character as that of a public place of worship, may admit of doubt, but that the effect of this portico is truly admirable, no unprejudiced person will deny; it possesses that essential feature *depth*, through which a portico appears to fulfil its apparent destination, that of affording shelter. The arched openings in the flanks present a bold and successful expedient in giving variety, where the stern simplicity of the building seemed to render the task hopeless—and, the few simple means, of producing picturesqueness are throughout skilfully applied. Who with a spark of sensibility in his composition, can gaze upon this building, and not feel that it is the work of a painter turned architect! This portico appears to great advantage when seen in conjunction with the crowds which assemble about it at the time of an election in the market-place; its grave and solemn aspect shed additional interest over the important scene, the whole realizing to the painter's eye and patriot's heart, a soul-intrancing picture, and one from which the enlightened mind reaps aid in its conceptions of kindred scenes, once enacted in the far famed Roman Forum.

In the portico of the East India House, we perceive a new era in taste, it displays the refinement of Greek feeling; but through the want of that great requisite depth it is scarcely entitled to the appellation of portico; for it presents nothing more than a graceful architectural frontispiece; and more graceful would it be deemed, if the pediment had been suppressed, and the cornice been horizontal, because then the design would have been harmonious, and it would have appeared to be what it really is, a mere front decorated with columns; for the introduction of a pediment over a façade of columns far from constituting a portico, on the contrary, becomes offensive, inasmuch as it imparts superfluous energy of character to a feature which lacks that balancing and corresponding vigour which it would acquire through depth. It were impossible to comment upon any portion of the East India House, without speaking in praise of the little Doric portico at the east front; though small, this work is full of attraction, abounding in grace, delicacy, and much energy of character.

In the front of the Mansion House, we see a Corinthian portico raised upon a basement of rusticated piers and arches: this certainly produces a very inharmonious effect; the latter features being of too ordinary a character to suit with the grace and dignity of the Corinthian order. There is in this composition another very glaring defect, viz., the portico leading to nothing; for the hall to which it leads from the street, instead of being of ample dimensions with the portico, is low and contracted. A stately portico should not lead to mere chambers, when it is necessary to have recourse to such economy in the interior, it is ostentation to apply so magnificent a feature, as the portico externally. The very effect of a portico is to exalt the ideas of the spectator, which become suddenly depressed when he least expects it, if it lead not to some feature of corresponding grandeur. Like persons, buildings should not promise more than they perform: and generally, the ideas raised by the external appearance of a building, should be realized in its interior.

In the Corinthian portico of St. Georges, Hanover-square, the order has been well attended to, and much vigour is produced by the columns being comparatively closely placed, the centre opening is somewhat wider than the rest, which is very admissible.

There is something very noble about the portico of St. Georges's, Bloomsbury; the order is boldly treated; and the deep tone of shadow obtained by the great projection from the line of wall, gives to the front columns a fine relief; but it is difficult to comprehend, how a pupil of Sir C. Wren could introduce columns attached to the wall and corresponding to those in front, thereby repeating in the back ground, the front part of the picture, which is surely as absurd in architecture, as it would be deemed in painting.

These porticoes and many others which adorn our metropolis, possess very great merits; and it is cheering to reflect that with the exception of one or two instances they display originality of thought, and that they are modified by circumstances peculiar to the buildings to which they attach: thus they afford us valuable lessons. A question seems here to arise, how is it that these porticoes, having so many claims to our admiration, are not oftener the theme of praise? The reply naturally is, that they have to contend against very overpowing circumstances: they are generally in confined situations, and much discoloured. It would seem from their being so placed, concealed and incumbered by buildings often of the meanest description, that great indifference must have prevailed towards art in general, at the time at which they were erected, and, that but little sympathy could have been entertained for the feelings of an artist, anxious about the effect his work was calculated to produce. We have to congratulate ourselves that the times in which we live, bear the stamp of a more enlightened and liberal sentiment.

As much solicitude is now shown in rescuing former works from oblivion as in erecting new ones; and London in its present stage may be compared to an old picture, in the hands of an intelligent repairer, to which the latter not only adds fresh parts, but is equally intent in giving value to its concealed beauties, by dexterously removing the excrescences of time and neglect. But there remains yet to be mentioned, a cause still more powerful in diminishing the effect of our porticoes, than any yet alluded to, viz., the tower, which becomes a real deformity, when seen rising immediately over the roof of the pediment. This feature so capable of being rendered beautiful when philosophically treated, becomes a positive eye-sore when seen shooting out of the roof of the pediment, and interfering with the severe and classical form of the latter; thus placed it produces all the deformity of a hump upon the back; and yet despite the incongruity resulting from this peculiar disposition of the tower and pediment, it has been persisted in by the generality of our architects, in spite of the better example shown us, by our immortal countryman Sir C. Wren, and his immediate followers. The system which the Italians have adopted, in disposing of these two features, which modern custom has rendered it necessary to combine, shows their nicer discrimination of the true principles of beauty. They have felt, that the forced contact of two elements, whose characteristics are so diametrically opposed—the perpendicular predominating in the one, the horizontal in the other—could not but be productive of an inharmonious result, and, have therefore invariably placed the tower at the end, or on the flank of the church; thus not only, is no unpleasant sensation created, but additional beauty results from this disposition, in the charm which both features give through an *agreeable* contrast.

St. George's, Bloomsbury, affords a striking instance of the last-mentioned method of treating the subject in question, and however opinions may differ with respect to the design itself, people of taste are unanimous in their approbation of the system which the architect has adopted, of combining those two important features, the portico and tower.

The following remark from the late Mr. Thomas Hope, is quoted as an introduction to some general observations respecting porticoes. Touching the important requisite *depth*, that author says, "a portico thus constructed becomes in the first place an object of real utility; it fulfils its apparent destination, that of affording shelter to the pedestrian, and screening the inhabitant waiting for the hour of prayer from the inclemency of the weather; it becomes in the second place a means of infinite beauty, and gives at once to the individual columns, more relief, more distinctness, and consequently more effect, through the deep shade it throws upon the wall behind; and to the entire façade, more motion, more picturesqueness, and more dignity."

Touching the utility of porticoes, it may be permitted to remark upon a fact connected with their projection from the face of the building, upon which circumstance so much of their utility depends; it is then quite consistent with good taste to give to the portico, if required, a projection greater than one intercolumniation, without placing any column in the return; owing to want of attention to this circumstance, it is not unfrequently seen, where the projection is a little more than one intercolumniation, that the intercolumniation itself is made out by a column, immediately behind which is placed the ante; a proceeding which produces the very reverse of a good effect; for the contrast of the cylindrical form of the shaft of the column, with the square form of the ante, pleasing when the eye is enabled, by a proper intervening space between them, to glance gradually from one to the other, is quite grating to the sight, when thus made sudden, by the almost immediate contract of features so dissimilar,—besides that, this union of column and ante, by producing irregularity in the distribution of the points of support, gives to the portico an appearance of weakness. This observation is of value to the architect who is desirous of making his portico an object both of utility and beauty; for in extending it across the foot-path, additional, and very requisite, shelter is afforded, and much picturesqueness is also produced by thus gracefully breaking the necessary long line of street architecture. The beautiful portico of Hanover Chapel, in Regent-street, those of the Haymarket Theatre, and Melbourne House, Whitehall, favourably illustrate this position.

A very important item in the composition of a portico, is the back ground, or wall immediately behind the columns,—this line of wall should always be made to recede, and if possible considerably from the front line of the ante, for by this means a deep tone of shadow is secured for the relief of the columns in front. It is not possible to admire too much the painter-like feeling displayed in this respect, in the above mentioned exquisite portico of Hanover Chapel, where the effect at night seems to have been a matter of study, as completely as that by day: the lamps within the portico are so happily placed that in two corresponding points of view they become concealed from the eye of the observer, who freed from their glare, contemplates more willingly the columns, which tell out in the picture, as dark objects, relieved upon a back ground of subdued light. It is important too that in this portion of the portico there should be as few lines as possible, at all analogous to those of the columns; all perpendicular lines should therefore be avoided; the introduction of pilasters behind the columns, according to the Italian school, is a vice in composition; they only tend to produce monotony and confusion, by repeating and interfering with the front lines of the portico; the obtaining of horizontal lines on the contrary should be aimed at as these by contrast, set off the columns well, especially if the latter be fluted.

The porticoes of the Greeks and Romans, are admirable in the conduct of the back ground, and in this feature we, who keep more to the ancients, greatly excel our ancestors, who designed more immediately in the style of the Italians, the back grounds to whose porticoes are oftentimes positively vulgar. The two celebrated circular temples of Vesta at Rome, and at Tivoli have no pilasters corresponding to the columns, which latter features thus unembarrassed, produce a striking effect. Bramante, that great master of the art, did not escape from this vulgarism, and has greatly impaired the effect of his well known little circular temple at San Pietro, in Montorio, by the introduction of these worse than useless appendages, pilasters.

Aspect is another grand consideration in the application of a portico; no portico should have a northern aspect, unless it have at the same time a famous projection. The grand portico of Rome, the front of which is due north, reads us a valuable lesson upon this point; it projects no less than three intercolumniations from the face of the wall, consequently twice in the day it receives abundance of sunshine, owing to which circumstance it never wears a gloomy appearance. Sunshine is to a portico, what a smile is to the countenance; though neither of the attributes be visible for the moment, their genial influence is ever apparent. A portico from the very boldness of its parts, and peculiar plan, being well calculated for a sunny effect, becomes on the contrary, a most gloomy object, if never enlivened by the the sun's rays; to wit, that doll looking portico affixed to the end of the College of Physicians. In the first place, the aspect of this portico is north, and stuck as it literally is against the wall, it remains throughout the year a complete stranger to the sun's rays; this portico never wears a smile, but cold, chilly and repulsive, even in the brightest season, it has the appearance of labouring under a fit of the dumps, and presents the novel spectacle of a portico requiring the physician's aid; its gloomy appearance offers a strange contrast to the gay scene around, whilst its oblique position, one can imagine it to have contracted from a habit of darting, side-long wistful glances at the sunny, cheerful faces of its neighbours, of the National Gallery and St. Martin's.

Surely it is a strange anomaly, that a conspicuous part of a building, which, from its destination of College, of the guardians of the health of the public, is so rife with associations of a cheering nature, should assume so dreary a look. The Faculty must not be surprised, should any one imagine them, to have laboured under a heavy attack of the portico-mania, when they pressed this woeful-looking object into their service, standing as it does, without reason, rhyme, or sunshine. And singular to observe, another branch of the healing profession, exhibits strong symptoms of having laboured under the same curious malady; the Royal College of Surgeons having, as it were, by hook or by crook, possessed themselves of something of the portico kind, in the shape of four columns, with a bit of an entablature pasted against the wall, affording no shelter, but screening the light, amputation here would be of use, for if the well known Italian question were put to these columns, of "Care colonne, che fate quà?" they might be excused answering, "non sappiamo in verità."

Touching the forms of porticoes, it may be observed that the number of columns should be in such proportion to the height, and perameter of the portico as to display at once its form, without the necessity of the eye glancing to the steps, or to the entablature, in order to deserv it. Great attention should be paid to this point, in designing circular porticoes, for, if the columns be scantily introduced, a doubt is raised in the mind as to whether the portico is polygonal or circular: and then the eye is distressed at the awkward appearance, portions of the architrave assume, in overhanging between the intercolumniations. A portico formed of a double tier of columns, viz., one tier above the other, produces by no means a happy effect, owing to its somewhat ricketty appearance, columns forming but a poor foundation to one another. Grouped columns, commonly called coupled columns, are wholly inadmissible in a portico. So licentious a system of composition but ill comports with the simple character of that feature, which should display architecture in all her severity. There is then no feature in his art, touching the effect of which a true architect will feel more solicitous than that of the portico; for well does he know, that the few, but striking members, which unite in the formation of a well designed portico, captivate the mind, whilst ravishing the eye of the spectator; just as in writing an elegant assemblage of words, conveying a simple thought, arrests and charms the mind of the reader.

ON MALLEABLE IRON IN PERSIA.

An Account of the Iron Mines of Caradogh, near Tabreez in Persia, and of the Method there practised of producing Malleable Iron by a single process directly from the Ore. By JAMES ROBERTSON, *Civil and Mining Engineer, Major Persian Service, and late Director of the Shah's Ordnance Works, Persia; Cor. M.W.S., and Cor. F.A.S.S. Read before the Royal Society of Edinburgh, March* 2, 1840.

THE ancient Greeks have laid claim to the earliest discovery of the method of manufacturing iron, but it will appear that the art was known in Persia at least as early as among the Greeks. The method of producing malleable-iron by a single process directly from the ore, is not indeed quite unknown at the present day, but it is believed to be altogether disused in Great Britain and throughout Europe; but there is no doubt that, in Britain, particularly at Castle Cough, Glamorganshire, and at Furness, near Ulverston, in Lancashire, as well as elsewhere, malleable-iron must have been known long before the discovery of cast-iron. In the 17th century, malleable-iron appears to have been made directly from the ore, in preference to the method now practised. In the Philosophical Transactions (for 1693, vol. xvii. p. 695), there is the following short notice by Mr. Sturdy, of the method as then practised at Milthorpe-forge in Lancashire. "The forge is like a common blacksmith's, with a hearth made of sow-iron, in which they make a charcoal fire, *and put in ore*, first broken into pieces like a pigeon's egg; it is melted by the blast, leaving the iron in a lump, which is never in a perfect fusion; this is taken out and beaten under great hammers, played with water, and, after several heatings in the same furnace, it is brought into bars. They get about one hundred weight of metal at one melting, being the produce of about three times as much *ore*; no limestone or any other flux is used." It has been doubted by an intelligent author (Farey on the Steam Engine, p. 271), whether, by the process here described, the iron was really made directly from the ore, or only from pig metal. The existence, however, of a similar process at the present day in Persia, evidently the same which has been practised in that country from a very remote period, will make it appear not the least improbable that iron may have been thus produced from the rich hematite or fibrous red iron-ore of Lancashire.

The writer of this paper having resided for more than two years in the neighbourhood of the Persian mines, and having been during that time engaged in superintending the manufacture of cast-iron, trusts that the following short account of the mines, and of the very primitive process of the iron manufacture, which came constantly under his observation, may be found interesting, if it be not also of some practical advantage, even where the manufacture is conducted with all the refinements of modern scientific improvements.

We have no historical record from which to ascertain the period at which the iron mines in the district of Caradogh were first wrought. But there is every reason to suppose that they were resorted to from the remotest antiquity. The district itself is very secluded, and is of a wild, forbidding aspect; it has, without almost any interval, formed part of the Medean, and latterly of the Persian empire; and, under the rule of native princes, has all along been free from the revolutions which have so frequently convulsed Western Asia. The iron mines themselves also bear evident marks of antiquity. They form large quarry-like excavations, thickly surrounded by immense tumuli of iron-sand and small pieces of ore, thrown out in the course of working. Upon a rough calculation, founded on the size of the excavated hollow which it exhibits, one only of the numerous iron mines which abound in the district, was estimated by the writer of this notice to have now afforded above 4,000,000 cubic feet of iron-ore. Taking the specific gravity of the ore at 5, a cubic foot would weigh about 300 lb., and consequently seven cubic feet would weigh about a ton; and 4,000,000 cubic feet, the total quantity excavated from that mine, would weigh 571,128 tons. Now, at the present day, 2000 horse loads is a full allowance for the yearly quantity carried away, and as each horse carries about 2 cwt., we have a total of 200 tons per annum as the exported produce at present. It may be reasonably assumed, that this quantity has, upon an average, never been exceeded during the many ages in which the mines have been wrought. Indeed, this estimate certainly exceeds the actual average yearly produce: for although a considerable quantity of Russian iron is now imported, to supply the increasing wants of the inhabitants, it cannot be imagined that, in periods of their early history, the natives would require nearly so much iron as they now do. Upon that assumption and without taking into account the other neighbouring mines, it would follow that 2857 years have passed since the soil was first removed from the surface of the mine alluded to. Were the other neighbouring mines taken into account, the antiquity of the whole would be proportionally increased. The writer has not by any means stated these as calculations, or as at all approximating to accuracy, but still he thinks that, from such data, fanciful as they may in some measure appear, an estimate may legitimately be formed on the very great antiquity of the Persian mines.

The native smiths are dispersed in small hamlets, situated in the woods which clothe the sides of the ravines, through which the mountain torrents flow into the river Arras (the ancient Araxes). The iron which is produced, although soft, is extremely tough. It is much superior to the Russian iron, with which the greater part of Asia is now supplied, and is manufactured chiefly into horse-shoes, and horse-shoe nails, for which there is a great demand in Tabreez and the surrounding districts, and among the Koords or Nomadic tribes who frequent the mountain pastures in summer. The trade in it is shared between the Mahomedans and the native Armenians; and although by no means extensive or deserving the name of the "Persian iron trade," it gives employment to a considerable part of the population, in quarrying the ore, burning the charcoal, and transporting these articles to the forge.

There are numerous mines in Caradogh, affording iron-ore of the most valuable description, and of various kinds; but those held in the highest estimation are the Jewant, Koordkandy, and Marzooly ores.

The Jewant mine is situated in an immense vein of red iron-ore. This ore, on its fracture, often exhibits streaks of prismatic colours, as if at one time it had been subjected to the action of heat; quantities of iron-sand are dispersed in the interstices of the vein.

The Koordkandy mine, situated on the summit of a very steep mountain, produces rich magnetic iron-ore, from a vein of great dimensions. The Marzooly mine also affords excellent magnetic iron-ore in great abundance. The vein in which the last is situated runs across several hills, and is in most parts 100 feet in width.

In working these mines, the richest pieces only of the ore are carried away, the remainder is thrown aside. They are worked very irregularly, and without concert, as there is no restriction imposed as to the mode of mining by the Government. A few individuals sink a shaft through the rubbish, and excavate as much as they require; another party soon after arrive, and fill the first hollow up in the course of sinking another shaft; and in this way the rubbish is repeatedly turned over, and gradually subsides and is consolidated into a mass as the ore is removed from beneath, thus forming a serious obstacle to any one who might attempt to work the vein in a more regular manner. The ore is carried to the villages only during the summer, as the depth of the snow in winter renders the mountain paths impassable. It is there retailed to the smiths, who purchase a horse-load of 2 cwt. for about 1s. sterling, or 10s. per ton.

The ores above described, when smelted singly, produce that kind of iron which by English workmen is called *hot-short*, and by the Persians *salt-iron*. The smiths, however, by means of a mixture, produce iron of an excellent quality, which they term *sweet-iron*. The most common mixture is two parts Jewant ore to one of Koordkandy, and two parts of of Koordkandy to one of Marzooly.

Materials for smelting the ore are found in an extensive natural forest which occupies the natural parts of the district of Caradogh. This forest covers the flat bottoms between the mountains, and spreads to a considerable height up their sheltered sides, dwindling into dwarf trees and bushes in the elevated and more exposed situations. It consists chiefly of coppice oak, which springs from the roots of trees cut and recut during a long succession of years. This jungle is partitioned among the villages situated on its confines, the inhabitants of which earn a livelihood by supplying the city of Tabreez and adjoining towns with fuel.

The charcoal is made in the following manner: a rectangular hollow is dug in the earth, about twelve feet long, six feet wide, and four feet deep. The sides are formed of the natural ground, or common alluvial cover; a small sloping doorway is cut at one end, and at the other a chimney is built rising to the height of about six feet. The pit is filled up to the level of the ground with cut branches of all dimensions, placed horizontally and lengthways in the hollow, and are covered over with earth, and secured effectually against the admission of air, excepting by a small hole in the built-up door-way, which is left open to produce a current; the heap is kindled through the small opening in the door-way, and after it has burned for two or three days the covering is removed, and the charcoal thus produced is then stored for sale. One of these hearths will produce about one ton of charcoal, which sells at thirteen shillings sterling.

The charcoal thus produced, however, is seldom used in the manufacture of iron, the smiths preferring that prepared in the following manner: the cut branches are merely laid horizontally on the surface of the ground, and piled up to a considerable height; having been lighted from beneath, they are allowed to burn in the manner of an open fire, till the smoke and flame have nearly ceased; the fire is then quenched with water, when there remains a charcoal which is very light, and is found to reduce the ores of iron in a much less time than the heavier charcoal produced by the first method.

As the iron is manufactured on a very small scale, a very simple forge answers the purpose. It consists merely of a hollow hearth dug out of the clay floor of the hut, about fourteen inches square in the bottom, and nine inches deep, for receiving the ore and fuel; and of another hearth immediately thereto adjoining, intended to receive the slag, and consisting of a larger excavation, about three inches deeper than the former, and situated betwixt it and the wall at the other extremity in which the chimney is constructed. A wall is built on each of the two sides, two or three feet high, and the whole is covered over with large stones capable of resisting the action of the fire. The whole of the first or iron-hearth into which the blast is introduced is left open above and at the sides; but a low wall is built next the bellows to prevent the heat from injuring them. The whole is afterwards plastered over with clay and chopped straw, in order to maintain the draught of the chimney entire. The chimney is carried up through the wall of the hut, and seldom rises higher than its roof.

The construction and dimensions of these hearths will be best explained by the accompanying drawings.

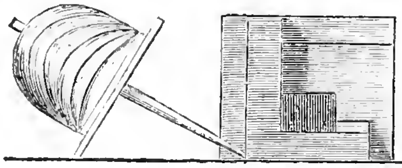

Fig. 6—Section of Ore Hearth.

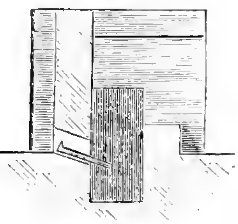
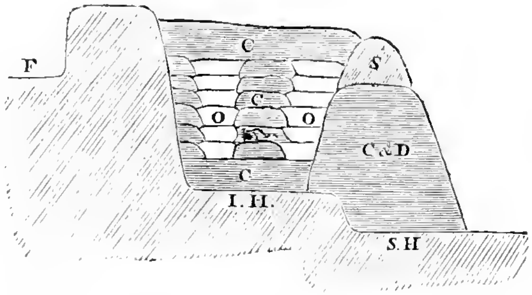


The operator having carefully selected charcoal of a small size and light weight, proceeds to clear it from dust and sand with a small meshed riddle, removing all the heavy pieces of charcoal or stones that may be accidentally mixed with it. The raw ore being next selected and mixed, and being broken into small pieces about the size of a hazel nut, is thoroughly moistened with water. A dam is then made between the iron and slag hearths, composed of charcoal and charcoal dust well rammed down, and the top is coped with iron slag from a former smelting. The following sketch will show this arrangement:

Fig. 7.



References.—I. H. Iron Hearth.—S. H. Slag Hearth.—C. and D. Charcoal and Dust.—S. Slag.—C. Charcoal.—O. Ore.—F. Floor.

The Twyére pipe, which is made of white clay, and bears a violent heat for a long time without melting, is then inserted through the small hole in the side wall of the first iron hearth. The point of the pipe is made to reach half way across the iron hearth, and within six inches of the bottom, as shown in Fig. 6. A layer of charcoal, of three inches thick, is then spread over the bottom of the iron hearth, and upon this two other layers laid across, one directly under the Twyére pipe of about six inches in breadth and three inches deep, and the other at the front of the hearth of the same thickness, to correspond with the overlying part of the dam. The two trenches which are thus formed are filled up with the moistened ore, well rammed down. A second layer of charcoal, in a state of ignition, is thereafter laid over the former under the twyére pipe, and other successive layers of charcoal and ore are filled in, corresponding with these in the bottom.

When the hearth has been nearly filled up in this way, a covering of charcoal is spread over the surface of the whole on a level with the top of the dam. The bellows are then blown, and a workman, who stands at the side of the hearth, keeps constantly pushing down the charcoal in the middle with an iron rod, and from time to time throws small quantities into the centre of the fire as it gradually subsides. At the commencement, one man at a time is sufficient to blow the bellows, but, towards the close, two are required, the one standing behind the other. The bellows shown in Figs. 1 & 5, are in general use all over Persia. After blowing for an hour or an hour and a half, part of the twyère pipe having melted from the violence of the heat, the blast is stopped for a moment, for the purpose of pushing the twyère pipe farther in towards the centre of the hearth. It is then again continued, and in about three hours, or three and a half hours from the commencement, the ore becomes consolidated, but not fused. The blast is then again stopped until that half of the bloom which is next to the slag hearth is turned over with an iron bar, and pushed on the top of the dam, while the other half is turned round to the centre of the fire. The blast is then immediately recommenced, and the metal of the half bloom in the centre of the fire speedily falls to the bottom. The remaining half of the bloom is then drawn into the centre, and treated in a similar manner, very little charcoal being placed on the top of the fire during this part of the process. When the metal has entirely disappeared by sinking to the bottom of the hearth, the whole semifluid mass is stirred about for a quarter of an hour longer with an iron rod. The blast being then stopped, the twyère pipe is withdrawn, and the operator taking his shovel, pushes the burning charcoal together with the dam into the lower hearth: the slag immediately runs off, and exposes the glowing iron lying in the bottom of the upper hearth; the metal is then beaten with the back of the shovel into a more solid state, and after being dexterously cut with an iron chisel bar, from the sides of the hearth, and forced from the bottom, it is removed to the floor of the hut with a large pair of tongs. The iron is next beaten with large hammers as it lies on the ground, in order to expel the slag and other impurities from its pores; and after being in this way formed into a rough mass, it is lifted to the anvil, when it is again hammered into a more regular shape. It is next cut into two pieces with large hammers, and is then fit for being drawn into bars of the dimensions required.

At a single smelting, one hearth generally affords about 30 lb. of malleable iron, to produce which there is only required about double that quantity of ore, and three times the weight of charcoal. One smith with his assistants will make about three or four smeltings in one day, or one cwt.

It must strike every one acquainted with the iron manufacture, that this *yield* is in a high proportion to the materials used. In England, about four tons of raw ore and eight tons of coal are required to produce one ton of bar-iron; while, by the process above described, the same quantity of iron, of a much superior quality, is produced in Persia from less than half of these materials. The greater productiveness is no doubt to be attributed in a great measure to the superior richness of the Persian ores, and the use of charcoal; but the simplicity of the process must also have a considerable share in diminishing the waste of materials; for the roasting, smelting, refining, puddling, shingling, balling, and drawing-out, or something very similar, is all there effected, as it may be said, at one heat, and in a very few hours.

The rich iron-ores of Cumberland and Lancashire, and many others in Britain, particularly the blackband ironstone of Scotland, which has so recently attracted the attention of iron-masters, if manufactured in the same manner, would undoubtedly produce similar results, and thus create a great saving in time, labour, and capital, as well as diminish the waste of materials.

In conclusion, the writer would beg once more to draw attention to the fact that malleable-iron can be readily made directly from the ore, contrary to what he believes to be the prevalent opinion in this country.

Since writing the preceding, the writer has had an opportunity of becoming acquainted with a similar process to the one already described, now successfully practised near the town of Malatia, on the Syrian frontier, in the central parts of Asia Minor. The iron-ores in this district are of the richest description, and were examined by the writer at the command of the Turkish government, with the view of establishing iron-works on the scale of British iron-works, for the supply of the Turkish ordnance. The method there pursued is, if possible, still more simple than that of the Persians, as the furnaces are in the form of a small cupola, and the fuel is simply dry wood.

SUTCLIFFE'S PATENT ROTATORY PUMP.

SIR—I take the liberty of forwarding you the enclosed engraving of a rotatory pump, in which you will perceive Mr. Sutcliffe is completely anticipated, and evidently (from the apparent age of the print) by many years. The coincidence between the two is more than remarkable, and I can but regret the want of the letter-press to accompany and explain; of this, however, you (and your readers, if you think fit to publish it,*) will judge. It is a French invention, and I consider, abandoned by our neighbours on account of its very great friction, and the difficulty there must exist in preserving, for any considerable time, the working surfaces in perfect contact. The ends or water-tight points of the ellipse experiencing so much more wear than the same extent of surface in the surrounding cylinder, or chamber.

If Mr. Sutcliffe, or any person from him, wishes to see the print, I will leave it with you for a time for that purpose.

A.

* [We have not thought it necessary to give the engraving, as it is so identically the same in principle as that of Mr. Sutcliffe's. The engraving, we should say, is at least 100 years old; it may be seen at our office.—Ed. C. E. & A. Journal.]

ADCOCK'S PATENT FOR RAISING WATER FROM MINES.

THE very peculiar and extraordinary degree of novelty exhibited in this process of raising water, and the high degree of importance attached to it by many of our engineering and mining friends, has induced us to open a correspondence with the patentee, who has forwarded to us drawings and a description, which will fully explain the invention.

It may be necessary to state, as the apparatus is for *raining upwards*, many of our readers may have a very inadequate idea of the effect which it produces, and comparing it with the velocity and quantity of rain descending from the clouds, may conceive its effect, as practically inefficient. And so unquestionably it would be, were the cases at all analogous. But in the apparatus erected at the works of Messrs. Milne, Travis, and Milne, at Shaw, where the pressure of the air was a ninth part of a pound upon the inch, the velocity of the rain upwards, and its abundance were such, that if the rain were to descend from the clouds with equal velocity and in equal abundance, it would cover the earth 18¼ feet in a single minute of time. While, on the contrary, it is well-known that the quantity of rain falling in the metropolis in a year, is not more than 22 inches.

To prove what we have here stated, we have only to detail the following:

The diameter of the up-east pipe at Shaw, was 14½ inches = 165 inches area.

Therefore the number of cubic inches in 1 foot of depth = 1980.

And through that pipe 130 gallons per minute were carried up 120 feet in height.

And each gallon contains 277·274 cubic inches.

Hence, 130 gallons × 277·274 ÷ 1980 = 18¼ feet, in depth.

Clearly proving what we have stated, that in a single minute, the earth would be covered rather better than 18 feet in depth.

Most probably we shall resume this subject in our next month's publication. In the meanwhile we shall give Mr. Adcock's description of the apparatus.

(Communicated by the Inventor.)

BY the present modes of raising water from Mines and other deep places, by pumps and pump-rods, and other mechanical contrivances, the water is raised through a series of pipes, in a compact or solid state; in other words, if the depth through which the water must be raised, by a pump or one lift, be 100 feet, then the pipes, extending to that depth, will be full of water, and the whole column of water in those pipes will be lifted at one and the same time.

A column of water 100 feet deep, presses with a force of about 45 pounds on each square inch of its base. Hence, if the diameter of the pump-bucket, or plunger, be 12 inches, and its area, as a consequence, 113 inches, the weight of water to be lifted, *at each stroke*, will be about 5085 pounds.—In a deep mine, therefore, containing 10 such columns or lifts of water, below one another, and acted on at the same time, by the same pump-rod, extending down the shaft or pit of the mine, the weight of water to be raised will be very great, being not less than 50,850 pounds, or about 23 tons. Hence, to lift such weight of water, and to overcome the friction of the water in the pipes, together with the *vis inertiæ* to put such columns of water in motion, and to support its own weight, the pump-rod must be made of great strength; and the steam-engine, water-wheel, or other prime mover, by which the effect must be produced, must be of large size and great power.

By consequence of that *vis inertiæ*, the friction, and the great weight to be put in motion—and when steam-engines are employed, the alternate action or reciprocation of the great lever or beam of the engine—the number of feet of *effective* strokes, made, per minute, is comparatively small, being generally, in deep mines, from about 50 to 80 feet. To explain this more fully, the whole mass of water in the ten columns, having to be raised at one and the same time, and therefore being equal in weight to one column of water of the same diameter and 1000 feet in depth, may be considered as being lifted in the mass, through a distance of 50, or from that to 80 feet in a minute. Whereas, by my "*Improvements in raising water from mines and other deep places, or from a lower level to a higher; which improvements are applicable to the raising of liquids generally, and to other purposes,*" I do not raise water or other liquids in the mass, nor do I find it necessary to exert a pressure, at one and the same time, of 45 pounds on each square inch, when the height to which the water must be raised is 100 feet; nor do I raise water by pumps and pump-rods: but in the manner to be described.

That is to say, by the aid of a steam-engine, water-wheel, or other prime mover, I give motion to a fan, or fanner (such as is used very commonly by foundry-men, engineers, millwrights, and others, to force a current of air into cupolas and other kinds of furnaces), or to the piston of a blowing cylinder (such as is used by iron-masters, and makers of iron, to force a current of air into blast furnaces, for the reduction of ores), and by aid of such fan or fanner, or blowing cylinder, I condense atmospheric air, that it may, when liberated from its confinement, have a tendency to escape into the atmosphere, with a velocity due to its pressure.

When atmospheric air is condensed to a quarter of a pound pressure per square inch, beyond the atmospheric pressure, and is liberated from its confinement, it moves, or has a tendency so to do, at the rate of 173 feet in each second of time; at half a pound pressure per square inch, the speed, due to the pressure, is 245 feet per second; at three quarters of a pound pressure, 295 ft.; at one pound, 340 ft.; at a pound and a quarter, 375 feet; at a pound and a half, 410 feet; at a pound and three quarters, 436 feet; at two pounds, 467 feet; at three pounds, 555 feet; at four pounds, 624 feet; and at other pressures, with other velocities or rates of speed, as may be known by reference to, or consulting the Treatises that have been published on the science of Pneumatics.

Now, instead of raising water in the mass, as herein-before described, by pumps and pump-rods, and such like contrivances, I avail myself of the mechanical effects that may be obtained from the velocities of the air, as due to the pressures herein-before made known, or any other pressures that circumstances connected with mines, in different localities, may prove to be desirable. I cause the water that must be raised from the mine, or from a lower level to a higher, to be dispersed and carried up in drops, like drops of rain; but the velocity of those drops, *upwards*, in consequence of the velocity of the air, is far greater than the *descending* velocities of rain.

For drops of rain, when not receiving an impulse from winds, can only descend through the atmosphere with a speed of about eight feet in a second, when the diameter of each sphere or drop of rain is the hundredth part of an inch. When the diameter of the drop is the sixteenth part of an inch, the greatest descending velocity through the atmosphere is about 17 feet in a second; and the velocities in a second, through the atmosphere, for drops of rain of other diameters, may be thus stated: for drops of rain an eighth of an inch diameter, 24 feet; for drops three sixteenths of an inch diameter, 30 feet; and for drops a quarter of an inch diameter, 34 feet per second. Whereas, the velocity of the air, when allowed to escape from a pipe upwards at one pound pressure per square inch beyond the atmosphere, and without making any deductions for the friction against the sides of the pipes, is about 340 feet in a second. But it should be stated that, when the air is commingled with the water that must be carried up by it from a mine, or from a lower level to a higher, its motion, to a certain extent, is retarded. The velocity of the drops of water *upwards*, however, by this mode, or by these modes of raising water from mines and other deep places, is far greater than the velocities at which rain usually descends, as herein-before has been described.

In the engravings, Fig. 1, Fig. 2, and Fig. 3, represent the apparatus, and Figs. 2 and 3 show a variation of the lower part. In each figure the same letters of reference denote contrivances to accomplish similar objects.

The three kinds of apparatus are shown in section—

a a, represents a pipe, made of zinc, iron, or other material, to convey air from the fan or fanner, or blowing cylinder, to the bottom of the shaft or pit of the mine—or, in a similar manner, air may be conveyed to any required place, or depth, from which water or other liquid must be raised.

b b, another pipe, somewhat larger than the pipe *a a*, to convey the air aforesaid, and the water which is carried up by it from the mine or other depth, in drops, like drops of rain, to the surface of the earth or to the adit, or to any required height, or place of discharge.

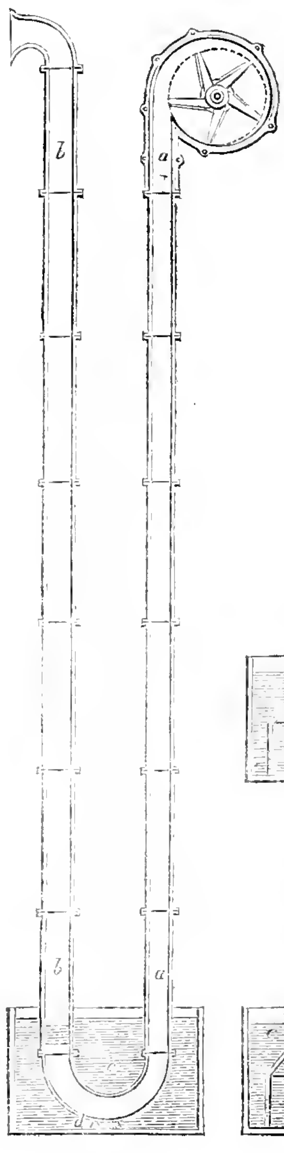
c, the sump, chamber, or reservoir, from which the water or other liquid must be raised.

d, metal, stone, or wood, to serve as supports.

By the rapid revolution of the fan or fanner, or the upward and downward motion of the piston in the blowing cylinder, by a steam-engine, water-wheel, or other prime mover, imparting motion to it, atmospheric air of the requisite amount of density is made to flow down the pipe *a a*, and where the pipe turns upwards in the chamber or reservoir *c c*, it comes in contact with the water or other liquid, disperses it into drops, forces it up the pipe, *b b*, and delivers it at the top.

In Fig. 1, a series of apertures is represented nearly at the bottom of the pipe, *b b*. It is through those apertures that water or other liquid flows into the pipe *b b*, *in jets;* there to be met with, dispersed, and carried up the pipe, by the ascending stream of air.

In Fig. 2, and in Fig. 3, the pipe *b b* terminates in a chamber, compounded, in shape, of a cone and cylinder; and the lower part of the cylindrical chamber is represented as perforated with a series of apertures, through which the water, or other liquid, flows from the reservoir or chamber *c c* into it. The water ascends, by the difference of



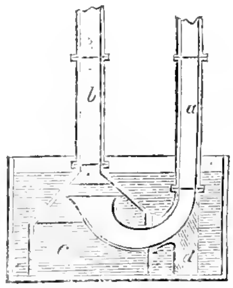


Fig 3.

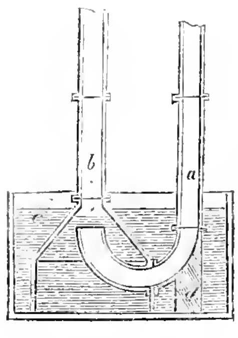

Fig. 1. Fig. 2.

head, above the termination of the air-pipe *a a*: it is there met by the ascending current or stream of air; it is dispersed into drops, and carried up by it, in the manner herein-before made known.

It should be stated that, in mines, and other deep places, where the water may accumulate and rise to some height in the pit or shaft, from the stoppage, by accident or otherwise, of the steam-engine, water-wheel, or other prime mover, or from other causes, I introduce a stop-cock, or other contrivance adapted to the purpose, to regulate the passage of water into, or to exclude it from, the pipe *b b*. I effect this, by putting the apertures aforesaid in connexion with, and in making them receive their supply of water from, a pipe to which such stop-cock is applied. I attach to this stop-cock, or other contrivance, a rod of wood or metal, of sufficient length to rise above the surface of any water that thus may accidentally accumulate in the shaft or pit, and of sufficient strength to enable the workman to open and shut the aperture of the stop-cock, or other contrivance, by it.

It is essentially necessary that this should be attended to, as otherwise the water, or other liquid, may accumulate and rise to such a height in the pipes *a a*, *b b*, as may prevent the passage of the air from the pipe *a a* into the pipe *b b*, and thereby stop the action of the apparatus. For a similar reason, the water or other liquid must never be allowed to stand at a higher level above the end of the pipe *a a*, than the pressure of the condensed air can displace; and to effect this, the reservoir *c c* must be so proportioned to the lower part of the pipe *b b*, that whatever number of inches the water or other liquid may descend by the pressure of the air in the one, it may ascend to an equal number of inches in the other, as in the two limbs of a syphon or bent guage; and to guard still further against the chance of any interruption of the process, either by an accumulation of water in the mine, as aforesaid, or by an imperfect state of the stop-cock allowing a portion of such accumulated water to flow past it into the lower parts of the pipes *a a*, *b b*, I connect with the lower parts of such pipes a small pump, to be worked by the hand of a workman, and rising sufficiently high in the mine to be above the surface of any water that, perchance, may thus accumulate. By such pump, the workman, labouring but a few minutes only, will be enabled to withdraw the water or other liquid from the pipes *a a*, *b b*, and such liquid will be discharged by him, not at the top of the mine, or at the adit, but back again into the shaft, that it may be subsequently raised by the ascending stream of air.

In applying my invention, in practice, I sometimes cause the water, or other liquid, to flow into the *up-cast* pipe, in any given time, in direct proportion to the quantity that can be carried up it, in that time; which may be effected by duly proportioning the sizes of the apertures or perforations, or by the adoption of regulating stop-cocks; and in other modes of applying it, I cause the air, after it has passed through the *down-cast* pipe, to be distributed and dispersed under a large surface of water in a confined chamber, or reservoir, that it may take up a portion of the water by adhesion, in the same way that water is taken up in the formation of steam,—excepting that, in the one case, the water is taken up by the air; in the other, by caloric.

The air and the water commingled with it, or that quantity which is thus taken up by it *in the state of vapour*, is then allowed to accumulate above the surface of the *solid* body of water confined within such chamber or reservoir (assimilating in its object to a boiler for the generation of steam), until it attains the same pressure, per square inch, as the air flowing down the down-cast pipe. After which, it is allowed to flow through a pipe, extending above the surface of the liquid in such chamber, into the lower part of the pipe, where it meets with, disperses into drops, and carries up a still further quantity, in the manner herein-before described.

The weight of water in the pipe, *b b*, at any one time, must be less than the pressure given out by the ascending current of air.

At the top of the up-cast pipe, *b b*, I cause the air and water taken up by it, to be received into a dome, or other appropriate chamber, that the greatest portion of the water may be collected together again in a body, and thence be allowed to flow freely away. The air, and that portion of the water still retained by it, is also allowed to escape.

In other modes of raising water by my improvements, as aforesaid, I produce and maintain, by any of the mechanical means adapted to the end, a partial vacuum in the pipe, *b b*; and instead of employing a *down-cast* pipe, *a a*, to convey condensed air into the pipe, *b b*, I allow air to flow into it from the mine, through pipes arranged for that purpose; so that, by the difference of pressure between the air in the mine, and that in the pipe, *b b*, the water may be carried up by an ascending current of air.

Another important feature of this invention is, that the ventilation of a mine may be carried on free of charge. For the fan or fanner, or blowing cylinder, may be made to receive its air from the open atmosphere; or, by means of pipes extending to the required distance, the air may be received from the depths of the mine; or without employing pipes, it may be received from the upper part of the *up-cast* shaft of a mine, which must be domed over for that purpose. By which mode of operation, the impure air of a mine may be withdrawn, that pure atmospheric air may descend the shaft or pit, by its gravity, to occupy its place.

Having thus described the nature of the invention, and the manner in which the same may be performed and carried into effect, I wish it to be understood, that the velocities of the air, as due to given pressures, and the descending velocities of drops of rain, when falling through the atmosphere, are given by me as approximative numbers only: for atmospheric changes, and other causes, will produce a material variation from them. And I wish it to be further understood, that I do not, in this patent, confine myself to the precise arrangements and dispositions of the combinations and contrivances herein described, and shown by the engraving; but I avail myself of all such other combinations and contrivances as in mechanics are equivalent thereto.

ADDENDA.

By some persons it is supposed, that air cannot be made to flow through pipes of great length.—This supposition has been produced by a statement made in Dr. Robison's "*Natural Philosophy*," art. "*Pneumatics*," respecting an experiment conducted, many years ago, at an iron-foundry in Wales.—It is there stated, that an engineer erected a machine, at a powerful fall of water, to work a pair of blowing-cylinders, or cylinder-bellows, the blow-pipe of which was conducted to the distance of a mile and a half, where the delivery-pipe, or *tuyere*, was applied to a blast-furnace in the usual manner. But notwithstanding that every precaution was used, in making the pipes as smooth as possible, the experiment failed; and the failure was ascribed to the impossibility of making the pipes air-tight.—Other persons, since then, have ascribed the failure, with much better judgment, to the friction of the air against the sides of the pipe; but, being unacquainted with the laws which regulate the passage of fluids, have thence fallen into the erroneous opinion, that air cannot be made to flow through pipes of great length.

I am not acquainted with the sizes of the pipes employed by the engineer in Wales; but it is certain that he was wholly ignorant of the subject, and that the pipes were not properly proportioned to the length. His ignorance is shown by the following:—1, by his making the pipes as smooth as possible in the bore; 2, by his expecting to get the same pressure of air from a pipe a mile and a half in length, as from a short pipe; and 3, from ten minutes of time elapsing after the action of the piston in the blowing-cylinder had taken place, before the least wind could be felt at the end of the pipe, whereas he had calculated that the interval would not exceed six minutes.

With the view to elucidate these errors, and consequently to expose the ignorance of the engineer, I shall adduce the following:—

1. It is well known to those who are acquainted with the flowing properties of air, that providing there be no sudden enlargements and contractions in the pipes, it is a matter of comparative indifference whether the pipes be smooth in the bore, or left in the rough as when cast. For the delivery under the same length of pipe, under the same pressure, whatever that length may be, is, as nearly as possible, the same in both cases.

2. That the greater the length of pipe, the greater, under certain definite proportions, must be its diameter, in order to overcome the friction, and to deliver, under the same amount of pressure in the blowing-cylinder, a given quantity of air in a given time. Hence, as the diameter, and consequently the area of the pipe *increases*, the pressure of the air must *decrease* in a correspondent proportion.

3. That atmospheric air, however compressed, and therefore under whatever pressure it may act, cannot, practically, flow with the rate of speed assigned by him, that is, 1320 feet in a second, *even into a vacuum;* much less through pipes a mile and a half in length, and under the moderate amount of pressure, which is three pounds per square inch, used, commonly, in blast-furnaces.

To illustrate this still further, and to show how easy it is for persons unacquainted with these subjects to fall into error, and thence to deduce erroneous conclusions, I will suppose that 3000 cubic feet of air per minute, at three pounds pressure per square inch beyond the atmosphere, had to be driven into a blast-furnace; and that the engineer, in Wales, finding that a pipe $4\frac{3}{4}$ inches diameter, when only from a foot to a foot and a half in length, would deliver that quantity, had put down a pipe of twice that area, or 6 inches and four-tenths in diameter.

The quantity of air, per minute, that would have been discharged through that pipe, when of different lengths, and under the same amount of pressure in the blowing-cylinder, would have been as follows:—

Length of Pipe.	*Discharge per minute.*
100 feet	3000 cubic feet.
200 "	2230 "
300 "	1870 "
400 "	1640 "
500 "	1470 "
1000 "	1060 "
½ mile	660 "
1	480 "
1½	380 "

Hence, we find that, by improperly proportioning the diameter of the pipe to the length, instead of discharging 3000 cubic feet of air per minute, at the distance of a mile and a half, it would have discharged only 380 cubic feet. In fact, that the diameter of the pipe would have been adapted, only, to 100 feet in length.

To have discharged the 3000 cubic feet of air per minute, the diameter of the pipe for each length, and under the same pressure in the blowing cylinder, would have been as follows:—

Length of Pipe.	*Diameters.*
100 feet	6·4 inches.
200 "	7·2 "
300 "	7·8 "
400 "	8·2 "
500 "	8·5 "
1000 "	9·8 "
½ mile	12·0 "
1 "	13·5 "
1½ "	14·7 "

With these diameters, and under any one of the lengths thus given, the 3000 cubic feet of air, per minute, would have been delivered. But, of course, at the end of the pipe, the furthest from the power, the pressure of the air would have been proportionably diminished, or nearly so. This diminution of the pressure of the air, in the *up-cast* pipe, in applying the patented modes of raising water from mines of great depth, is an advantage rather than a disadvantage: it gradually reduces the speed of the ascending current, and allows the water, when delivered at the top of the mine, the more freely to be collected together again in a body, that it may thence flow freely away.

The *down-cast* pipe may be so proportioned as to maintain nearly an equal pressure throughout its length.

Henry Adcock,
Civil Engineer.

One of Mr. Adcock's patent apparatus is now being put down at the Pemberton Colliery, Wigan.

CANDIDUS'S NOTE-BOOK.
FASCICULUS XVIII.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. Notwithstanding the flunky sort of admiration professed to be entertained by many for Sir John Soane, no one, it seems, cares to imitate him, I do not say in his peculiar style—or rather, fantastic mannerism, but in those matters wherein he has set a really good precedent. It is true he is an exceedingly bad authority to follow because his architectural merits and vices are invariably so mixed up together that it requires some study to disentangle them. While the outside of his house in Lincoln's Inn Fields exhibits the most paltry and puerile taste, and has a most offensive gim-crack and gin-palace physiognomy, the interior offers much that deserves to be adopted: not that it is by any means particularly good in itself, but on account of the hints and ideas as to contrivances and effects, which it affords, and the suggestions it holds out. While there is much in it that is exceedingly poor or even paltry,—what no one would think of copying, or rather would be at some pains to avoid, there are several things which might frequently be imitated, and applied in a variety of ways, and in many cases with little trouble or expense. For instance, the very same contrivance which is adopted in the Picture Cabinet, is susceptible of many modifications, some of which might be conveniently applied to screens, bookcases, and similar pieces of furniture, without fitting-up the whole of a room in that manner.

II. I find that Bartholomew is exceeding angry with me, pouring out the vials of his wrath upon my head, asserting that Caninus would be a more suitable name for me, and among other compliments insinuating that I am descended from Gehazi the servant of Elisha—which is certainly tracing back my genealogy further back than that of any one now living. But what if after all if my real name should turn out to be White, and that I have taken the liberty of latinizing it; instead of arrogating to myself by my assumed appellation any particular stock of Candour? Any one who is not absolutely as blink-eyed as B. might instantly have perceived from the very motto I have chosen that I disclaim all pretensions to greater candour than my neighbours. Besides there are two different sorts of candour;—one of which consists in *ingenuously* confessing our own faults, the other, in *ingeniously* exposing those of our friends; which last is that possessed by me. After all, whether I am candid and indulgent, or quite the reverse, has nothing to do with the matter: what chiefly concerns my readers is whether my opinions are well founded and deserving of consideration. Even Bartholomew himself does not pretend to say the contrary—at least he has not cared to call any one of them in question, by pointing out its absurdity and fallacy. His compliments apart, the worst it would seem, that he can find to say of me is that I am given to barking—which is no more than I myself confess in the very passage he has quoted,—and that I like to have all the "cutting" to myself. Granting this last allegation to be well founded, though I am not conscious of having uttered any thing that can be construed as a desire to monopolize that operation;—granting this, I say, it would follow that there exists a perfect harmony of tastes between myself and Bartholomew, for he is not at all sparing of cuts at his professional brethren; and he not only barks, but growls too, most doggedly. This man who makes such a pleasant outcry against cutting and maiming, makes no scruple of stabbing poor John Nash's reputation, asserting that he was not gifted with one of the accomplishments "so necessary to an architect." Nay he may be said to massacre reputations by wholesale, damning, as he does, in the lump, both the taste and practice of professional men at the present day;—for which he may perchance one day or other be sainted by them, that is converted into a *St.* Bartholomew, by being flayed alive.—Most surely when he calls Holland, who died in 1806, one of the last of England's *real* architects, it is tantamount to a sweeping condemnation of all the members of the profession at the present day. Nevertheless poor little Bartholomew affects to be shocked at me;—which is undoubtedly highly amusing.

III. There is, I admit, one very great point of difference between us, for as he belongs to the profession himself, Bartholomew may probably feel that he has a right to abuse it as much as he pleases, without any body's interfering to hinder him; whereas I being no more than one of those whom he denounces as self-made critics, cannot reasonably look to enjoy a similar privilege. With all due deference, however to Saint Bartholomew, I conceive that all critics are and ever have been self-made or self-constituted: at least I never heard of their taking their degrees as such at any college: or of their being appointed to that capacity by Her Majesty; or of critics being made by Act of Parliament. Critics, I should fancy, are one and all volunteers in the service they engage in,—and of course myself among the rest. The day will perhaps arrive, when matters will be managed far differently, and we critics be elected in the same manner as members of the House of Commons. In the meanwhile the Gwilts and the Bartholomews must submit whether they will or no to our present self-election. One comfort for them is that they are not obliged to read our impertinences, or to waste their precious time in refuting what they would persuade others is only arrant ignorance. It certainly is extraordinary that architects—and architects alone, should show a disposition to gag criticism and stifle discussion, or even the expression of opinion. Notwithstanding which the generality of them, I believe, have no particular aversion even to ignoramusses giving their opinion to the world, when it happens to be complimentary to themselves, and of course, most sensible, and most orthodox.

IV. Whether Mr. Wightwick will be considered altogether orthodox by Bartholomew, is to me a matter of very great doubt, or rather no doubt at all; the avowed object of the author of the "Palace of Architecture," being to popularize the study of the art, to divest it of all that mystery and humbug which have so long rendered it an arcanum,—an art which the public are no less funnily than modestly called upon to admire with all possible admiration, and assured in the very same breath that they can neither comprehend nor properly relish it! With what unspeakable horror must such gentlemen as Gwilt and Bartholomew read the following sentence in Wightwick's book: "and now we would finally address a concluding question to our fair COUNTRYWOMEN. Can they do better than give some of their leisure to an art so essentially decorative as that of architecture?" This is liberality with a vengeance! Is there no salic law to prevent this threatened female tyranny over architecture? Why in another generation we shall have a swarm of Candidi or rather Candidæ in petticoats! By the shades of Vitruvius and Palladio, Wightwick's doctrine is most

Pestiferous! and devoutly is it to be hoped that he will receive an exemplary good thrashing from St. Bartholomew the Little.

V. Upon one point, indeed, Bartholomew and Wightwick, though in all other respects almost antipodal, agree tolerably well; namely in their estimate of the Elizabethan style, against which they both formally utter their protest,—Wightwick briefly yet energetically, and Bartholomew at considerable length, cataloguing its vices and deformities one by one. So far, however, from attempting there to contradict him, I am more inclined to say *ditto* to his strictures; and if nothing else, they certainly do show some boldness in venturing to run quite counter to the taste of the day, for that barbarous fashion has been taken all of a sudden most wonderfully into favour, and has in consequence had several ably executed and expensive works, by Joseph Nash, Richardson, &c., especially devoted to it; which productions are not calculated to allay the feverish admiration of the public.

VI. "Elizabethan carving," says my worthy friend Bartholomew, "resembles the schoolboy's performance with a penknife upon sticks of firewood, some degrees below the workmanship of Dutch toys"!! This is tolerably strong—nay, shows that the tender and merciful B. is quite as well entitled to the epithet *Caninus* as myself, and no less fond of cutting up, what he does not like,—which I take to be in general the case with all of us—both saints and sinners.—Let us proceed: "some persons," he afterwards observes, "very highly praise the Elizabethan buildings, solely on account of their general effect; but they never can defend any of their licentious and childish details, which indeed may at once be said to contain all the *faults and corruptions of design and composition which have ever been condemned in every style of architecture, by every description of critics, of every age, and of every country in the world*" !!! Now for one who dislikes "barking," this is valiantly vituperative.

VII. Our amiable St. Bartholomew verifies the adage of *Clodius accusat mœchos*, for though he professes to be quite scandalized at my naughtiness, he, as has already been shown, leaves it to be inferred plainly enough that the race of "*real architects*" is now altogether extinct among the profession; and even talks of "*the sneaking, fraudulent, pickpocket system which has led to extensive Fauntleroyism in modern architecture*" !!!

— Bartholomew, my boy! we are now quits: you are a d — honest, plain-speaking, though somewhat hard-mouthed fellow,—one who does not mince matters at all. I would advise you, however, to have a little more fellow feeling, and not serve me as the pot does the kettle; nor be quite so unmindful of your own dear self as to imagine me the only canine candid creature in this naughty world who has a taste "for abusing every body, and every thing," when you are pleased to libel the whole profession at one fell swoop, and to represent modern architecture as little better than a system of fraudulent knavery coupled with the most disgraceful ignorance.

PUBLIC BUILDINGS IN LONDON.

A Critical Review of the Public Buildings, Statues and Ornaments in and about London and Westminster—1734.

By Ralph.

(*Continued from page* 264.)

I suppose my readers have already observed, that during the course of my essays on this subject, I have not contented myself with bare remarks on the ornaments I find finished to my hand; but that I have taken all opportunities, beside, of pointing out ways and means which either may, or might have been made use of to refine upon some, to adjoin others, and make the most of every situation for the beautifying and adorning the whole.

It is in this view I often mention things, which by the interfering of property can never take place: and hold myself excused, in the presumption that a neglect in one particular, may be made a spur to the improvement of another.

The new church (St. John's), with the four towers, at Westminster, is situated in such a manner, with respect to Old Palace Yard, that it might have been seen from thence, at the end of a noble vista, to the greatest advantage imaginable: the sight of the towers over the tops of the houses, put every body in mind of this, and it is with much regret that we lose such a beauty.

As to the building itself, it is in a very particular taste, and has a great mixture of beauty and caprice in it: there are many parts of it which I approve, and many more which I condemn: it is to be sure a fatal mistake, to endeavour at an excellence, and than err so wide of the mark as to stumble on deformity; all false ornaments become faults instantly, and only serve to make an absurdity more conspicuous. If the architect of this pile had once thought of this rule, I am persuaded he would have been abundantly more chaste in his compositions, and cut his towers, like that of Babel, off in the middle.

Henry the Seventh's chapel has an undoubted right to be taken notice of in a very particular manner, as being one of the most expensive remains of the ancient English taste and magnificence: to be sure there is no looking on it without admiration; but then its beauty consists much more eminently in the workmanship than the contrivance; which is just the reverse of what it ought to be.

The proportion and harmony of a plan is the first grand secret in building; nicety, and point in execution the last: thus it happens that the edifice before us has nothing in its form to surprise or charm: and all the expence of art, which is lavished away upon it, only excites pity that the subject deserved it no better.

I am very sensible I run no small risk of being censured for making so free with so celebrated a pile as this: but as I profess myself clear of all prejudice, and only in pursuit of truth, so I shall take all the liberties which are of a piece with such a character, and resolve to be governed by reason and judgment only.

On these principles, therefore, I will boldly affirm, that nothing could be more absurd than erecting this fabric at the end of the Abbey; it now serving only to spoil the symmetry of both, and make a botch instead of adding a beauty: if there were any point of view where both these pieces might be seen together, the truth of my assertion would be apparent, and as it is, a little imagination will answer the same end.

Let us farther add that, by this unnatural conjunction, the whole magnificence of front, which might have been given to this costly chapel, is entirely lost, and those who admire it most implicitly and devoutly, cannot help enquiring for an entrance suitable to the rest of the structure.

Let us for once then suppose, that it had been entirely detached from the Abbey, and erected opposite to the House of Lords, with a sumptuous front to the street; let us suppose the new Parliament House finished on the other side, and the before-mentioned vista laid open to the new church, and the consequence would then be another group of beauties in building and decoration, which few cities in Europe could parallel.

By the many things I have said of the advantage of space before a building, in order to add magnificence to the view, no body will wonder, I presume, that I am for levelling the Gate-house, demolishing a large part of Dean-yard, and laying open the street at the west end of the Abbey, at least, to an equal breadth with the building. I must frankly own nothing appears so miserable to me, as such incumbrances round a grand or elegant building: they abate the pleasure of the prospect most exceedingly, and are real disadvantages to the builder's fame.

Westminster Abbey is a fabric of great antiquity, and challenges some kind of veneration on that account: it is besides of prodigious bulk, and fills the eye, at least, if it does not satisfy it: to glance at it in the landscape, without examining its parts, it pleases tolerably well; to examine its parts, we are under a necessity of disliking the whole: if the height surprizes, we are out of humour with its form; and the fronts in particular ought to have rose eminently above the rest, in order to have varied the lines, and given that grace it so visibly wants. We now rather think of a barn than a church; I believe this image is owing intirely to the extreme sharpness of the roof, and if that was rectified, it would be greatly to the advantage of the building in general. It must be owned indeed, that the west end was never finished, and there is much reason to believe that the two towers, on each side of it, were designed to give the elevation, it is now so apparently defective in.

There is indeed a rumour about the town, that the Dean and Chapter still design to perfect this scheme, and raise the towers according to their first projection: but I think it is rather too late to begin, for unless they would new-case the church all over, the mixture of the new and old would have a worse effect, than the defect we complain of, and make a sort of patch-work in building, which is ever offensive both to judgment and taste.

As to the inside of the church, it is certainly more perfect and judicious than the out: the perspective is strong and beautiful, and strikes the spectator in a very forcible manner, as soon as he makes his entrance; and yet it owes the greatest part of its effect to a fault in symmetry. It is the exceeding height of the grand isle which gives the astonishment; but if that was only in exact proportion to the rest of the parts, it would not be distinguished so much, and yet would deserve much greater praise.

Some of my readers would perhaps take it ill, if in this place, and writing on the curiosities of the Abbey, I should not say something in honour of the fine wax-work figures which are placed so curiously up and down this venerable building; particularly the king William and queen Mary, which have been lately so amicably shut up together in the same box. To oblige them therefore, and in compliment to the reverend Dean and Chapter, who permit these noble decorations, I will throw away a moment or two in giving my opinion of them. In the first place, therefore, with all submission to better judgments, I think they are ridiculous and unnatural in themselves, expressing neither figure like statuary, nor colour like painting: secondly, I am humbly of opinion that they would become a puppet-show better than a church, as making a mere farce of what should be great and solemn: and, thirdly, I think them highly injurious to the characters they represent, as showing them like jointed babies, to the stupid admiration of the vulgar, and the contempt of men of sense; instead of characterizing their persons, and perpetuating their virtues.

For all which, and many more reasons, I beg leave to move that the whole present set of waxen worthies may be demolished without benefit of clergy, and that all their present patrons and abettors may be substituted in their place; and that, as fast as any future reverence should endeavour to seduce his brethren to the like idolatry, he should be immediately chronicled in wax, and shewn with a cap and bells, to distinguish the extent of his understanding, and the perfection of his taste.

The inclosure, behind the altar, commonly known by the name of St. Edward's chapel, has nothing remarkable in it but certain Gothic antiquities, which are made sacred by tradition only, and serve to excite a stupid admiration in the vulgar.

There is indeed, at the end of this place, a sort of gate to the tomb of Henry V. which was intended for a piece of magnificence, and no cost was spared to make it answer that design; but the taste of it is so unhappy, and the execution so wretched, that it has not the least claim to that character. The tomb of that prince challenges attention only because it was his, and because the statue on it has lost its head: to account for which singular injury, we are told a ridiculous tale of its being silver, and that the value of it occasioned the sacrilege.

One thing, it is true, we meet with in this place, which merits a peculiar regard; that is, a wooden chest of bones, said to be the remains of Catharine, daughter of the king of France, and consort of Henry V. If this account is authentic, I think nothing can be a greater violation of decency, or more injurious to the memory of such illustrious personages, than to expose their relics in so licentious a manner, and make a show of what once commanded respect and adoration. If the clergy are advocates for the decency of burial, as no doubt they are, because of the profits which attend it, why do not those, who have this church under their care, comply but with their common tenets, and grant this indulgence to the ruins of majesty? To be sure I can have no other answer but this, that they bury some for gain, and some they leave unburied for the same reason.

It is beyond controversy, that there is something extremely shocking in this violence to the secrets of mortality: the ancients had even a superstitious regard for the dust of their ancestors, and surely we are under some obligation to treat ours with good manners: and how the reverend Dean and Chapter can reconcile this principle with their conduct, I leave to the most learned casuist, among them, to determine. If they would hearken to my humble advice, they would not be so very intent on worldly interest, as to neglect worldly reputation: reputation is interest too, and such trespasses as these, in the eyes of men of delicacy and understanding, are not easily forgiven or forgot.

The arch at the entrance of Henry the Seventh's chapel, is exceeding grand and ornamental: the steps underneath are a fine preparation for the scene at landing, and the three doors an admirable expedient to favour the perspective within: but this, and several other beauties, are utterly spoiled by the stalls, which cut off the collateral isles of the chapel intirely, and thereby spoil the beauty and symmetry of the whole.

The roof of this structure is certainly one of the finest things in the world, I mean in the Gothic style: nothing can be in a better form, or more richly decorated: perhaps had it been more simple it had shown to greater advantage; but still it is a wonder that one continued cluster of ornament could be contrived to please so much, and answer so well.

Were the absurd partitions mentioned above thrown down, the roof would appear still more surprising, and the area before more spacious and proportionable: all those tombs which are now shut up in such a manner, that they are no where to be seen as they ought, would then come foreward to the eye, and give an additional grandeur and solemnity to the scene: the perspective would be finely broke, and every object properly terminate in the founder's mausoleum, as the principal point of the whole view.

There are few tombs in Europe more famous than that of Henry VII. neither indeed are there many which deserve to be more so. The undertaking, in itself, was vast and surprizing, the cost prodigious, and the execution exceedingly difficult and laborious. And yet the artist has succeeded in it to admiration; there is hardly a part in it that is not excellent, from the chief figures to the minutest point of the decoration: the statues of the king and queen are grand and noble, and the bas-relief on the sides below, beautiful and expressive. I am of opinion the workman, whoever he was, was equal to the noblest scheme of this nature, and would have made a figure even amongst the ancients. What a pity it is, therefore, that such a genius, and so much art should be lavished away on a thing entirely out of taste, and which, at the same expence and study, might have been made the wonder of the world! To explain myself farther on this head, nothing can be more stupid than the laying statues on their backs, in such a situation, that it is impossible they should ever be seen to advantage, and of course, that all their perfections must be utterly thrown away. In the next place, the brazen inclosure, which surrounds this tomb, wonderful as it may be, considered by itself, is a monstrous blemish, with regard to the thing it was intended to preserve and adorn; because it rises abundantly too high, and intercepts the view intirely from the principal objects.

Without doubt, the statues of the king and queen, ought to have been in living attitudes, erect, and bold, and the decorating figures should have formed a corresponding group, which in every light, should have stood the test of criticism, and given the spectator an intire satisfaction: a few more steps too should have been added to raise the foundation higher; a magnificent arch might have been thrown over all, and the boundary below should have been only a guide, not an incumbrance to the prospect.

Yet, erroneous as the taste of this fine monument may be, it may be called excellent to that which prevailed several years after in the reign of king James I. as may be seen by the wretched things, which were erected at his command, to the memory of queen Elizabeth, and his mother, Mary queen of Scotland: in these all the blunders that can be imagined, are collected together: want of attitude and expression, harmony and proportion, beauty and decoration: nay, the very columns, which support the superstructure, are of different sorts of marble, and, to make the figures splendid and natural, they are painted and dressed out to the life, as if they were just retired from a drawing-room, and laid down there for a little repose.

But these whims seem to be again out of repute in the reign of his son, as appears by the monuments of the Dukes of Richmond and Buckingham: in these there are several fine figures in brass, and something like meaning and design; though even then they had not learned to distinguish the principal characters, and place them in such attitudes, as should command the spectator's first and last attention and regard.

Both these faults are intirely avoided by Rysbrack, in the monument erected in the honour of the late Duke of Buckingham; there the Duke himself is the principal figure in the group, and though he is in a cumbent posture, and his lady, in the most beautiful manner, sitting at his feet, yet her figure is characterized in such a manner as only to be a guide to his, and both reflect back a beauty on each other. The decorations are exceedingly picturesque and elegant: the trophy at his head, the finger of Time above, with the medals of his children, fill up all the spaces with so great propriety, that as very little could be added, nothing can be spared. In a word, I have yet seen no ornament that has pleased me better, and very few so well.

I will conclude my remarks on the Abbey, with some brief reflections on the use of sepulchral monuments in general, which will, at once, serve to illustrate what has been said on the tombs already erected, and likewise be of some service to the statuary in designing those which may succeed hereafter.

However amiable fame may appear to the living, it is certainly no advantage to the dead: whatever dangers they have dared, whatever toils they have undergone, whatever difficulties they have surmounted, the grave is deaf to the voice of applause, and the dust of the noble and vulgar sleep in the same obscurity together. It is possible the conscious spirit may have an idea of the honours that are paid to his ashes; but it is much more probable, that the prospect of this imaginary glory, while he lived among us, was all the pleasure it ever could afford him. I make this observation, because most monuments are said to be erected as an honour to the dead, and the living are supposed to be the least concerned in them: whereas on the contrary, there are few but what were rather founded in compliment to the builder's vanity, than in respect to the name they are inscribed with. One man's fame is made the foundation of another's, who ordered this sentence to be made his epitaph; here lies Sir Philip Sidney's friend. Some there are that mention only the names of the persons whose dust they cover, and preserve a noble silence with regard to the hand who raised them; but even here, the dead can receive no benefit from such disinterested affection; but the living may profit much by so noble an example. Another thing that displeases me, is the manner of the inscriptions, which frequently mistake the very design of engraving them, and as frequently give the lie to themselves. To pore one's self blind in guessing out *Æternæ memoriæ sacrum* is a jest, that would make Heraclitus laugh; and yet most of them begin in that pompous taste, without the least reflection that brass and marble cannot preserve themselves from the tooth of time; and if mens' actions have not guarded their reputations, the proudest monument would flatter in vain.

I do not say these things because I am an enemy to the custom: so far from it, no one can admire it more: but what I intend is, to place every thing on its right principle, and recommend the properest means for the consequence. It is certain there is not a nobler amusement in the world, than a walk in Westminster Abbey, among the tombs of heroes, patriots, poets, and philosophers; you are surrounded with the shades of your great forefathers; you feel the influence of their venerable society, and grow fond of fame and virtue in the contemplation: it is the finest school of morality, and the most beautiful flatterer of the imagination in nature. I appeal to every man's mind that has any taste for what is sublime and noble, for a witness to the pleasure he experiences on this occasion: and I dare believe he will acknowledge, that there is no entertainment so various, or so instructive. For my own part, I have spent many an hour of pleasing melancholy in its venerable walks; and have been more delighted with the solemn conversation of the dead, than the most sprightly sallies of the living. I have examined the characters that were inscribed before me, and distinguished every particular virtue. The monuments of real fame, I have viewed with real respect; but the piles that wanted a character to excuse them, I considered as the monuments of folly. I have wandered with pleasure into the most gloomy recesses of this last resort of grandeur, to contemplate human life, and trace mankind through all the wilderness of their frailties and misfortunes, from their cradles to their grave. I have reflected on the shortness of our duration here, and that I was but one of the millions who had been employed in the same manner, in ruminating on the trophies of mortality before me; that I must moulder to dust in the same manner, and quit the scene to a new generation, without leaving the shadow of my existence behind me; that this huge fabric, this sacred repository of fame and grandeur, would only be the stage for the same performances; would receive new accessions of noble dust: would be adorned with other sepulchres of cost and magnificence; would be crowded with successive admirers; and at last, by the unavoidable decays of time, bury the whole collection of antiquities in general obscurity, and be the monument of its own ruin.

Yet in spite of these sage reflections, this plain prospect of general decay, I must own, it is a great pleasure to me to see a new statue added to the last; to see another name of glory increasing the catalogue: it is a taste I am particularly fond of, and what I congratulate the present age for encouraging so much. I am always one of the first to survey a new monument, to criticise on its beauties, and point out its defects. I have sometimes the pleasure of observing a beauty, and often a fault in our modern artists; and should be glad to take an occasion of applauding the first, and mending the last. I would have all works of ornament perfectly beautiful and elegant; or else they disappoint the very intent of their being. I would have all statuary, in a peculiar manner, excellent. A polite people are most distinguished as such, by their buildings, their statues, and their inscriptions; and I am sorry to say it, we are generally defective in all. There is one noble lord amongst us indeed, who has taken great pains, and been at vast expence, in improving our taste in one of these particulars; but I do not find so eminent an example has influenced many more to an emulation of what has done him so much honour. In a word, sepulchral monuments should be always considered as the last public tribute which is paid to virtue; as a proof of our regard for noble characters; and most particularly, as an excitement to others to emulate the great example. In a word, I cannot look upon that which is raised over the ashes of Sir Isaac Newton in any other light: his honours were all owing to his own merit; neither is it in the power of the finest statue, or the sublimest inscription, to afford him any addition. Had his remains rested without a name, like Milton, or Shakespere, or Shaftsbury, or Nassau, it would have been a new reproach to an ungrateful people, but no injury to him. On the other hand, the utmost magnificence of funeral honours would only be a credit to us, without doing him any service. Having lately observed that this stately mausoleum had made the entrance into the choir irregular; it was answered, that if we waited with an equal name among the moderns to make it uniform, it would hardly be so to eternity; and if an inferior was to be ranged with him, it would be a disadvantage to both. It is most certain, that there are few characters that approach any thing near to an equality, and the many vain trials that have been made for his epitaph, are the highest compliment to his desert: it is a proof that language was too weak to express it, and hyperbole itself too faint for the admiration that was due to his accomplishments.

THE NELSON MONUMENT AND TRAFALGAR SQUARE.

REPORT.

The Select Committee (of the House of Commons) appointed to inquire into the Plan sanctioned by the Commissioners of the Woods and Forests for laying out the vacant space in Trafalgar Square, in front of the National Gallery, and who were empowered to report their Observations, together with the Minutes of Evidence taken before them, to the House,—have considered the matters to them referred, and have agreed to the following Report.

YOUR Committee must begin by observing, that the nature of the projected works in Trafalgar Square not having come under their consideration till after those works were begun, they found themselves in a position less advantageous for the performance of the task which was placed in their hands, than had the field of inquiry been completely disembarrassed. They endeavoured, however, to free their minds from all extraneous circumstances, and only to consider what would most contribute to the embellishment of that part of the town.

They felt, that under the terms of their appointment, all that was to be done within the area of Trafalgar Square came within the limits of their inquiry, and that they should have ill discharged their duty to the House and to the public, had they not adverted to whatever works were designed for that situation; a situation which is indisputably one of the noblest in the metropolis; an area which has been obtained at a great cost, and the final decoration of which must have so large a share in determining the character of that conspicuous part of the capital.

Your Committee will begin with adverting to the plan for laying out the area itself. They find that, so long as 1837, a plan for laying out Trafalgar Square was submitted to and approved by the Lords of the Treasury; but, for reasons which do not appear, was never begun. In the course of April, 1840, the plans supplied by Mr. Barry, for the same object, were approved by the Woods and Forests, and are now in progress. The estimate for these works amounts to £11,000, independent of the pavement of the square, and of certain ornaments of bronze, which, in the judgment of Mr. Barry, are desirable. The chief features of Mr. Barry's plan are, the levelling of the area from front to back, and the construction of a terrace 15 feet high, on the south side of the street, in front of the National Gallery. The effect of this terrace will be greatly to improve the appearance of the National Gallery, by giving it the elevation, for the want of which it has been chiefly censured. Mr. Barry, on being questioned by your Committee, gave it as his opinion that the appearance of the National Gallery might be further improved, by continuing the order of pilasters through the whole length of the front, and relieving the baldness of the cupola, by encircling it with pillars, and giving it a bolder cornice; which additions, he is of opinion, the existing walls would be capable of supporting.

Your Committee having satisfied themselves that Mr. Barry's plan for laying out the ground in front of the National Gallery was, under all the circumstances of the case, well adapted to reconcile the various difficulties of the spot and attain the desired end, proceeded to inquire what effect the column which is about to be raised by the Nelson Committee in the centre of the south side of the square, would have upon the National Gallery; how far a column of such dimensions would be seen to advantage in such a position; and how far it would contribute to the embellishment of that part of the metropolis. In order to assist their judgment on this important point, they called before them several architects of acknowledged merit, and availed themselves of the opinions of eminent sculptors and men of taste. These gentlemen were allowed an interval of two or three days to consider the subject: at the end of which they all sent in their opinions in writing. In the opinions of these gentlemen, as might be expected in a matter of taste, there is not perfect unanimity; but your Committee feel to have derived great advantage from having consulted them, and by carefully weighing their opinions and examining the principles upon which these opinions are based, have arrived at conclusions of their own.

Your Committee are of opinion that such a column so situated would have an injurious effect upon the National Gallery, by depresssing its apparent altitude, and interrupting that point of view which should be least interfered with.

They are of opinion that a column of such dimensions will render the surrounding buildings less important, and, so situated, will not group well with anything in its neighbourhood.

They are of opinion that, as approached from Whitehall, as seen at the termination of this grand avenue, which forms one of the principal entrances of the metropolis, the appearance of the National Gallery will be much injured by the column. In this point of view the column will cut the National Gallery through the centre, and the pedestal of the column alone will nearly conceal both the portico and the cupola.

They are of opinion that the site selected is not a favourable position for the column itself.

There is another point to which your Committee will advert, which is, that the statue of King Charles is not in a line with the column; nor could this defect, from the proximity of the two objects, fail to catch the eye. So long as there is no column in the proposed situation, the statue of King Charles, where it now stands, is a fortunate circumstance, offering a subordinate object in front of the National Gallery, which serves as a scale, without obstructing the view.

Your Committee, entertaining these opinions, are unable to avoid arriving at the conclusion, that it is undesirable that the Nelson Column should be placed in the situation which is at present selected. If it is desirable in a great city to suggest the idea of space, and having once obtained space, not to block it up again—if the general architectural effect of Trafalgar Square, or of the buildings around it, is to be at all considered—or if, at any time, an equally conspicuous position should be desired for any other monument—the situation at present selected for the Nelson Monument is most unfortunate.

Your Committee having arrived at this decision, proceeded to inquire at what cost a change of plan in the position of Nelson's Column could now be effected, and how far it would be consistent with good faith now to interdict the Nelson Committee from prosecuting their work in the situation in which it is commenced.

What has actually been done towards the erection of the Nelson Column is no more than the excavation for the foundation, and pouring in the concrete which is to form a bed for the masonry, the expense of which, in Mr. Barry's opinion, would be more than covered by 1,000*l.* Contracts, however, have been entered into by the Nelson Committee, a failure to complete which would subject them to actions at law. It is not, however, probable that, if the same work were entrusted to the same persons in another situation, such actions would be instituted. The pecuniary loss, therefore, would not of itself entail so great a sacrifice as to preclude the idea of even now adopting a preferable course.

"But it appears by the Treasury Letter, bearing date 27 January, 1840, that the Lords of the Treasury have authorized the Commissioners of the Woods and Forests to deliver over the site appropriated for the Nelson Monument to the Committee for carrying that object into effect; and according to the evidence of Mr. Scott, it appears that the Architect has taken possession of the site, and has commenced the concrete and brickwork of the foundation, in which considerable progress has been made, and on the completion of which the Nelson Committee are bound to pay the contractors the sum of 2,000*l.*"

Your Committee cannot doubt that the Lords of the Treasury in authorizing the Commissioners of Woods and Forests to give that site to the Nelson Committee for the erection of the proposed column, entertained the fullest confidence that funds would be provided for carrying out the work in conformity to the plans and drawings which had been seen and approved; and they feel they should be wanting in their duty if they failed to direct the attention of the House to the fact that, according to the evidence, the subscription is at present deficient for the purpose, to the amount of some thousand pounds. Mr. Railton informed the Committee that his estimate of the column amounts to £28,000, whilst the sum subscribed does not exceed £18,000, nor does it appear that any well-grounded hope exists of any considerable addition.

It is true that contractors have engaged to complete the pedestal and the column for £15,000, and the metal for the capital is expected to be supplied by the Ordnance. But your Committee submit that a perishable statue of Portland stone is most objectionable; and supposing the terms of the contracts to be fulfilled to the letter (which in works of such a magnitude is seldom the case), the remaining £3,000 is wholly inadequate to meet the expense of casting the capital, of obtaining such a statue as ought to crown the summit, and of providing the bronze bas-reliefs for the sides of the pedestal, and the lions at the corners of the base. Even if the fund should prove sufficient to complete the masonry, no statue can be raised but one of Portland stone, and the column without its bas-reliefs will remain a denuded mass, which, however gigantic, will have a mean effect.

[The following is an analysis of the examination of the Witnesses.]

William Railton, Esq., was examined, he stated that he was an architect—that his plan was selected for the Nelson column. The height of the column altogether is now 170 feet, including the steps and everything: the original height was 203 feet; it was reduced about two months after the last competition, by order of the government. In consequence of a representation which was made to the Government, that the height of the column, exceeding that of any other column of the Corinthian order, which had ever been executed, would expose the column itself in that position to risk; the Government thereupon referred the consideration of the possible danger, and the character of its capital, to Sir Robert Smirke and Mr. Walker, the President of the Institution of Civil Engineers.—It was reduced altogether 33 feet in height, both from the shaft and the pedestal. So as again to put the whole building of the column into just architectural proportions, the other proportions were diminished altogether: the height of the shaft is 98 feet six inches; the pedestal of the statue 12 feet six inches; the statue 16 feet; the steps seven feet, and the pedestal 36 feet six inches high. The breadth of the square part of the pedestal is 17 feet. The amount of his estimate was £30,000. It will be done for less than that. He did not consider the reduction made any difference, as granite is to be used instead of freestone, which is of course very much dearer; the alteration has been no pecuniary benefit, though it may increase the durability, granite being stronger than freestone. From the use of granite instead of freestone it mounted up to 28,000*l.*; if it had been in freestone it might have been 203 feet high for the same amount: in granite it would, of course, have been more expensive at the 203 feet; it is to be completed in two years. He did not think the alteration in the position renders any other alteration necessary. As far as it intercepts the view of the National Gallery, the present position of the column is a great improvement. Where it was before, it was no detriment to the National Gallery; the Gallery is a very long line, and requires to be broken; therefore it brings it more into keeping. The position of the column is now settled to suit Mr. Barry's plan. The original site of the column was nearer the National Gallery than is now proposed. He considered that the position Government has selected for the column is as advantageous for its effect, and the general architectural effect of the whole site, as the position originally selected. He would have selected it himself, but at that time the ground did not belong to Government. They have obtained it since. He is better satisfied with it, as it is at present; it is certainly an improvement to the whole square; and it is seen better from the Strand and Cockspur-street, and from different places than it was before. He considered that a column was best calculated for this. He had well considered many other designs, and came to the conclusion that a column was best suited to this site, as it obstructs the view of the Gallery and all the buildings in the square less than others possibly can do, and by putting it in the centre, you have a better view of the National Gallery from every point than by putting it in a different situation; he did not think any other species of monument would so little interrupt the view of the National Gallery. The height to the top of the dome of the National Gallery is about 120 or 130 feet. The height of the spire of St. Martin's Church is 180 feet from the ground; to which must be added 12 feet six inches for the difference in the level, making 192 feet six inches; so that St. Martin's Church is considerably higher, and nearer the National Gallery than my column; and if that does not injure it, he did not see how his column could. Allowing for the difference in the elevation of the two, the difference in the height of St. Martin's Church is 22 feet six inches above the National Gallery.

Charles Barry, Esq., was examined, he stated that he was employed in laying out the ground in front of the National Gallery. He explained to the Committee the nature of his design for laying out the square. The area is proposed to be level; on the north side, in front of the National Gallery, a terrace is proposed 165 feet long and 32 feet wide, with a flight of steps at each end to the area below the same width (each step being two feet wide and five inches high), with ample landings in the circular corners of the square. The terrace is proposed to have at each end two large oblong pedestals for groups of sculpture, and circular pedestals for candelabra are proposed to be placed at the foot of each of the flights of steps, as well as at the angles of the square towards Cockspur-street and the Strand. The terrace and flanking walls of the steps are proposed to be surmounted by a balustrade. The terrace wall and balustrade will be 14 feet in height. The embankment or retaining walls to the surrounding streets are proposed to be surmounted by a solid parapet three feet high. The front or south side of the square, and the north side of the terrace towards the road in front of the National Gallery, are proposed to be enclosed by ornamental stone posts, so placed as to be a barrier against carriages and horses. The area is propossd to be covered with asphaltum. The terrace to be paved; and the whole of the masonry in the terrace and retaining walls, the steps and landings, the pedestals, balustrades, and lateral parapets, as well as the posts on the south side of the square and on the terrace, are proposed to be wholly of Aberdeen granite. The enclosed area from east to west is about 350 feet; from north to south, including the terrace on the north side which is 32 feet wide, is 290 feet. The area between the building from east to west is about 500 feet wide, and from the statue at Charing-cross to the front of the portico of the National Gallery, the length is about 470 feet. From the proposed column to the front of the National Gallery the length is 300 feet. From the column to Craig's-court, the length is 400 feet. From the column to Whitehall chapel, the length is 1,180 feet. From the column to the angles of Cockspur-street and the Strand, the length is 240 feet. From the column to the north-west angle of Northumberland House, the length is 180 feet; that is, as regards the dimensions of the square and the distance. The measurements are from the shaft of the column. The levels of the square below the road in front of the Gallery are as follows: at the base of the proposed terrace wall, 11 feet; at the proposed column, 11 feet; at Craig's-court, 25 feet; at Whitehall chapel, about 30 feet. The amount of his estimate is 11,000*l.*; the groups of sculpture and candelabra surmounting the pedestals should be of bronze. The asphaltum covering of the square, the pavement of the terrace, and the groups of sculpture on the pedestals, form no part of the estimate. He stated to the Committee the effect of the proposed column upon the National Gallery, when viewed from Craig's-court and Whitehall. When viewed from

Craig's-court, the stylobate will conceal the entire centre, extending to the columns in front of the gateways in breadth, and nearly the whole height of the portico; the bottom step of the pedestal will conceal rather more than the half width of the portico in breadth, and up to two feet from the bottom of the columns in height: the top step will conceal rather less than the width of the portico in breadth, and up to eight feet from the bottom of the columns in height: the die of the pedestal will conceal one half of the portico in breadth, and up to within three feet of the springing of the dome in height. When viewed from Whitehall Chapel, the stylobate will conceal the whole of the portico and the projections on each side in breadth, and one half of the podium in height; the bottom step will conceal three-fourths of the portico in breadth, and five-sixths of the podium in height; the top step will conceal five-eighths of the portico in breadth, and up to two feet from the bottom of the columns in height; the die of the pedestal will conceal one-third of the portico in breadth, and to the top of the order in height: the shaft will conceal one-fourth of the portico in breadth, and the whole height of the building.—Mr. Barry gave it as his opinion that the area of Trafalgar-square was too small and confined for a column of the height and magnitude proposed: the effect of it would be to reduce the apparent size of the square, and render the surrounding buildings insignificant. The National Gallery, being small in its parts, and low in elevation, will suffer materially in this respect, more especially when viewed from Whitehall and Charing-cross, where the pedestal steps and stylobate, forming the base of the proposed column, will conceal a considerable portion of the portico, which is the most effective part of the building. The irregularity in the form of the area, the variation in the levels of the surrounding streets, and the direction of the several lines of approach, are not calculated to afford a favourable view of the column, except from Charing-cross and Whitehall, where, as he has before stated, it will have an injurious effect upon the National Gallery, whilst the Gallery will form an unfavourable background for the column. From all other points of view, the unsymmetrical position of the column, in respect of the surrounding objects, will be striking and unsatisfactory. The views of the proposed column from the ends of Duncannon-street and Pall Mall East, as well as from the road in front of the Gallery, would be unfavourable, in consequence of the points of sight being from 11 to 14 feet above the base of the stylobate on which the column rests. For these reasons, he was of opinion that the column will be improperly placed in Trafalgar-square.—In the event of the removal of the column, he should not wish to make any change in the general principles of it; it would in his opinion be desirable that the area should be left wholly free from all insulated objects of art, which in consequence of the irregular form of the square, and its level with reference to the higher and variable levels of the streets which surround it on three sides, would be unfavourably seen from many points of view. The four pedestals at the top of the flights of steps from the terrace might be surmounted by groups of sculpture, say of a man and horse, exhibiting the characteristic varieties of the human and brute form of each quarter of the globe; in the centre of the terrace-wall might be a fountain, composed of sea-horses, naiads, and tritons, surmounted by a semi-colossal figure of Neptune, which for the sake of the composition, and obtaining an effective view of it both from the square and the terrace, might be placed above the level of the balustrade. The four circular pedestals, two of which are proposed to be placed at the foot of the flight of steps from the terrace, and the others at the angles of the square towards Cockspur-street and the Strand, might be surmounted by candelabra, supported by groups of figures, and containing each a Bude or Drummond light, from which the entire square should be illumined by night. Thus, an opportunity would be afforded of giving scope and encouragement to sculptural art of a high class, and of giving that distinctive and artistic character to the square, which is so much needed in the public areas and squares of London, to excite amongst all classes that respect and admiration for art, so essentially necessary to the formation of a pure and well-grounded national taste.—In answer to a question put to him by the Committee, if he could suggest any other place for the Nelson monument? Mr. Barry stated that the centre of St. James's-square, if a central street were made into it from Pall Mall, would perhaps be eligible, or the Crescent at the top of Portland-place, or such a situation as the Circus between Oxford-street and Regent-street; or out of London, perhaps the best and most appropriate site would be in conjunction with Greenwich-hospital.—Mr. Barry gave the dimensions of the streets which would be left on either side of the area. Seventy-five feet would be the average width on the east side. The thoroughfare on the side of the Union Club and Morley's Hotel will be nearly the same as on the north, opposite the Gallery. On the north side in front of the National Gallery the width will be about 80 feet, which is the width, not of the pavement, but of the thoroughfare for carriages; the width of the street in the three cases as regards the thoroughfare for carriages, exclusive of the foot pavement, 50 feet in front of the National Gallery; 52 feet is the average width of the road on the east side of the square, and the width of the road for carriages on the west side is 40 feet. —There is a difference of several feet in the level of the general range of the ground line of the National Gallery, of three or four feet at least; the ground is highest near St. Martin's Church. It rather falls towards Pall Mall East. He had attended to the extreme difference of those two levels, and met that difficulty by lowering the end of Duncannon-street, and raising the street at Pall Mall East, and making a variable hanging level in the road in front of the National Gallery. By accommodating the fall of the road in the front of the National Gallery to the terrace, he makes it more in one place than the other, so as not to create an unpleasant effect to the eye; the balustrade is perfectly level, parallel to the foot of the National Gallery, and on the same plane. The plan has been sanctioned by Government, and the estimate is before Parliament for its completion as to the terrace. He had no doubt that by the introduction of the terrace, the effect of the National Gallery, as a building, would be improved. His object is to give an increased apparent height to the Gallery. He had no doubt that the erection of so high a column would have the effect of making more prominent the defects of the National Gallery. He was of opinion that the appearance of the National Gallery might be further improved; he explained to the Committee in what way it might be done. He considered that a continuation of the order of columns or pilasters through the whole length of the front would be one means of improvement, and by raising the dome and altering the design of it, would be another means of improving it. He was not prepared to say that the existing walls were strong enough; he had very little doubt they would, for the walls that carry the present mass would probably carry much more.—The cupola could be encircled with pillars; he would recommend a bolder cornice, and an increased height of the parapet, so as to conceal the lanterns which now just appear; he thought the walls probably would bear that. He was not prepared to state the cost of such an alteration. He had not considered the effect of removing the columns. He could not say that the proposed alterations would have the effect of completely curing the existing defects of the National Gallery. The great defect is its lowness; this would in part be obviated by raising the centre, and giving more elevation to the dome, but it would not make the entire mass appear high enough for effect. The original defect would in part be remedied, but it would still be there. He could not then form a rough estimate of the cost of executing some such plan as that, and of pulling down the materials and rebuilding it; the difference would be considerable: it would be cheaper.—The defects such as they are, of the National Gallery, as it now is, or even if the National Gallery is altered, would be more prominently brought forth by the erection of a column of that altitude in its front. In either case it would operate disadvantageously to the building. He did not consider that it would be worth while to do anything for the improvement of the National Gallery, if the column is to be placed in front of it.—In answer to the following question, do you think if it were thought desirable a trophy to Wellington and to Nelson should be erected in that area, that they could be so contrived as to contribute to the embellishment of that whole scene?—"Mr. Barry said, I think they could be so contrived, but I do not think it would be desirable. I think the area is not large enough for two monuments of a proper size for effect. And there is this objection, that the levels of the surrounding streets being higher than the level of the square, you would look at any monuments placed on the level of the square to a disadvantage." "Not if they were erected in bronze, would you?"—"It would depend on the nature of the monument; it might be lifted up by a rough basement; but I would rather that the area should be free." "Do you not consider it would be a glorious thing for the nation to hand down to posterity the two great men of both services, land and sea, on the same spot, and whom England had produced in the same war, and at the same time?"—"Most desirable." "But the spot you would select would not be the area in Trafalgar-square?" —"I think not."

Answers to Questions proposed to the Witnesses by the Committee, to which they were requested to furnish Answers.

QUESTION 1.—What effect, in your opinion, will a column, of which the pedestal including the steps is 43 feet high, and the height altogether 170, have upon the National Gallery?

Answer by Edward Blore, Esq.—An object of the magnitude of the column in question, that is, including the plinth, 170 feet high, and occupying so prominent a position, whether considered as an ornamental object or not, will form by far the principal feature in any point of view in which it may be considered, and the National Gallery and the surrounding buildings will only have the effect of back grounds or accessories to this principal feature.

Decimus Burton, Esq.—The column will apparently diminish the size of the Gallery.

Sir Francis Chantrey.—Although I have attentively examined Mr. Railton's very beautiful perspective drawing, and Mr. Barry's plans, yet, in the absence of a geometrical drawing, or a model, showing the relative height of the column with the adjacent buildings, they do not convey so clear a conception to my mind as enables me to give a decided opinion: perhaps to the more practised understanding of an architect they may be sufficiently intelligible: I cannot, however, believe that a column, or other ornamental object, placed where this is intended to be, can injure the present appearance of the National Gallery, except so far as it may interrupt the view, and perhaps tend to lower its apparent altitude.

T. L. Donaldson, Esq.—It will render the inadequacy of the National Gallery for the important position which it occupies still more apparent: the want of altitude in the National Gallery, the littleness of all the features, the number of parts into which the elevation is divided, are so many circumstances which give an insignificance to the building. If any other ornamental erections are to be placed in Trafalgar-square, and restricted to being subordinate in scale to the National Gallery, the area will consist of a vast space occupied by insignificant objects. The only way to restore to it that importance which it deserves, and which it has lost through the National Gallery, is to place within it a lofty towering edifice, to which all the buildings around will be subordinate, and form the background. I conceive, therefore, the size of the proposed column to be no objection.

Joseph Gwilt, Esq.—A column, whose pedestal is to rise to the height of 43 feet, of proportionable width, will, in every view from the south, have the effect of destroying whatever unity of design the National Gallery possesses, by cutting it into two parts, equal or unequal, as the place of the spectator may be varied. This, of course, can only take place in the view from the south. As respects its grouping with the Gallery and other buildings about it, as seen from the eastern and western sides, I do not think it possible that it can in any position be seen advantageously in connexion with them. This opinion is founded on a survey of the spot itself, with the proposed pedestal and steps set out by the eye; but as the matter is reducible to strict mathematical reasoning on a plan and section of the ground and levels of the neighbourhood, it may be tested by such means to positive proof, by drawing lines, touching the boundaries of the pedestal from every point of view, and continuing them to intersect the façade of the National Gallery, by which will be seen the portions of it intercepted. The portico, the best part of the building in question, will thus be found to suffer much more than the subordinate parts.

Philip Hardwick, Esq.—I am of opinion that a column of which the pedestal including the steps is 43 feet high, and the height altogether 170 feet placed, as it is proposed to be, in front of the National Gallery, and in a line with the centre of the portico, must in certain points of view, on approaching it from the south, conceal so much of it, that its effect cannot be favourable on that building.

Sidney Smirke, Esq.—I think that the column and its pedestal will have the effect of detracting, in some degree, from the importance of the National Gallery as an architectural object.

Sir R. Westmacott.—I am of opinion that a column, of which the pedestal including the steps is 43 feet high, and 17 feet wide, and the height altogether 170 feet, will be injurious to the effect of the National Gallery.

Question II.—What effect, in your opinion, will the said column have as an ornamental object, in combination with the surrounding buildings?

Edward Blore, Esq.—The effect of the column considered as a whole, in combination with the surrounding buildings, will vary very much according to the different points of view in which they are seen, offering with every change of position, some new combination of greater or less merit.

Decimus Burton, Esq.—To render those buildings less important.

Sir Francis Chantrey.—This question involves all the difficulties contained in the first. As an ornamental object, the beauty and just proportions of a Corinthian column, as forming part of a building, are matters settled 2,000 years ago; what its effect may be standing alone must depend much on the base, and the object which crowns the summit. An injudicious association of modern things with ancient may put the column out of the pale of classic beauty. Of the statue which is to be made I can give no opinion, but if it be only to measure 17 feet, its bird-like size will not be much in the way, and if formed of Portland stone, will not be long in the way. The Trajan, the Antonine, and the Napoleon columns, are the only monumental objects of this class that I have ever looked upon with entire satisfaction; I read the history of the man on the shaft of the column, and the mind is thus reconciled to see the statue so elevated. I may be told we have not money enough for a work of this character, that naval exploits furnish bad materials for sculpture, or that the arts of this country are in too low a state to accomplish so noble a work; then I say, abandon the impossibility at once, and try something more in keeping with our means and our genius.

T. L. Donaldson, Esq.—An advantageous effect, as the judicious design prepared by Mr. Barry for laying out the area will mask to a great degree the distortions and inequalities in the levels, and the irregularities in the plan, and render them inapparent to the general mass of people. St. Martin's church is already of such a scale, and so peculiar and distinct in character, that it cannot suffer from the column. The masses to the east and west, although imposing in style, are not sufficiently monumental to deserve any sacrifice being made to them; and the National Gallery is so insignificant as to require some other object to redeem the opportunity which has been lost.

Joseph Gwilt, Esq.—I do not think the proposed column will combine so as to group well with any of the surrounding buildings, and least of all, if there be any difference, with the National Gallery. In this the intention seems to have been to preserve a strictly Greek style, in contradistinction to one of Roman or of Italian character, whereof the small inclination of the pediment seems to be such an indication, that a vertical feature (such as the column would be) rising through it, I think likely to produce even a ludicrous effect. Viewed with the group of buildings on the east side of Trafalgar Square, (St. Martin's church excepted) I do not think any bad effect would be produced, because I do not consider them as of sufficient architectural importance to weigh in the matter; but with those on the west side, and also of St. Martins portico on the east, and to the south-east with a building of great architectural merit and consistency, I mean Northumberland House, I see no lines about the column nor its appendages which make it desirable to choose such a site for it as that in question.

Philip Hardwick, Esq.—Architectural objects well designed, and of good proportion, almost invariably combine well with surrounding buildings, and I think it probable that such will be the effect of the proposed column.

Sidney Smirke, Esq.—It will have the same effect upon all the adjacent buildings; but, when viewed as a whole, in combination with the surrounding architecture, including the intended terrace, &c., I should expect that a very fine architectural scene will be produced, however much each building composing the group may suffer in individual importance.

Sir R. Westmacott.—As an ornamental object, in combination with the surrounding buildings, I cannot hesitate in saying, that I think the effect of the column itself and those buildings, from the absence of harmony of proportion with each other, will in itself be bad; and considered in reference to those buildings, by reducing their scale, and more especially of St. Martin's church, have an injurious effect on those edifices.

Question III.—What effect will the column have on the National Gallery, as you approach it from Whitehall?

Edward Blore, Esq.—As regards the National Gallery, the combination as you approach it from Whitehall will be one of the least favourable, inasmuch as the column in this point of view will cut the portico and dome of the National Gallery almost through the centre; still, however, it must be borne in mind, that the National Gallery, from the superior height and the prominent position of the column, will in this point of view (pictorially considered) have only the effect of a back-ground, an effect which will be more obvious from the great distance interposed between the two objects, and the aerial tint which the more remote one will acquire by this distance; so that the disadvantage of combination will be very much mitigated by the relative distance of the objects, and the atmospheric modification resulting therefrom.

Decimus Burton, Esq.—Its pedestal will obscure a portion.

Sir Francis Chantrey.—I expect that when the column and the National Gallery are seen together in their whole extent at the same moment, which will be the case when viewed between Whitehall and Charing-cross, that the Gallery, as I have said before, may suffer somewhat in its apparent height; but I do not regard this as of much importance, when I consider that Mr. Barry's plan of sinking the base line 10 or 12 feet, must improve the elevation of the National Gallery considerably.

T. L. Donaldson, Esq.—The Gallery will then form a subordinate background to the column; the portico, which is the least exceptionable feature in the building, will be intercepted; the cupola over the centre is too paltry in scale and character to render the interposition of the column, when seen from Whitehall, of any consequence.

Joseph Gwilt, Esq.—This is answered in the reply to Question I, and it would be easy to show, by carrying out the test there proposed, that whatever importance the National Gallery possesses, will be destroyed by placing the column on the spot selected.

Philip Hardwick, Esq.—The answer to this question may be considered as included in that to the first, as it is in the approach to the National Gallery from the south or Whitehall, that the effect of the column would be unfavourable to that building.

Sidney Smirke, Esq.—From the more distant parts of Whitehall, the column will be the most conspicuous object, and will of course interfere with the present view of the National Gallery; and when the spectator advances, say to the door of Messrs. Drummonds' bank, I apprehend that the pedestal of the column will pretty nearly exclude from view both the portico and dome of that building. I would suggest the erection of a slight boarded scaffold, representing three sides of the pedestal and base; the Committee and the public would then see, without the exercise of any imagination, the actual effect that would be produced by that the more bulky part of the monument.

Sir R. Westmacott.—It would have the effect at the distance of Whitehall of concealing a great portion of the portico; and on a nearer approach to Charing Cross, the pedestal of the column being seen at an angle, and increased several feet in width, would obstruct the view of two-thirds of the portico, and a considerable portion of the west wing of the National Gallery.

Question IV.—How far do you consider that position a favourable position for the column itself?

Edward Blore, Esq.—I have no hesitation in stating that, in my opinion, the position is peculiarly favourable for a lofty object, such as a column or obelisk, provided it be in good proportion, and designed with good taste; and that, taking into consideration all the circumstances of the ground, and the surrounding buildings, that no substitute could be found for such a form to produce an equally good effect.

Decimus Burton, Esq.—For the column itself, a very favourable position.

Sir Francis Chantrey.—I consider this position to be the most favourable that can be found or imagined for any national work of art; its aspect is nearly south, and sufficiently open on all sides to give the object placed on that identical spot all the advantage from light and shade that can be desired; to this may be added the advantage of a happy combination of unobtrusive buildings around; but to conceive a national monument worthy of this magnificent site is no easy task.

T. L. Donaldson, Esq.—One of the finest in the world. The best possible position for a lofty monument is when the spectator comes upon it unexpectedly, and when it can only be seen from a short distance; Trafalgar Square unites in an eminent degree both these requisites. To those approaching from the Strand and Pall Mall, it will come upon them by surprise, and the column will present itself in all its grandeur. To those approaching from Westminster, it will appear majestically on a rising ground, with the contrast of the low National Gallery behind it, to increase its apparent size; both which circumstances will give it dignity. The eye can embrace without inconvenience an area of 60 degrees; but it is no objection to the dignity of an object, that it compels an effort on the part of the beholder in order to embrace all its parts; and the very circumstance of those approaching Trafalgar Square from the east or west being obliged to raise their heads, and use some exertion in order to see the full height of the column, will create an impression of dignity upon the mind; and the first emotion which a monument produces upon the spectator is all-important. When a lofty object is first seen from far, and kept in view up to the moment that the beholder gets close up to it, the impression is not so overpowering, however small may be the other objects which may surround it, as when it bursts suddenly upon the view close upon him. The gradual approach to it from a distance begets impatience and weariness; the impressions of grandeur only progressively develop themselves, and are therefore comparatively weaker. The ancients well understood this; their temples were never seen isolated and from far; they were always surrounded by colonnades and enclosure walls. The column of Trajan was on one side of a square court of small dimensions, probably not more than 100 feet square.

[And see General Observations by T. L. Donaldson, Esq.]

Joseph Gwilt, Esq.—I do not think the position favourable for any columnar monument; because when such a form is selected, it is, in my opinion, desirable that the whole, or at least the greatest part of the outline, if it be good, should be distinguishable or marked against a back ground, whose colour and quality are different from the material whereof it (the column) is composed. I would instance, in illustration of my meaning, the effect of the back ground of trees and sky, in walking down Regent-street from Piccadilly, on the Duke of York's column; and in Paris that of the column in the Place Vendôme, in walking from the Boulevard down the Rue de la Paix towards the Tuileries gardens, the foliage of whose trees and sky above give peculiar value to the outline and its effect. The effect of the majestic and beautiful Column of London, perhaps the finest in Europe, would, I believe, be vastly improved if it could be seen in a long street or centre of a square, whereof it only intercepted the portion of a vista, and became thus susceptible of having its form thoroughly developed, instead of being backed on three sides by mean buildings, which confuse its forms, and tend to render them mixed and indistinct, except under broad lights.

Philip Hardwick, Esq.—There are so many circumstances in favour of the position selected, that I am of opinion it is altogether an eligible site for the column.

Sidney Smirke, Esq.—I think that the situation in question is a most favourable one for the monument; if no site for it be adopted but one where it would not affect the apparent magnitude of adjacent buildings, it must be removed to the middle of Hyde Park or Regent's Park, where it would be entirely thrown away. I would not, out of regard for the surrounding buildings, be afraid of the height of this monument: to give it all the effect of which it is capable, should be, I think, the paramount object: and with that view, instead of dropping it down to a ground line sunk below the level of the terrace, I would lift it up on to a terrace levelled out from the portico of the Gallery: and, may I venture to add, I would have selected a design for this monument that could be prudently built without the serious curtailment of its dimensions which has been found necessary.

Sir R. Westmacott.—As a site for the column itself, or indeed for any monument, (without reference to objects now erected,) the position referred to is most favourable.

C. R. Cockerell, Esq. R. A.—In answer to the first and second questions of your Honourable Committee, on the proposed column in Trafalgar Square, I beg leave to offer as my opinion, that such a column, on a pedestal 43 feet high, the whole being 170 feet high, will have no ill effect on the National Gallery and the surrounding buildings, on the score of its scale and dimensions, viewed from the north, west, and east sides of the square, because I believe that the juxtaposition of colossal and ordinary proportions has been practised in all times and in all styles of architecture with success, especially by the ancients, who observed this principle more strictly than the moderns; witness the column of Trajan, in an area 82 feet by 62 feet; that of Antonine, in a square not much larger; the ivory and gold colossal statues of Jupiter and of Minerva, which occupied the entire nave of their temples. Again, the Tower of St. Mark, at Venice, 42 feet wide at the base, and 316 feet high, in a square 562 by 232; the Column of London, and that of the Duke of York; none of which can be said to deteriorate from the architecture in connexion with which they are seen. The placing such colossal objects in extensive areas, as in the front of St. Peter's at Rome, Place Louis XV., at Paris, at St. Petersburgh, and other places, is wholly a modern practice, and a departure from the principle of effect on which they were originally founded by the ancients. My conclusion therefore is, not that the proposed column is too large for the site, but that the site is too large for the full effect of the proposed column.

With reference to the third question of your Honourable Committee, I beg leave to suggest that the principle in question appears to apply to colossal objects seen rather from a near point of view than from a distant one; because, in the first case, their position with respect to the objects beyond is altered with every step of the spectator, and the contrast and combination of their ever varying forms with those in the back ground may be advantageous to both; but in the latter case, where the gross disproportion is viewed almost geometrically, is unrelieved by detail or change of form, and fixed, during an approach from some distance in a straight line, the interposition of such an object actually exceeding the height of the entire building, and growing larger in the advance towards it, must divide and disunite the whole composition of the back ground, and obstruct the view of the central feature by its bulk, to its great disadvantage.

I believe it will be found the constant practice of the best architects to consider the central object in front of a great building, as a scale for the appreciation of its magnitude, and to make it always subordinate to the uninterrupted view of its principal feature. Thus the statue of Queen Anne, before St. Paul's, presents an admirable centre and scale to the whole front, without in any degree obstructing its view. The statue of King Charles plays the same part, with reference to the National Gallery, from Whitehall Place, and the contrast is greatly to its advantage in approaching from Parliament street. The proposed column would supersede that well-proportioned centre, and present a succession of centres, contrary to the usual architectural practice, which places successive objects at the sides, but never in the centre of an avenue, especially when such centres would obstruct the view of a fine object in the back ground.

In answering the fourth question of your Honourable Committee, I am constrained, for the above reasons, to offer my humble opinion, that the proposed position for the column is not favourable to it with reference to the whole square, nor to the National Gallery as seen from Whitehall. And in differing, with very great regret, from the able architect who has suggested this position, and the distinguished Committee who have sanctioned it, I feel myself in candour bound, with your permission, to offer some further explanation, both in fulfilment of my duty towards your Honourable Committee, and the great public object you have in view, and in deference to those gentlemen, since my judgment may have been biased by a preconceived view of the subject, which may apologise for the objection which I have ventured to express in reply to the questions of your Honourable Committee.

I was not able to offer the result of my reflections on this great national intention in the general competition, but deeming the square too large to admit of a central column with that effect which the ancients attained, I had always conceived that the proposed memorial of a naval commander should occupy one side of the square, leaving the other for a future and at least equally interesting record of a military commander.

Two such columns, placed at the distance of 70 or 80 feet from the south angles of the square would connect its somewhat straggling proportions, present an admirable picture in emerging from Charing Cross, and leave the Gallery open; they would group admirably in the views from the Strand to Cockspur Street, they would conceal the defect of the inclined roads, according to the long projected terraces now forming, and their colossal proportions would gain greatly by their juxtaposition to the buildings. By such an arrangement the whole area would be left open for all those monuments which in process of time will, we hope, increase upon us, reproducing that altis, or forum, in which the gratitude of the country may be expressed in all the variety of design suited to the situation.

It will be remembered, that the enthusiasm of the country placed the remains of the immortal Nelson in the centre of St. Paul's, as if no future hero could deserve such a position, and perhaps a much greater than Nelson will have to be recorded by us; if, therefore, the centre of Trafalgar Square is now to be occupied, it is certain that no other equally large monument can be erected there, and yet it would be difficult to find elsewhere, in the metropolis, a site equally eligible for such a memorial.

I trust these observations in explanation of my view of the whole subject, may not be deemed obtrusive by your Honourable Committee.

John Deering, Esq.—I think the proposed Nelson Monument presents that precise character of altitude most to be desired at the particular site intended, where a great and wide street of entrance necessarily branches off right and left into a principal artery of the metropolis, and where the idea of termination is the impression most essential to be avoided: for we must recollect that the object is not to arrive at Trafalgar Square or the National Gallery, it is to convey to the mind of the stranger the true and peculiar character of our capital, its endless continuation.

If this view be correct, the worst object would be a plain unbroken mass, which like the County Fire Office to its site (grasped by the eye at once), conveys the idea of obstruction, and limits consideration to its own pretensions alone, as the sole object of the whole arrangement. The broken line of architecture in the National Gallery obliges the eye to travel along its length, but the proposed form completely gets over the difficulty, presenting a magnificent object in the vista of approach, while it leaves the idea of space beyond, and suggests the idea of divergence, without obstruction, where that idea is most essential.

I cannot suppose the effect would be unfavourable upon the National Gallery, for although that building could be no longer seen in its whole extent from any point more distant than the column, I doubt whether its broken character of outline and laboured details, as well as smallness of parts, do not require that it should not be seen, as a whole, beyond the distance whence those features could be visible at the same time, and so form as it were a part of the design; but on the whole, I think it equally certain that, in its magnitude, this monument, in reducing to comparative insignificance, not only the Gallery, but St. Martin's Church, (its pedestal being nearly as large as the portico, and the whole nearly as high as the spire of that building,) will not also be a monument equally unfavourable to the memory of those who spoilt the National Gallery inside and outside for the assumed sake of a building, of which the unimportance will be thus placed in its true light.

But notwithstanding, we must not forget that the great end should be to adorn the metropolis, and not to persuade the unwilling of the architectural beauty of Trafalgar-square, or any particular building around its circuit.

General Observations by T. L. Donaldson, Esq.—The opinions I have given are strictly confined to the questions put in reference to the column, and I therefore do not offer any judgment as to whether any other arrangement of Trafalgar-square would be more advantageous. As the Nelson column must necessarily, from its size, be the most important feature in the area, it is essential that it should form a central object, as it were, to which all the rest must be subordinate and merely contribute. Size alone will not be sufficient. It is to be hoped that its decorative embellishments should be of a character consistent therewith: a denuded mass of masonry, however gigantic, will have a mean effect, and bear a parsimonious character disgraceful to the nation. The examples of the ancients and that of the moderns prove, that the enrichments of sculpture, and a due decoration in the subordinate parts are essential to convey all those impressions which it is necessary to produce when erecting a monument to the honour of one of the greatest men of a great country. It is to be hoped that the erection of the Nelson column may not become an instance of miserable national parsimony on such a noble occasion.

Appendix.

Estimate of Proposed Works, Trafalfar-square.

		£.	s.	d.
19,214 cubic yards of digging and carting away	at 3*s.*	2,882	0	0
345 cubic yards of concrete	at 6*s.* 10*d.*	117	17	6
71 rods reduced brickwork	12*l.* 10*s.*	887	10	0
630 feet run, 12 in. gun-barrel drain	at 2*s.* 3*d.*	70	17	6
9,370 cubic feet of Aberdeen granite, with a fine axed face, joints and beds included	at 6*s.*	2,811	0	0
372 feet superficial extra sunk work	at 1*s.* 6*d.*	27	18	0
200 ditto . ditto circular ditto	at 2*s.*	20	0	0
1,016 ditto . ditto moulding to ditto	at 4*s.*	203	4	0
74 ditto . ditto circular ditto	at 5*s.* 6*d.*	20	7	0
180 ditto . ditto rock face	at 1*s.* 6*d.*	13	10	0
2,615 cubic feet of Aberdeen granite steps	at 7*s.*	915	5	0
Bosting and carving 16 blocks in four principal pedestals	at 4*l.*	64	0	0
98 Aberdeen granite posts complete, including fixing	at 6*l.* 10*s.*	637	0	0
8 pedestals in balustrade of Aberdeen granite, comp.	at 4*l.*	32	0	0
213 Aberdeen granite balusters	at 40*s.*	426	0	0
6,062 cubic feet Irish or other granite, with a fine axed face, beds and joints included	at 5*s.* 6*d.*	1,667	1	0
487 yards superficial Roman cement	at 2*s.* 3*d.*	54	15	9
2 sink stones	at 40*s.*	4	0	0
Cast-iron work to cable bars		220	0	0
Commission, Clerk of Works and Contingencies		720	0	0
Total	£.	11,794	5	9

June 1, 1840. (Signed) C. Barry.

Danish Railway.—It is not generally known that a railway from Altona, two miles from Hamburgh to Kiel, in the Duchy of Holstein, has been projected, and is about to be constructed, under the auspices of the King of Denmark, with a view of effecting a communication between the North Sea and the Baltic. Mr. George Watson Buck, engineer-in-chief to the Manchester and Birmingham Railway Company has been selected as the engineer to the undertaking.

A NEW PROCESS FOR MAKING GAS FOR ILLUMINATIONS FROM BITUMINOUS SCHIST.

The utilization of bituminous schist is a subject of great importance, as promising to make this substance profitable. M. Selligue is the inventor of the process for distilling this mineral, and has works for the purpose on a large scale. His mines are in the department of Saone and Loire, between Autun and the Central Canal; his three works are at St. Leger-du-Bois, Canton of Epinal; Surmoulin, near Autun, and Igernay, Canton of Cardesse. In these works the schist is distilled in close retorts, they leave a residuum of carbonaceous matter, which may be used for disinfection or discolouration, but not yet made serviceable. The volatile products are oils consisting principally of different carburets of hydrogen, which are made available for profit. A great quantity of inflammable gases are also disengaged during the distillation, and are directed into the furnace and used as a combustible.

The schists of Autun are very variable in character, but all are rejected which afford less than 6 per cent. of oil on distillation, but those now used average 10 per cent., it is not rare however to find as much as 20 or 25 per cent., some were as much as half their weight of oleaginous products.

The composition of 100 parts of liquid bitumen is as follows:

Light oil of variable density from 0·766 to 0.810, used for gas	35·57
Oil of greater density susceptible of being used in lamps	25·85
Fatty matter containing 12 per cent. of *paraffine*	12·
Pitch or tar	17·28
Residue	9·3
	100

It has long been suspected that the olefiant gases derive their illuminating properties from the oleaginous vapours which accompany the generally slightly carburetted hydrogen gas which always forms the base of these gases. M. Pelletan maintained this view in a paper read before the Academy in December 1816, and it has been confirmed by M. Selligue. It has been on the other hand asserted and received as certain that oxidated carbonic gas is always injurious in illuminating gas, and that it diminishes the brilliancy of the flame by lowering its temperature, on account of the low degree of heat developed during its combustion. M. Selligue has however established the fallacy of this doctrine.

M. Selligue's process is as follows:—Three tubes or retorts, situated vertically in a new and ingeniously constructed furnace, are heated red. The first and second contains charcoal, and as fast as the charcoal disappears it is replaced, which is every five hours. This carbon is for the purpose of effecting the decomposition of the water introduced into the first tube in a continued stream, and where it is converted into hydrogen gas, and carbonic acid, and oxide of carbon. But as the production of carbonic acid is to be avoided, the gases produced by the first tube are conducted into the next, where they are exposed again to incandescent charcoal, by which means the carbonic acid first formed is converted into oxide of carbon. The furnace is so arranged that this tube is the hottest of the three, so as to favour the total decomposition of the carbonic acid.

The third tube is fitted with iron chains, the use of which is to present a large incandescent metallic surface, capable of distributing caloric in an equal and rapid manner to the gases or vapours passing through. On the one side this tube receives the gases produced by the decomposition of the water in the two preceding tubes, and in the other a continued stream of *light schistose oil.* This light oil is decomposed into new products still more volatile, and passes with the gas into a refrigerator, which by cooling down the products causes some of them to reappear. The schistose oil is therefore not entirely gasified, but that which does not change into gaseous matter is preserved uninjured. What is very singular is that the links of the chain in the tube are never covered with any carbonaceous deposit. Thus while the schistose oil is evidently decomposed by heat during this operation, its decomposition is modified in a successful manner by its diffusion amid a large volume of gas, such as that produced from the decomposition of water, and which serves as a vehicle.

From the third tube is produced hydrogen and oxide of carbon, produced from the decomposition of the water, and the gases or vapours from the decomposition of the oil. By passing into the apparatus 20 gallons of water, and 25 of schistose oil, 50,000 gallons of oil fit for illumination are produced in twenty hours. The gas so produced requires no farther purification, having passed through a refrigerator where are deposited the nondecomposed oil, and steam from the water. From the refrigerator the gas passes into the gasometer.

M. Selligue's process and apparatus are represented as being so simple, as to be easily used in factories and private establishments, while the price of the gas so produced is low enough to be employed for lighting the streets. It has been proved by experiment not to deteriorate, but to improve at a distance from the gasometer; at five miles distance the flame was purer than when just issuing from the gasometer. When cooled down to 13 F. below zero, its illuminating power was not sensibly diminished. The gas is also free from sulphuretted compounds, and gives no unpleasant smell. The odour of coal gas, we may observe, however, is attributed by some chemists to vapour of naptha, and not to sulphur solely. As it does not act upon metallic reflectors, M. Selligue is able to use these additions with great advantage, so much indeed that with a parabolic reflector one of his burners enables a middling size print to be read 80 yards off.

M. Selligue has set up gas apparatus at the Royal Printing House, and the Batignolles at Paris; at Dijon, and other cities, all of which work well.

We may observe that this process is on similar principles to that of the air light, in which air was decomposed and the oxygen burned with oily or bituminous matters, and in this case water is decomposed and the hydrogen similarly combined.

STONE FOR THE NEW HOUSES OF PARLIAMENT.

Sir—I wish your correspondent in No. 33 of your valuable Journal who stiles himself "Amicus," had done that which he started to do in the first part of his letter, or at least what he pretended his epistle should do, and have endeavoured to correct the many "inaccuracies and misstatements," which have already appeared, and not have added to their number by writing the letter under notice, which is nothing more or less than a perfect puff, to extol his fortunate purchase of "Mansfield Woodhouse Quarry," as well as his other "White Sandstone Quarry," as he calls it.

It is very true and well known that Commissioners were appointed by Government to select the best material the united kingdom could produce, as to durability; and well they have performed their task, certainly. In the first place they only go two-thirds over the kingdom, leaving out the only part that could yield them the article wanted, such an article as is to be found in most parts of Ireland, for it is well known that that country abounds with stone of an *undecaying nature* (as for instance look at her "Round Towers,") and selected a material not half so good as that which could have been procured as above, and from a quarry too according to their own showing, that could not produce the necessary quantity or blocks of sufficient magnitude for the purpose intended, as witness the Report published by the House of Commons (which any one can purchase for sixpence), there it is stated the depth of workable stone to be only "12 feet," and the size of the blocks to be no more then from "8 *inches to* 2 *feet.*" Now how can such slovenly conduct be tolerated, but this is not all, for as "Amicus" shows, they were within a few months obliged to abandon this mighty quarry and seek a new one, in the newly discovered quarry purchased by Mr. Lindley, alias Amicus, which that gentleman states to be of a quality and character precisely similar "to that of the beds on the Moor," if that is so, and we have no reason to say otherwise, then the stone will be found wanting in the same manner as the Balsover, in not possessing blocks of the size required. So much for "Amicus," having set at rest the "inaccuracies and mis-statements," that have gone abroad. But before I have done, I must ask him a question or two, which no doubt he will be enabled to answer, which will show how the public are generally imposed on in jobs of this nature, has the New Mansfield Woodhouse Quarry been enabled to supply the Works yet, with either quantity or quality as to size of blocks, or will it ever? If it has, why have the said works been so nearly at a stand still for some time, and why has the *Steetley Quarry* been applied to for the required supply, and whether that application has not been answered by the sending of great quantities to Westminster to carry on the building? And lastly, though not the least point of the business, whether this said stone has ever been tested by the Commissioners aforesaid? If so, I can find no report thereof, which ought to have been done, the public having a right to expect that no material should be stealthily used in their national buildings without having it duly tried in all possible ways, particularly after the heavy sum that has been paid these gentlemen to protect their interest and fame.

If these questions are well and truly answered, then indeed will "Amicus" be correcting the "inaccuracies and mis-statements" that have gone abroad, and be rendering the public infinite service by showing them how they are generally hoodwinked in such matters.

I cannot conclude this letter without referring him and your readers to a most excellent article in the same number, "On Limestone in Ireland," by W. Bald, F.R.S.E., &c., a gentleman of the very first rate talent and ability, which I have no doubt has been duly seen and read by all who are fortunate enough to take in your valuable journal, but should it have escaped the eyes of any, I can only say it will well repay their looking back to and reading it with attention, then all will I am sure bear me out in my censure of the neglect, nay insult that has been offered to Ireland; particularly as to the stone that has been tendered (at least so I have seen stated in several of the public prints) *gratis* to the public.

I have the honour to be, your's,

A LOVER OF FAIR PLAY.

[We always view with suspicion any offer that is made *gratis*—it is frequently a complete delusion. We have also heard of offers being made by noblemen and gentlemen to supply the stone for the New Houses of Parliament *gratuitously*, but when the offers were sifted, they were generally found not worth accepting, for what is meant by the word *gratis*, in this business, is to supply the stone embedded in the quarry, which may be generally obtained at any new quarry upon paying a *royalty* of 1*s.* to 1*s.* 6*d.* per ton, or about 1*d.* per foot cube—this royalty forms the most trifling part of the price of stone—the cost is made up by the heavy and unavoidable expences of quarrying, getting, carriage to the water side, and freightage. Besides it is often found that the stone is of such a hard quality that the labour upon working it, is double the price of another stone which fully answers the purpose—for instance the labour upon granite in working it in gothic mouldings is treble the price of labour on Portland stone, and the same with other stones and marbles; which would render the cost of the stone work of a building when worked, nearly double, if not more; thus instead of the country gaining by the gift, it would be very materially the loser—so much for *gratis*. As to the injustice to Ireland, the Scotch might as well complain of the refusal of their granite which was offered by a nobleman to be supplied gratuitously; but when it was explained to him that the cost of the stone when worked would be far more than the stone which is being supplied for the New Houses, he immediately acknowledged that his offer was not worth accepting.—EDITOR.]

IMPROVED LAND SURVEYING CHAIN.

SIR—Observing in a former number of your Journal a description of an improved surveying pole, I venture to trouble you with an account of what I consider an improvement which I have lately made in the chain, namely, having the 11th, 21st, 31st, and 41st links made of brass, the rest being of iron; by this arrangement the brass link, being in all cases nearer the middle of the chain than the token, will at once point out whether such token be 10 or 90, 60 or 40, &c., and as a matter of course the liability to mistake 40 for 60, and so on, entirely done away with. In mineral surveying a chain of this construction is incalculably superior to one of the old.

If you think the hint is likely to be useful to any of your readers, I shall feel obliged by your giving it a place in the Journal.

Most respectfully your's,

WILLIAM JAMES HINDLE.

Barnsley, Aug. 3, 1840.

PARISIAN AND LONDON HOUSE BUILDING.

[THE following, from a series of letters in the "Dublin Evening Post," is, we conceive, well worthy of being transferred to our Journal, where it will be better and more conveniently preserved than in the columns of a newspaper. Besides some direct information, it contains some clever and pertinent remarks, although we do not subscribe to every one of the writer's opinions.]

Paris, as a city, pleases me more this time than last year, though it cannot boast of the grace of novelty in my travelled eyes. But I have looked, and am endeavouring to look through it more carefully. There is a cheerfulness in the warm colouring of the buildings in that beautiful stone, of which the city is made, which cement can never imitate. It is not one gray, uninteresting, and monotonous brick like Dublin—nor, like London, is the dirty and smoky red interrupted in some quarters of the town by the masks of stucco, of all colours and in all states of decomposition, which covers the skeleton palaces. The finest and most showy parts of London are gingerbread and pasteboard to the buildings here. I doubt not, however, to an unpractised eye, several parts of London—I am not now talking of public buildings—will appear as fine as the general run of houses in this city—such as the shops in Regent Street, and the mansions in the Regent's Park. I select these, for they were the first erected under the new system. They were the earliest efforts of George IV., a man magnificent enough in his aspiration, but of a taste most tawdry and glaring. He wished, apparently, to say, with Augustus, that he found his capital of brick, and that he left it of marble. But he forgot that the Roman Emperor spent his life—and he attained the purple at a very early age—in building up the *alta mœnia Romæ* such as Attila found it—and that he had, in the mean time, the absolute command of all the riches of the world, and of the genius of Greece and Italy—those riches for such purposes would have been useless. The Regent of England—and he deserves some credit for the design, childish and ridiculous as it was, inasmuch as it evinced the presence of some germs of imagination in a man whose character was stained by many degrading vices—the Regent, I say, thought to accomplish, in a dozen years, what occupied the entire reign of the second Cæsar. He set about the scheme with great zeal—he had ready a class of secondary architects—he had drawings and plans in abundance—and, above all, he had the sanction of Parliament. To work he went—but it was not to marble, nor yet to Portland stone, or to granite that he applied himself—it was to making Roman cement. It was to plastering the houses with a very pretty, nay excellent composition, I admit, and cutting out the fronts of the dwelling-houses as Temples of Theseus, Parthenons, Acropolises, and fanes dedicated to the winds. All was dirty and perishing brick within—without all was a coating of architectural painting. And then the strange variety in which all orders and ages of architecture were jumbled together. The tailor's house had a Grecian portico, and his next door neighbour, the draper, rejoiced in a Gothic castle. Here was a temple of Bacchus—there was a thing somewhat resembling a Chinese pagoda, only more full, if possible, of pretension and exaggeration. You saw at a glance, that this part of the city of London was made for the nonce—that it was gotten up for a show—that it was fine and glaring scene-painting, not half so fine, or half so striking as Stanfield's sketches, because the designs and the executors of the plan had not half the genius of that excellent artist. But let me be just. The design of trying to alter the dirty and ferruginous aspect of London was commendable; and if he deserves any praise for anything—an hypothesis upon which I am very unwilling to insist—George IV. is entitled to some commendation for what he attempted, rather, certainly, than for anything he accomplished. An impulse was given to architectural improvement, in a city which, though it contains many splendid edifices, was, until this endeavour was made, the most uninteresting—and, may I not add, notwithstanding its situation on a river twenty times more magnificent than the Seine, the hugest and ugliest collection of brick and mortar in the world—nothing but tiles and brick. Why, there is the Corporation of London—I have seen the halls of some of their guilds made to dine—and principally made for that purpose—seven or eight hundred individuals—I have seen one which was as big as a Methodist meeting-house, and as ugly as a barn; the building itself (and it was a new one when I saw it) was placed in a nook or alley, and piled up with brick, I know not how many *fathoms* high. The money expended to make such an edifice, would, in Paris or in Petersburg (a city of yesterday), produce a beautiful building, architecturally elegant in the exterior, and containing within all the accommodation—all the appurtenances and means to boot, of dining gloriously on green fat, and getting gloriously drunk with dancing champaign. The truth is, that until a recent period, John Bull was thinking of nothing even in his public buildings, but being *comfortable*—a word that he delights in, and which you hear in France pronounced with great *gusto*—John insisting, truly, I believe, that the French language is without an equivalent term—his notions of comfort, however, in this regard, being confined to eating and drinking. The admission is due to George IV., I must repeat again, that to his absurd zeal, in trying to convert the brick of London into marble, the *real* improvements which that great city is now in the process of acquiring, may be fairly enough attributed. A better order of architects are forming; private buildings, as well as public, are not any longer left to the taste of the bricklayer, or the cunning of the carpenter. The two-foot rule and the plummet are indispensable, and the builder must employ them; but it has been found out at length that there are other things indispensable in building an edifice for an imperial city. When sought for, talents of the kind required are always to be found. They existed in what are called the dark ages, when Westminster Abbey and Rouen Cathedral were built. It would be an uncourtly satire on England—it would be a most false misrepresentation of her intellect, ingenuity, and taste, to pretend that architects would be wanting if they were required. They are not wanting. It is true the National Gallery is a national disgrace, and the Royal Exchange, when it arises from its ashes, may prove an ignominy, if the city don't look to it; but, on the whole, within the last twelve or fifteen years, the signs and tokens of a better order of things are manifest even to an observer the most cursory. But *ages* must elapse before London can be what she ought to be architecturally, and what she will be, no doubt, should she hold, as she has done, with such transcendant glory, the sceptre of the seas.

But Paris has been, since it first became *great*, an *architectural* town. During all her eventful history, her public buildings held a prominent place in the minds of her kings and politicians. The French are fond to madness of glory—of martial renown principally—but all sorts of fame, even to the making of a cap or periwig, are prized, perhaps, beyond their value. They value themselves upon their poets, their orators, their historians, their painters, their architects. In Louis XIV. they had a king who was as vain as any of his subjects on all these national *vanities*—if you will, a king, too, that had the power to execute his will, at any expense of treasure and oppression. The policy of his reign may be questionable, and he may have been himself a tyrant; but he adorned Paris, and he completed Versailles. It was pride, if you like, and selfishness; but to it the present generation is indebted, at least, for fixing, propagating, and, I think, perpetuating the taste of the people in this regard. The *improvements* of Paris began nearly two hundred years ago, and they have been in constant progress. Those of London are scarcely thirty years old. But, in the interim (of 200 years) London has increased nearly fifteen fold in population and houses, while Paris has certainly not been trebled. At the commencement of the reign of George III., a comedy—I forget the name—was produced—I saw it acted myself, when they used to play comedies—in which two interlocutors are introduced, discussing the relative population and size of the two greatest cities of Europe. In those days, statistics was no science; but, the circumstance is enough to show, without hunting your library to ascertain the truth, and missing the game, most probably, at last, that, about seventy or eighty years ago, the population of these two cities were nearly alike. In population, London is now doubled, at least, and she contains six or eight times as many houses, and consumes much more ground. But London has been built at *random*. It is not houses they *run up*—a good, familiar, and descriptive phrase—but *streets*. Aye—streets. An instance has been known of a street of considerable extent being built in three months. It takes three years to build a house in Paris; but then it *is* a house—a great house—three or four times the extent of a mansion in Merrion-square, for example. The Merrion-square house may be, and is, no doubt, more comfortable, in conformity to our notions of comfort. It contains only one family, while the great buildings I speak of gives magnificent apartments to two or three. And do not imagine that the families which inhabit these houses pay less for their houses than the gentry of Merrion-square. Two, three, and even four hundred francs a year is not an uncommon rent for these separate families in one house. Some have been mentioned to me which brings the proprietor in from £1,500 to £2,000 a year. Observe, that I am not discussing which is the best mode of living—the French or the English. For my part, I should like to have a house to myself; but *that* is not the question here. I am stating a fact with a view of showing you why it is that Paris is so much superior in its buildings to London. First, they build in Paris greater houses; secondly, these houses occupy a longer time in building; and thirdly, they are built of materials vastly superior to those employed in England. They are built of a coarse marble, or of a beautiful stone, as *I* think it is, supplied by the quarries of Normandy and the valley of the Seine—the stairs in many of them are of marble—the floors, all that I have seen of them, in the latter order of houses, are made of oak—the landing places, and little ante-rooms, are constructed of marble, or a Roman cement, or some superior preparation of tile. In short, these houses are made to *last*—not for one generation or two, but, perhaps, for ten. When finished, there they stand compact and fine, and *knit together*, with a view of enduring for centuries.

To build a house in Paris is a very serious thing; the ground rent is enormously high. You go to the stone quarry for your material, and not to the brick-field. You must employ oak instead of Canada pine. You must employ stone-cutters and masons instead of bricklayers. In short, for the private houses of the first class, that is to say, for houses in the first class of streets, you must proceed in Paris as you would in London or Dublin if you are about to design a public edifice. They are built, therefore, most substantially, and, as in public edifices, their exterior is designed on architectural principles, and with a view to suit the *genius loci*. Now, as I have said, this system has been in operation for centuries, and you can almost pronounce the age of a building, if you have given any previous time to the study, on inspection. Hence it is that, notwithstanding the vast number and beauty of the buildings made by Napoleon, and the great addition that has been made during the present improving reign, the *air* of Paris is that of an old city; while London looks, and will always look, from the material it is made of, neither new nor old, a sort of *Provisional City*, a multitudinous congregation of houses, that are constantly changing their aspect—that are constantly in a state of transition of being run up or run down—*quadrata rotundis*. But it cannot be expected that on a town passing away, as it were, with the autumnal leaves, and renewed with the swallow and the zephyr, architecture can have impressed her permanent type. Brick, however, neatly put together, will not take the impression. It is too perishable and flimsy to bear the weight of her machinery—and, indeed, it has never been tried. The bricklayers and carpenters of London content themselves with erecting houses of three or four stories high, with a comfortable basement for the kitchens and pantries, a hall, a front parlour, and a dining-room—above, two drawing-rooms, opening into each other, best bed-rooms higher up, and inferior apartments next the stairs. They are all alike—like as eggs—the only difference being in the size—from a sparrow's egg, or a pigeon's, to a duck or a goose's egg. In regard to the apartments and their disposition, you might, after describing number one in any given street of London or Dublin, write ditto against number two, and ditto to the bottom of the page, and to the bottom of the next, and to the end of the volume. It is curious that our ordinary builders exhibit such a poverty of contrivance—no taste, no variety, no resources, apparently, except in fixing a water-closet, or managing a projecting recess. I have little doubt that these deficiencies are attributable, in a great degree, to the materials we employ, and are obliged to use, as well as from long habit, which has grown up into a second nature. Houses are built, in London, to answer temporary purposes, or for the accommodation of two, or three, or four generations. They are made of brick—a perishable article—they are made of Canada deal—a decaying wood. But they answer the ends of their creation. Art, science, in the disposition of the interior, and considering also the size of the mansions, would be thrown away, or rather would not have space to move about in "the cribbed, cabined-in and confined" precincts of a London or Dublin private house. In this city, from what I have already said, you will readily infer that the case is quite different. I have been in several houses since I came to France, and I did not find two of them alike in their interior arrangements. It would be, indeed, a sad puzzle to an ordinary London or Dublin builder to make a house in the French fashion; to *design* a house like that, for instance, in which I am now residing—poh! he would eat it as soon.

But, as I have said before, a better taste is arising amongst ourselves. When people shall be convinced, that even in the construction of an ordinary building, it will not be amiss to employ an architect as well as a builder—and, I should hope, this taste is beginning to prevail, our children, and our childrens' children will see a finer London and a finer Dublin than we do now—and, *I expect* that our country-houses—I mean the houses of our gentry—if they can keep their station, which so many of them are built upon endangering, will not be made up by a country mason and his helps—but, will exhibit the common sense and understanding in which the mansions of their grand-papas have been so lamentably deficient. With respect to public buildings, the prospect for our posterity is still more cheering. Our superior artists are studying the Greek models with a zeal that promises excellent effect. There are drawings and elevations of all the architectural remains of Greece and Italy. The taste in England never died entirely, from the time of Athenian Stuart, but it slumbered in the interval deeply, until a few years after the last war. But, the pure taste to be acquired from the study of these immortal models has had to struggle hitherto with the so called Gothic, Norman, and above all with that thing, now the most fashionable of all, called the Tudor or Elizabethan architecture, of which it may be asserted, *meo periculo*, that it is the worst of all the rest—and only better than the poor, bald, and miserable system prevailing in England since the Revolution. But, Ancient Greece will conquer at last—though they are building the parliament house after a model of their own.

This is a long letter, and upon a subject which can be popular only in certain, perhaps, rather restricted circles. But, I am writing with the glorious Madeleine looking in at my window—that most superb copy of the finest and purest architectural powers of Greece. Here is a building that the eye never tires in gazing upon—so sublimely simple, so quietly beautiful, and such a magnificent array of Corinthian columns. But, I am not here to describe the Madeleine, any more than any other edifice. But, looking around me, and with this memento constantly before my eyes, I could not resist the topics which the contemplation of these objects suggested.

ON RAILWAY AND CANAL TRAFFIC.

By Charles Ellet, Jun., of the United States, Civil Engineer.

[The following judicious remarks on Railway and Canal Tolls, which we extract from the "Franklin Journal," are well deserving of the serious attention of all parties connected with either railways or canals, there will be found many hints worth their consideration.]

The object of this essay is to point out, in a brief and popular view, the consequences of some of the errors which are committed in the charges assessed on the public works of this country.

The writer has recently published a work* in which he has attempted to expose the true principles of trade, and to show the only correct mode of determining the tolls proper to be levied on our great lines of canals and railroads. But it has been suggested to him by some intelligent readers of that work, that the method of analysing the subject which he has been compelled to adopt in it, is not the best adapted to the pursuits of the class of readers most likely to be interested in the subject; and that some advantage might be derived from exhibiting, in a popular form, a few of the results which were there obtained by a different process. This essay is intended to subserve that purpose; and to show that the principles on which all the tariffs in the country are based, are unsound, and lead, in their application, to oppressive injustice to a portion of the community, and to great loss of trade and revenue to the improvements.

Of the Importance of the Subject.

1. There are no questions of public policy which are thought to concern so intimately the general and particular interests of the people of this country, as those which relate to their internal improvements. The consideration of this subject constitutes the greatest part of the legislation of nearly all the states in the Union, and the employment of the privileges sanctioned by the law, constitutes a prominent portion of the efforts of individual enterprise. There are now completed and in use in the country more than three thousand miles of railroads, and not less than three thousand miles of canals, the construction of which has occasioned an actual expenditure of probably 150,000,000 dollars, and for which loans have been incurred by the state governments or incorporated companies, to nearly an equal amount.

This enormous investment of capital is by some viewed as alarming; and might, indeed, appear so, when it is considered that a draft of some eight millions of dollars will be annually made on the country for the payment of the interest on this sum, and that the principal itself, in the brief space of twenty years, may possibly have to be refunded. On the other hand, there are sanguine advocates of improvements, who look to the revenue to be derived from the works themselves, consequent on the rapid growth and progressively increasing productiveness of the country, as offering an ample guarantee for the prompt payment of the interest, and the due liquidation of the principal, of the debt.

It is not the intention now to discuss this momentous question, or to endeavour to ascertain which of these hypotheses approaches nearest the truth. Both are but surmises, advanced as the result of a hasty glance at the facts, or possibly based on no safer evidence than the prepossessions, or mere conjectures, of the parties. They are wanting in that detail, that exhibition of

* "An Essay on the Laws of Trade in reference to the works of Public Improvement in the United States."

statistical information, without which it is impossible to generalize with security.

Doubtless many of the works of the country will possess abundant means to sustain their credit; and among so many enterprises, it is equally probable that some have been undertaken which will fall very far short of the expectations of their patrons.

But, whatever may be the general ability of these immense lines of improvements, it is certain that the success and profitableness of those which are now progressing under the fairest auspices, are not so well established but that it ought to be an object of deep solicitude with their proprietors to find the means of increasing their productiveness. To every State that has embarked in a career of internal improvement, and to every individual who has invested his property in such stock, it is an interesting question to ascertain the most efficient means of equalizing the charges on the trade, and increasing the revenue and tonnage of the line.

The public improvements of Pennsylvania are sinking that commonwealth in debt about *a million and a half per annum*—or, in other words, the interest on the loans incurred for their construction, added to the annual charges for repairs and superintendence, exceeds the gross revenue of the works from one to two millions of dollars per annum.

Of the Incorrectness of the Principles on which Tolls are at present assessed.

To be able to appreciate the necessity of a departure from the principles on which the present charges for the use of our public works are established, it is essential to examine into the effective operation of the scale now in use. To render the view which I design to take as little complicated as possible, it may be confined for the present to one of the principal divisions of the trade of the country. For, in treating of the laws of trade, it is found convenient to divide the commerce of the line into two principal classes; in the first of which is included all those commodities which will bear but a limited charge for their transportation, and which, if taxed beyond that limit, will be excluded from the line and from market. This division usually consists of stone, coal, lumber, ore, lime, and many agricultural productions. Indeed it embraces all articles which will seek a market along the line in question, and no other; and in this respect is to be distinguished from that division of the trade which consist of more valuable commodities, and which, if not accommodated on one line, will find a passage by the route of a rival work.

Our present investigation will be confined to the first of these divisions.

The charges which are levied on this trade consist of what are usually termed *freight* and *toll*. If the work be a canal, by freight is understood the charge of the carrier, and by toll that of the state or corporation owning the work. In the management of railroads, it is usual for the company to act as carrier on their own line; and to make but one charge, which is called toll, for both objects. In this essay I shall make a somewhat different application of these terms, and designate by freight, in either case, every expense actually incurred in the carriage of the commodity, and by toll, the clear profit on its transportation. So that if the carrier, or transporting company, charge seven *mills* per mile for the carriage of one ton of any article, and the cost of repairs and superintendence of the line due to the passage of that ton is three *mills* per mile, I call the freight on the article one cent per ton per mile; and any charge exceeding this three *mills*, which is assessed by the state or company, is what I denominate their toll.

In nearly every tariff of toll adopted in this country, the charge on every article is proportional to the distance it is transported on the line. The toll is some fixed amount per ton per mile. This scale of taxation, I contend, is improper and unjust.

To examine the question, let us suppose the article to be lumber, of which the market value, at the point to which it is sent, is 10 dollars per ton. Let us also assume that the cost of producing this article, or preparing it for shipping on the canal, is 6 dollars per ton. It is then most obvious that if the charge for transportation on this commodity exceed 4 dollars per ton, it will be wholly excluded from the line; for then the cost of carriage, added to the cost of production, would exceed the market value of the article, and there could be no profit to remunerate the producer. But if the charge be less than 4 dollars, there will be a certain profit, and the article will be found to seek the market.

If now, this lumber is carried a space of 100 miles to its mart, and the charge for freight is one cent per ton per mile, the freight for that distance will obviously be one dollar, and there will remain a balance of three dollars for the extreme limit which the article will bear to be charged for toll. The toll levied by the state, at one cent per ton per mile, will be one dollar, or one third the amount which the article could in this case sustain.

Let us next suppose that similar lumber comes upon the line at a distance of 300 miles from the same mart. The charge for freight would now be three dollars, and there would consequently be a residue of only one dollar on which the state might levy for toll. The commodity could bear no more than one dollar, since that sum added to the three dollars freight, would be four dollars, or the difference between the cost of producing the lumber and its price in market. But, by the principle of taxation usually adopted, the toll assessed at one cent per ton per mile, would here be three dollars, or three times as much as the article would bear. In other words, at the distance of one hundred miles from the mart, in the usual tariffs, a commodity is charged one dollar where it might bear a charge of three, and at three hundred miles it is charged three dollars where it could bear but one.

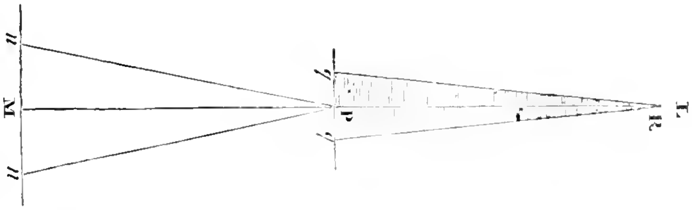
Does it need any argument to prove that a scale producing such results is neither compatible with principles of equity or good economy? Is it not manifestly unjust to charge the man who is situated 300 miles from market three times as much as he can afford to pay, while the man at 100 miles can afford to pay three times as much as he is charged? Is it not any thing but good economy to tax all the trade in this article beyond 200 miles so heavily that it is totally driven from the line, when, if the tolls were differently assessed, it might be invited, and made to pay a respectable revenue to the state? And is not the primary object of the work defeated by the adoption of a tariff that excludes those commodities from it which it was especially intended to draw to market, an effect which is accompanied by a direct sacrifice of trade, revenue, and even justice?

I think it can scarcely need more than this plain exposition to make clear to any reflecting mind that some of the charges on the public works of this country need revision; that they are based on principles which are unsound, and at once do injury to the proprietors of the work, and injustice to a large portion of the public. The commonwealth, as the constructor and owner of the improvement, is a sufferer in the loss of the trade that is excluded, and the revenue that might be derived from it; the citizens of the emporium which is the mart of the line, suffer from the contraction of their business in consequence of the exclusion of the articles in which they traffic; and the country traversed by the improvement, and taxed, perhaps, for its construction, suffers from its inability to share the benefits which the work was designed to confer.

Further evidence of the loss of Trade consequent on uniform Charges.

To render more palpable the fact that a charge for toll proportioned directly to the distance will cause the exclusion of a certain amount of tonnage without conferring any compensating advantage, we will consider the subject with the aid of a diagram. (See Fig. 1.)

Fig. 1.



Let M in the figure be the position of the mart, and ML the line of the improvement; and let us assume, as before, that the commodity will be capable of sustaining a charge of four dollars per ton for its transportation; that the toll is one cent per ton per mile, the freight likewise one cent, and the cost of carriage on the lateral roads by which the tonnage is brought to the work, is ten cents per ton per mile.

The distance M n from which this commodity can be brought to the mart at M on the lateral roads n M, n M, will then be forty miles; and the distance M P which we can afford to carry it along the improvement, at an aggregate charge of two cents per ton per mile, will of course be 200 miles. The area of country, therefore, which will supply trade to the line, will be represented by the triangle n P n, having a base n n of eighty miles, and a height M P of 200 miles.

Now, it is apparent that the line will receive no tonnage of this article, from beyond the point P; and therefore, that if the trade were permitted to come free of toll from beyond that point, there would result a certain increase of tonnage, which would be accompanied by no diminution of revenue.

Under such an arrangement of the tariff, the charge for freight from P to M, for produce coming from the country beyond P, would be only two dollars, and there would consequently be left a balance at P of two dollars out of the limit of four dollars which the article could sustain, to bear the cost of its carriage along the lateral roads to the improvement, and down the improvement to the mart.

This balance will be sufficient to pay the cost of transportation on the lateral road from q to P, a distance of twenty miles, at ten cents per ton per mile; and the charge for freight along the improvement, from R to P, a distance of 200 miles, at one cent per ton per mile. It would, therefore, be within the ability of the state or company, in this example, to extend the benefits of the improvements 400 miles into the interior instead of 200, and increase the tonnage of the line, with all the incidental advantages, 50 per cent., without sustaining any loss of revenue.

It is far from my intention here to advocate a tariff arranged with a view to this effect, but merely to show what is lost by those which are commonly adopted. Instead of draining only the country contained in the triangle n P n, which will supply the trade where the charge for toll is one cent, and freight one cent, by charging toll from M to P, and permitting all articles brought from beyond the angle P to pass free of toll, the shaded triangle q R q in the figure will be added to the area using the work and supplying its tonnage. The value of the improvement to the country will be increased one half; the trade of the city at M will likewise be increased one half, and the value of the property of the commonwealth, as far as it is dependent on the activity of the work, will be proportionally augmented.

But such an arrangement would effect injustice, and could not therefore receive the sanction of a government administered in a due regard to the first principles of its existence—the equal protection of the citizens, and an equitable distribution of the benefits which its constitution was intended to confer.

Such a tariff would augment the tonnage of the line—but it would produce that result by taxing the citizen immediately at P four dollars, and excluding him from the work, and the neighbour immediately beyond P but two dollars, and inviting him at the expense of a premium.

Besides these objections to this arrangement, there exists the additional and important one, that it would not fulfil another imperative condition—that of obtaining the greatest revenue from the trade.

Of the most judicious charge on articles of heavy burden and small value.

I conceive that it is essential to the fulfilment of the condition, that the tax levied on the trade of the line shall be reconcilable with principles of equity, that the charge at each point shall be proportional to the ability of the article to sustain it; and, it fortunately happens, that when the charges are regulated in the mode that will produce the maximum revenue, this condition will be fully satisfied.

We are to understand by the ability of a commodity to sustain a charge for carriage, the difference between the cost of production and the market value of the object. If the article be worth ten dollars in market, and it costs six dollars to produce and prepare it for market, it will sustain any charge for transportation, including both freight and toll, not exceeding four dollars. But its ability to sustain a charge for toll only, depends on the position in which it reaches the line of the improvement. For, after deducting the cost of production from the market value, the residue may go to bear the whole cost of carriage; but we must still deduct from this residue the charge for freight, to obtain the sum which it will bear to be charged for toll.

If, for example, the above article reach the line at 100 miles from the mart, and the freight be one cent per ton per mile, the charge for freight will be one dollar, and the residue will be three dollars. If it reach the line at 200 miles, the charge for freight will be two dollars, and this residue will be two dollars. If it come on the work at 300 miles, the charge for freight will be three dollars, and the residue will be one; and if it reach it at 400 miles, the freight will be four dollars, and the residue will be nothing, I say, therefore, that to make the tax for toll proportional to the ability of the commodity, the charge levied by the State for its passage along

100 miles should be proportional to 3 dollars,
200 miles should be proportional to 2 dollars,
300 miles should be proportional to 1 dollar,

and along 400 miles it should be allowed to pass free. From which it appears, that the greater the distance the commodity is carried, the less should be the toll levied upon it. In short, I propose that the tax should be proportional to the ability of the trade to sustain the charge; and, by such a tariff, to supersede those now in use—by which the tax is increased in proportion as the ability of the trade to bear the tax is diminished.

Now, it may be demonstrated, that when the toll is assessed on this principle, both the tonnage and the revenue will be greater than if the most profitable uniform charge per mile that it is possible to levy were adopted.

But the method of determining this most productive charge, cannot be conveniently pointed out, with a demonstration of its correctness, in a mere popular discussion. I have, however, elsewhere considered the subject in some detail, and have shown that the toll on this division of the trade which will yield the greatest possible revenue, is about three-eighths of the charge which would exclude the article from market; or three-eighths the limit of the tax which it would bear.

In the above example, therefore, the charge at

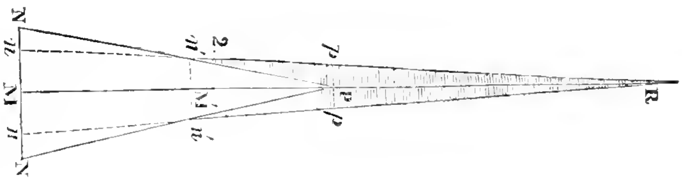
100 miles, should be $\frac{3}{8}$ of 3 dollars, or 1 dollar	$12\frac{1}{2}$	cents.
200 miles, should be $\frac{3}{8}$ of 2 dollars, or	75	"
300 miles, should be $\frac{3}{8}$ of 1 dollar, or	$37\frac{1}{2}$	"
400 miles, 0	00	"

The difference between these sums and those above given constitutes the profits of the proprietors.

It cannot be objected to this scale of charges, that it deprives the citizen on the line, near the mart, of any of the advantages of his position. The work, on the contrary, furnishes him with the means of transporting the products of his estate to a market for one fourth or one fifth the sum he was compelled to expend before its construction. This is a positive advantage for which he is indebted to the commonwealth; and he has no right to complain if the same commonwealth extend the benefits of the enterprise to more distant citizens. The avowed object of the improvement is to bring to market productions which could not otherwise reach it, and, generally, to reduce the tax on transportation. And if the objection, that the mode of charging here recommended may seem to disturb the relative advantages of position of the near and distant denizen, be a valid one, it is *a fortiori* a conclusive argument against all improvement. A consequence of the construction of any canal or railroad, is to increase the value of estates to which it affords new facilities, and of course disturb the relation between the advantages possessed by such property and other estates in the commonwealth, on which it has no effect.

But such an objection, even if a legitimate one, cannot be applied to the scale here advised. It is not proposed to tax the distant man less for the transportation of his effects than the nearer one; on the contrary, he is charged more. The method merely proposes to make that portion of the tax which is to be considered as the profit of the State—that portion which is levied for revenue—proportional to the ability of the trade to pay it. And this is just.

Fig. 2.



If, now, we represent by a proper scale, as in Fig. 2, the area of the country which, with the data of this example, would furnish the tonnage, in the hypothesis of an uniform charge of one cent for freight and one cent for toll, we shall have, as before stated, a triangular figure N P N, with a base, N N, of 80 miles, and height, M P, of 200 miles.

But if the charges were adjusted with a view to the obtaining of the maximum revenue, the triangle would have a base, *n n*, of 50 miles, and a height, M R, of four hundred miles. In the one case the area of the country would be represented by the triangle N P N, and in the other by the triangle *n* R *n*.

But, instead of aiming to obtain the maximum revenue on all the trade which would reach the improvement from R to M, we may, by the system which it is intended to recommend, adopt in both instances an uniform charge for toll, as one cent per ton per mile, from M to M′—the point which corresponds with the intersection *n*′ of the sides of the superior and inferior triangles—and confine the arrangement made with a view to the maximum revenue, to that portion of the country situated between M′ and R.

The consequence of this arrangement would be to obtain the same tonnage and revenue from the country traversed by the portion M M′ of the line, in both cases, since the tariff would in that distance be common; and at the same time to increase the area of the country trading on the improvement, a quantity equal to the whole of the shaded space in the figure, and to increase the revenue a quantity equal to whatever would be due to this additional trade and the charge upon it, determined in accordance with the principles here laid down.

It will be perceived that the increase of tonnage and revenue which, in the first part of this article is shown to have place, will be obtained without any increase of toll on any part whatever of the trade. We have only to take the present tariff of New York or Pennsylvania, or any other state or company, and obtain these results by a reduction of the charges.

For, at the point P, which is supposed to be 200 miles from M, we have seen that a toll of one cent per ton per mile would entirely exclude the trade. But if, instead of a charge of one cent per ton per mile, at that point, or two dollars for the entire toll from P to M, the article were taxed but 75 cents per ton, as is stated to be the proper toll under the circumstances, there would remain out of the two dollars, which is the limit of the charge for toll it would bear at that position, a balance of one dollar 25 cents, to pay the expense of its transportation from *p* to P—a distance of $12\frac{1}{2}$ miles on each side of the line. So that, by simply reducing the charge resulting from a tariff proportioned to the distance, we shall here obtain, instead of nothing, a revenue due to the tonnage that would be furnished by a district *p p*, 25 miles in breadth, at a charge of 75 cents per ton.

It is true that a much more important increase of revenue might be experienced by a modification of the uniform charge supposed to be levied from M to M′, and a reduction from the new tariff beyond M′. For, even where we to adopt the principle of fixing on a determinate toll per ton per mile for a certain distance, we should bear in mind that there is a certain uniform charge which will yield a higher result than any other. But, without any reference to this, or any of the other advantages which would be derived from a thorough and strict regard to the laws of trade in the establishment of the tariff, I have only sought to render clear the fact, that by simple reduction of the charges on a portion of the trade on all our public works, the revenue and tonnage may be simultaneously increased, and the tax on the public may be rendered more equitable.

EXPERIMENTS ON THE AMERICAN COTTON-GINS.

On Wednesday the 12th July, a deputation of the Board of Directors of the East India Company, paid a visit to Liverpool, for the purpose of witnessing a series of experiments in the cleaning of East India cotton by means of the saw-gins brought to England by Captain Bayles. The object of these experiments was two-fold: firstly, to show that by the introduction of the American saw-gin into India, the cotton of that country might be so well cleaned, and with so little injury to the staple, as to render it a marketable article to an almost unlimited extent; and, secondly, to ascertain which of the four gins was best calculated for the cleaning of Indian cotton, in order that other machines might be manufactured, either precisely on the same principle, or with such improvements as might seem desirable.

The experiments took place on Friday the 14th ult., on the premises of Messrs. Fawcett and Preston, where the gins had been fitted up, and steam-power applied to them. There were present the directors, deputations from the Glasgow and Manchester Chambers of Commerce, the Mayor of Liverpool, and a great number of extensive spinners, influential merchants and brokers, probably to the extent of 150 persons.

The Chairman of the directors having explained briefly the objects of the Board, the experiments were commenced, under the superintendence of Captain Bayles, who was assisted by the four American planters remaining with him. A quantity of Surat cotton, in the state in which it had been gathered, and which had been two years in this country, was first exhibited to the company. It seemed to have been gathered when wet, and was very dirty; and the general opinion seemed to be that in its then state it was nearly, if not altogether, worthless. Twenty-one pounds of this cotton were put into each of the three American gins; No. 1, being the invention of Mr. E. Carver; No. 2, that of Mr. Jones; and No. 3, that of Mr. W. R. Brooks. Two of the gins have 60 saws; the other has 40; the time occupied in ginning therefore varied somewhat. Two, we believe, accomplished their work in about 9½ minutes; the third in about 11½.

The result of the experiment with the gin No. 3 was first tested; it was as follows:—cotton, 5 lbs. 3 oz.; seeds, 12 lbs. 8 oz.; waste, 2 lbs. 11 oz.; making within 10 oz. of the original quantity of 21 lbs. put into the machine. The yield of cotton. it will be seen, was one quarter. A sample was submitted to the inspection of the company generally, and they were requested to put upon it a value. Mr. Hardman Earle, Mr. Ashton, and another gentleman, were appointed special valuers. They decided that this sample was worth 4¾d. per lb.

Gin No. 2.—Cotton, 5 lbs.; seeds, 14 lbs. 10 oz.; waste, 12 oz. Value of sample, 4d.

Gin No. 1.—Cotton, 5 lbs. 5 oz.; seeds and waste, 15 lbs. 6 oz. Value, 4½d.

It is necessary to mention that the machines were not, as may well be imagined, in the best working order. This was especially the case with No. 2, between the saws of which numerous seeds had forced their way, thus injuring the staple more than would otherwise have been the case. The saws having been cleaned, a second experiment was made with this gin, the result of which was the production of a better cotton, valued at 4½d.

An experiment was then made upon the fourth saw-gin. This was also from America, but it was a machine of older date than the foregoing ones. Patterns of it had been made and sent out to each of the Presidencies, and the machines had been tried, but were pronounced to be a failure. They were in India worked with hand-power. Steam-power was employed in the present experiment; and 21 lbs. of the old Surat cotton was put into the gin. The time occupied in ginning this was 14½ minutes; but the comparative increase of time may in part be accounted for from the fact of the machine having a less number of saws. The result was—cotton, 4 lbs. 10 oz.; seed, 15 lbs.; waste, 10 oz. The cotton was well cleared of the seed and dirt, but the staple was very much cut. The estimated value was 4d.

As steam-engines are at present almost unknown in the interior of India, animal power will probably be employed, at least in the first instance, in the working of the gins. The above four are so constructed that either steam or animal power may be applied to them.

An experiment was now made on a hand-gin, constructed by Messrs. Fawcett and Preston, under the superintendence of Dr. Jones, who had only commenced the machine twelve days beforehand. The doctor stated that his great object had been to produce a machine which should possess the essential quality of standing the climate of India without warping. That, he thought, would do so; and he felt convinced that it would, with the substitution of properly finished saws, and the outlay of a little more time, turn out a good working gin. It has twenty-five saws, and may be worked with horse power. As, however, it was scarcely in a finished state, a regular experiment of its capabilities was not made. A small, but unspecified amount of the Surat cotton hitherto employed was put into the gin, so as to obtain samples. At first the result seemed unsuccessful. The cotton was said to be more cut than in any other instance; but, after closer inspection, the staple was allowed to be very fair, and the machine to have done its work well. A sample was compared with the others, and the cotton was pronounced to be equal to that produced by gins Nos. 2 and 4.

These were the most important experiments of the day, and were generally considered sufficient to prove that cotton of East Indian growth may be well cleaned by the saw-gin, without any very material injury to the staple. The establishment of this important fact will thus enable India once more to enter into competition with America as a producer of the raw material, and to occupy the place from which she was driven by the invention and general adoption of the saw-gin in America.

Improvements in obtaining power; patented by Moses Poole, Lincoln's Inn. July 7.—The intention consists in obtaining power by means of an apparatus, which has a series of blades or surfaces like flyers fixed in an oblique direction to an axis, which is made to revolve, and, consequently to carry them round at any velocity required, the atmosphere acting as the power of resistance, whereby a great power is obtained for propelling boats, carriages, &c. The inventor proposes to work this apparatus by means of an engine, which, if placed in a boat, carriage, or car of a balloon, the flyers or blades acting on the atmosphere will cause the machine to move in any direction required.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

March 3.—The President in the Chair.

The following were balloted for and elected:—Robert Napier and Daniell Mackain, as Members; John Salkeld, Robert Batson, John Gandell, and Siegerick Christopher Kreeft, as Graduates.

"*Description of the 'Nonsuch' Iron Passage Boat plying on the Limerick navigation, between that place and Killaloe.*" By Charles Wye Williams, Assoc. Inst. C. E.

The attention of Mr. Williams having been attracted to the successful plan for the conveyance of passengers adopted on the Glasgow and Paisley Canal, where light sheet-iron boats of great length travel at a speed of nine miles an hour, he was induced to attempt the introduction of the same system on the Irish canals. A great difficulty, however, presented itself, as the locks there would only admit boats 60 feet long, which length was quite inadequate to the carrying out with advantage the principle involved in the long light Scotch boat. To overcome this difficulty, he constructed a sheet-iron boat, 80 feet long and 6 feet 6 inches wide at midships, having the stem and stern ends (each 10 feet long) attached by strong hinges to the body, and susceptible of being rapidly raised to a vertical position by means of winches, thus reducing the length to 60 feet when required to pass through a lock. It is evident that by this means there would be gained not merely the apparent additional buoyancy of 10 feet at each end of the boat, which, from the form, would not be very effective, but in reality the buoyancy due to an addition of 20 feet of the midship section. The boat thus constructed has been found to answer perfectly; the buoyancy is equal to that of the Scotch boats of similar dimensions; no crankness or unsteadiness accrues when the ends are raised; it is capable of carrying 60 passengers, travelling at a speed of 9 miles per hour, with the same power that was required to draw a 60 feet boat with a less load, and there is a much less action on the canal bank, in consequence of the increased length, which at the same time imparts stiffness, and enables passengers to enter and leave the boat with safety. Considerable time is saved in passing the locks, by the opposition of the square end when the bow is raised; the boat may thus be run almost at full speed into the lock, and both ends being raised simultaneously, it is stopped much more easily than if the tapered ends were down. No provision is necessary for keeping the ends down, as the weight of the bow and steersman answers the purpose.

This boat has been working without intermission for three years between Limerick and Killaloe, traversing twice daily a distance of 15 miles, on a navigation of considerable intricacy, and passing 11 locks, without any accident having hitherto occurred.

Mr. Parkes observed that, independent of the advantages of carrying more passengers, by continuing the midship section to the length of 60 feet, considerable speed was gained by the 80 feet boat, in consequence of its fine entrance and run. Mr. Williams informed him that the velocity was found to depend on the position of the boat on the wave; that the rider of the horses employed in towing the boat knew exactly the proper position of the wave with respect to the boat, and regulated the exertion of the horses accordingly—the velocity of the boat and the tractive force depending on the relative position of the boat and wave.

Mr. Field, in reply to some remarks respecting the effect of these rising ends on the buoyancy of the boat, stated that he did not understand it to be Mr. Williams's design to obtain additional buoyancy thereby. The ends only press on the water as much as is due to their own weight, and are principally useful in giving a fine entrance and run to the boat; thus having the whole space between the rising ends for the accommodation of passengers, and obtaining an absolute gain of the whole space that is lifted at each end, as in a boat of the ordinary length there must be the same tapering of the bow and stern ends. So great is the facility in managing the ends, that on quitting a lock the bow end is lowered as the gates are opening; the boat is set in motion at the same time, and as it moves on the stern end is let down, and the usual speed is obtained very soon after it clears the lock. When a lock is to be entered, the boat is suffered nearly to reach the gate at full speed, when the bow end being raised, the additional resistance caused by the square section being suddenly opposed to the water stops the boat almost immediately. The weight of one man at each end is amply sufficient to keep down the ends when the boat is in motion.

"*On the experiments and results of Mr. W. J. Henwood, as to the power of the Huel Towan Engine.*" By George Woods.

In this communication, the author refers to the experiments of Mr. Henwood, published in the second volume of the Transactions, and to the result there stated, that the curve traced by the pencil of the indicator during the expansion of the steam deviates from a true parabola, according to the temperature of the medium contained in the jacket. Mr. Woods comes to the conclusion that, the temperature remaining constant, the curve will deviate very considerably from a true parabola. The results obtained by the author as to the relative powers of the engine before and after the steam is cut off, and the mean pressure, as given by the indicator diagram, do not differ materially from those given by Mr. Henwood. But Mr. Woods differs from Mr. Henwood as to that portion of the curve which the latter selects as representing the true value of expansive working.

"*Description of a Running Gauge for ascertaining the Parallelism of a Railway.*" By Edward Cowper. (Described in the Journal, vol. ii, p. 245.)

"*An Azimuth Cap as an addition to the common Level.*" By Edward Cowper.

It is sometimes desirable in levelling operations to ascertain the bearing of objects which are either above or below the field of view of the telescope. The common level alone cannot take the bearing of such objects; for, by elevating or depressing the telescope, the action of the compass is destroyed; but, by slipping the azimuth cap on to the end of the telescope of the level, objects 50° above or below the field of view may be observed without disturbing the compass or altering the level of the telescope.

This instrument consists of a brass cap containing two slips of looking-glass placed at an angle to each other, precisely as in Hadley's quadrant; one glass being fixed at an angle to the axis of the telescope, and the other being moveable about a centre. When any object is required to be brought within the field of view, the cap is placed on the end of the telescope, and the angle of the moveable glass is varied until the object is reflected on the fixed glass, and thence to the eye.

The following were balloted for and elected:—John Manby, as a Graduate; Frederick John Evans, Richard Ravenhill, and John Clutton, as Associates.

"*A mode of bending Discs of Silvered Plate Glass into Concave or Convex Mirrors by means of the pressure of the Atmosphere.*" By James Nasmyth.

The difficulty of obtaining large specula for telescopes, together with the disadvantages attending the weight, the brittleness, and liability to oxidation, of the speculum metal generally used, induced Mr. Nasmyth to turn his attention to the employment of silvered plate glass for telescopic purposes, as it possesses perfect truth of surface, is lighter than metal, is not liable to oxidation, and a greater quantity of light is reflected from it than from any metallic surface.

To give a concave or convex form to a disc of plate glass, a certain pressure must be made to act equally over the surface. This equal pressure is obtained on Mr. Nasmyth's plan, by taking advantage of the weight of the atmosphere.

A disc of silvered plate glass, 39 inches in diameter and $\frac{3}{16}$ of an inch in thickness, is fitted and cemented into a shallow cast-iron dish, turned true on its face so as to render the chamber behind the glass perfectly air-tight; by means of a tube communicating with this chamber, any portion of air can be withdrawn or injected.

To produce a concave mirror so slight a power is required, that on applying the mouth to the tube and exhausting the chamber, the weight of the atmosphere, which amounts in this case to 3558 lb., acting with equal pressure over a surface of 1186 square inches, causes the glass to assume a concavity of nearly three-quarters of an inch, which, in a diameter of 39 inches, is far beyond what would ever be required for telescopic purposes. On re-admitting the air, the glass immediately recovers its plane surface, and on forcing in air with the power of the lungs, it assumes a degree of convexity nearly equal to its former concavity. The degree of concavity or convexity may be regulated to the greatest nicety, and it is proposed to render the degree of concavity constant, by placing in the air tight chamber a disc of iron turned to the required form, and allowing the pressure of the atmosphere to retain the glass in the form given to it by its close contact with the iron disc. The curve naturally taken by the glass when under the pressure of the atmosphere is believed by Mr. Nasmyth to be the catenary, inasmuch as its section would be the same as that of a line suspended from each end, and loaded equally throughout its length.

Mr. Lowe did not feel well assured that the curve naturally taken by the "Pneumatic Mirror" was a catenarian, as the plate being set in a frame was supported all round its periphery, and resembled an arch resting on its abutments. He suggested the propriety of attempting to attain given curves by grinding the plate of different thicknesses in parts, so that the pressure of the atmosphere should affect it unequally.

Mr. Macneill was inclined to believe the curve assumed was the "Elastic Curve," the properties of which were examined by James Bernouilli, in the Memoirs of the Academy of Science, 1703.

"*An Account of the Performances of the Locomotive Engines on the London and Birmingham Railway during the year* 1839." By Edward Bury, M. Inst. C. E.

The engines used on the London and Birmingham Railway are all constructed on the same principle as to the main parts, the whole being upon four wheels, and only differing from each other in some of the minor details. The engines used for the conveyance of passengers have cylinders 12 inches diameter, with an 18 inch stroke; the driving wheels are 5 feet diameter, and the carrying wheels 4 feet diameter. The merchandize engines have cylinders 13 inches diameter, with an 18 inch stroke, and differ from the others in having all the wheels of 5 feet diameter and coupled together. The framing is of wrought iron, fixed inside the wheels for the greater convenience of connecting it with the boiler. The cylinders are attached to the frame by two strong wrought-iron bars passing beneath the lower semi-diameter, and secured by bolts to the ears cast on them. The cranks and fore axles are also fixed to the frame. By this arrangement, any concussion is received directly by that part of the machine best calculated to bear it, and when the force of the engine is exerted in either pushing or drawing, it is done directly through the line of the framing, and thus any strain is diverted from the boiler or from those parts of the machine liable to be injured. There are only two bearings on the axles, and they are inside the wheels. Any tendency towards depression in the centre from the weight would be counteracted by the continual upward pressure, arising from blows received by the flaunch of the wheels striking against the rails on curves, passing crossings, &c. The bushes which the axles run in are fitted into the frame in such a manner as to allow the springs to play vertically, but have flanches which prevent any tendency to lateral action beyond that necessary for the irregularities of the road, and they are of such a length as to enable them to hold up the engine in case of the breakage of one of the axles. It would appear that the breakage of the axles is a very rare occurrence, and that even when it has happened, the engines have performed the remainder of the journey and brought home the train with only a slight diminution of speed. The engines differ in weight according to the class they belong to. A passenger engine, with its coke and water in the fire-box and boiler, weighs 9 tons, 13 cwts. 1 qr.

	Tons.	cwts.	qrs.
The fore end	3	19	1
The after end	5	17	2

A merchandize engine, with coke and water, weighs 11 tons, 13 cwts. 1 qr.

	Tons.	cwts.	qrs.
The fore end	5	4	1
The after end	6	12	3

This form of engine was adopted by the author as early as the year 1829, when he constructed the "Liverpool," which was the original model engine with horizontal cylinders and cranked axles. It was set to work on the Liverpool and Manchester Railway in July, 1830. This form of engine has been invariably used on the London and Birmingham Railway since its opening.

The paper is accompanied by complete drawings of the engines, and tabular statements of their performances during the year 1839, showing the number of miles traversed by each engine, the weight conveyed, with the cost in detail of coke, oil, tools, wages, repairs, and general charges.

The performances of the engines extend over a distance of 700,000 miles, and a period of 12 months; and it appears that with the passenger engines,

For the first 6 months the average total cost of conveyance was . . . $\frac{352}{1000}$ of a penny per ton per mile.
For the second 6 months the average total cost was . . . . . $\frac{380}{1000}$ ditto.
While with the merchandize engines—
For the first 6 months the average total cost was . . . . . $\frac{203}{1000}$ ditto.
And for the second 6 months the average was . . . . . . $\frac{227}{1000}$ ditto.

"*Earth Falls at the Undercliff in the Isle of Wight.*" By William Rickman.

The remarkable tract of coast called the "Undercliff" extends from the south point of the Isle of Wight, nine miles to the eastward. Its surface is distorted in form, somewhat resembling in miniature the volcanic features of Southern Italy; for although the latter has been formed by the action of fire, and the former by that of water, both have been moulded when in a state of partial fluidity. The soil is of a boggy nature, is intersected with numerous springs, and in it are imbedded, in the utmost confusion, detached masses of the weather-worn cliff-rock, forming in places natural terraces on the face of the cliff, and inclining inwards at different angles towards the land.

A sectional view taken through the south point, bearing north to the summit of St. Catherine's Down, would present these features.

From the sea beach of iron sand, strewed with shingle and boulders, rises a cliff of 60 feet, and from it a rugged and irregular ascent of 320 feet in height, half a mile in extent, composed of vegetable soil, chalk, green sandstone in masses and fragments, and of blue marle, the whole mingled indiscriminately and irrigated by numerous springs. Thus much constitutes the Undercliff. Above it appears the perpendicular, serrated profile of the Upper Cliff, 260 feet in height, from which the surface of the Down proceeds with a slight descent for a quarter of a mile, and then gradually rises in the extent of half a mile to a vertical height of 200 feet, being the highest land in the island—780 feet above the level of the sea. The strata are nearly horizontal, with a slight dip to the north-east. They are the upper part of the secondary or supermedial order, and consist of chalk, chalk-stone, green sandstone, blue marl, and iron or red sand.

This stratification would account for the subsidences of the Cliff which have occurred so repeatedly. The water collected by the extensive surface of the Down would percolate through the chalk and sand-stone beds until it reached the impervious blue marle, where it would accumulate until it finally escaped by oozing out over the edge of the stratum, carrying with it portions of the sandy subsoil; in this state it has the appearance of a slimy grit, consisting of particles of the sand-stone lubricated with clay; it is familiarly called "the blue slipper." A continuation of this infiltration for any length of time must end by undermining certain portions of the face of the Cliff, which, being unsupported beneath, detach themselves from the main rock and settle; the first settlement may not exceed a few inches, but a fissure having been formed the whole length behind the subsidence, the surface water pours into it, and continuing to moisten and undermine it, at length causes the slip to assume its present aspect. This soakage of water at the back of the mass may be supposed to sap its foundation at the rear and to give it the dip inwards, which is observed in all cases, and most evidently in such as are farthest advanced in their descent. A number of natural terraces are thus formed, and the process may be traced in every stage of its progress at different parts of the Cliff, as at Mirables, in the Pelham Walks, at Ventnor, and at the Luccombe landslip. These subsidences appear to have succeeded each other at long intervals of time, but there is no record of any so extensive as that which occurred in 1799, at which time upwards of 100 acres were set in motion. That the principal landslips took place prior to the Norman Conquest is proved by the existence of Bonchurch and St. Lawrence Chapel, which are supposed to have been built soon after the manor was surveyed for entry in Doomsday Book.

The President observed, that although papers of this kind did not appear to be exactly adapted for the meetings of the Institution of Civil Engineers, yet, as geology was so intimately connected with engineering, and it was always essential to ascertain accurately the nature of the ground where works were to be executed, such communications became not only acceptable, but very valuable, to the profession.

Mr. Lowe had paid much attention to a similar formation at Hastings, and while he agreed to the general correctness of the observations, he did not think a sufficient reason had been assigned for such a mass of iron sand with its incumbent chalk being driven seaward. He would attribute the subsidences at the Undercliff to the action of water percolating through the fissures into the thin beds of clay interspersed with lignites, with which the iron sand abounded. This, when moistened, would ooze out and permit the chalk to crush it outwards, causing the subsidences so ably described by Mr. Rickman.

March 24, 1840.—The President in the Chair.

The following were balloted for and elected:—Charles Lanyon, as a Member; Henry Addams, Thomas Macdougal Smith, and Robert Richardson, as Graduates; Henry Heathorn and Ardaseer Cursetjee, as Associates.

"*On the manufacture of Flint Glass.*" By Apsley Pellatt, Assoc. Inst. C. E.

Flint glass, called by the French "cristal," from its resemblance to real crystal, is composed of silex (whence the English name), to which is added carbonate of potash and litharge, or red lead; to which latter material is owing, not only its great specific gravity, but its superior lustre, its ductility, and power of refraction.

It is necessary for optical purposes that flint glass should be perfectly free from striæ, otherwise the rays of light passing through it diverge and become distorted, and this defect is caused by the want of homogeneity in the melted mass, occasioned by the difficulty of perfectly fusing substances of such different density as the materials employed. The materials, being properly prepared, are thrown at intervals into a crucible of Stourbridge clay, which will hold about 1600 lbs. weight of glass when fused. The mouth of the crucible is then covered with a double stopper, but not luted, to permit the escape of the moisture remaining in the materials, as well as the carbonic acid gas and excess of oxygen. It requires from 50 to 60 hours application of a rapid, intense, and equal heat to effect the perfect fusion of the materials and to drive off the gas; during which time the unfused particles and excess of salts are skimmed off as they rise to the surface. The progress of fusion cannot be watched, nor can any mechanical means for blending the material during fusion be resorted to, lest the intensity of heat requisite for the production of a perfectly homogeneous glass should be diminished, the quality of the product being influenced by any inattention on the part of the fireman, as well as by the state of the atmosphere or of the wind. It has been ascertained, that there is a certain point or crisis of fusion at which the melted metal must be kept to insure a glass fit for optical purposes, and even when that point be attained, and the crucible shall furnish proper glass during several hours, should there be such diminution of heat as to require the furnace to be closed, the remainder of the metal in the crucible becomes curdy and full of striæ, and thus unfit for use. It is the same with the glass made for the flat bore tubes for thermometers, which are never annealed, because the smoke of the annealing furnace would render the interior of the bore unfit for the reception of the mercury. These tubes will only bear the heat of the blow-pipe when they are made from a metal which has been produced under all the favourable circumstances before described. It is, therefore, to be inferred, that the most homogeneous and perfect flint glass can only be produced by exposure to an intense and equable degree of heat, and that any excess or diminution of that heat is injurious to its quality.

The English method of manufacturing the flint *plate* for optical purposes is thus described. About 7 lb. weight of the metal is taken in a ladle of a conical shape from the pot at the proper point of fusion, and then blown into a hollow cylinder, cut open, and flattened into a sheet of glass of about 14 inches by 20, and varying in thickness from $\frac{3}{8}$ to $\frac{1}{4}$ of an inch. This plate is afterwards annealed, and in this state goes into the hands of the optician, who cuts and grinds it into the requisite form. When a glass furnace is about to be put out, whole pots of metal are sometimes suffered to remain in it, and cool gradually. The crucibles being destroyed, pieces of glass may be cloven from the mass of metal, softened by heat, and made to assume the requisite form, and then ground. It is believed that the excellent glasses made by Fraunhoffer, and other manufacturers on the continent, are produced by some such means. On attempting to cut glass ware, it is easily perceived if it be sufficiently annealed; if not, the ware is put into tepid water, which is heated, and kept at the boiling point during several hours; it is then suffered to become gradually cold. This method is more efficacious than re-annealing by the ordinary means. A piece of unannealed barometer tube of 40 inches in length being heated and quickly cooled, contracted only $\frac{1}{16}$ of an inch, whereas a similar piece, annealed by the usual means, contracted nearly $\frac{1}{8}$ of an inch. Unannealed flint glass, being heated and suddenly cooled in water, exhibits the appearance of a mass of crystals; it is thence inferred that the process of annealing renders the glass more compact and solid; it thus becomes incapable of polarization.

Flint glass being remarkably elastic, has caused it to be used for chronometers. To prove its elasticity, a hollow ball of unannealed glass of 3 inches diameter, weighing about 16 ounces, was dropped, when cold, from a height of 7 feet upon a stone floor; it rebounded uninjured about $3\frac{1}{2}$ feet, but broke on falling to the ground after the rebound. Similar balls, both at a bright and a low red heat, were dropped from the same height, and both broke immediately without any rebound; thus demonstrating that its elasticity only exists while cold. Glass being sometimes deteriorated in the process of reheating, not only in colour, but in its faculty of welding, by the sulphur existing in the coal or coke used in the furnace, this is prevented by occasionally throwing about a quart of cold water on the fire; the explosive vapour thus raised carries off the sulphureous gas.

The process of annealing has the remarkable property of carrying off from the glass the reddish tint imparted to it by manganese; and in large masses, not only the reddish tint disappears, but the glass sometimes becomes green or blue, probably by the action of the sulphureous acid gas from the coke. The reddish tint will however return, and the greenish one disappear, should the annealed glass be afterwards heated or remelted. Should the pot crack during fusion, and the flame or smoke come in contact with the melted metal, a green tint and abundance of dense striæ will be the consequence. Such an accident can only be repaired, if the crack be accessible, by throwing cold water on the exuding metal, which thus becomes gradually cooled, and itself forms a lute, so as to enable the process of melting to be continued. Long experience has shown that the best fuel for melting glass in the furnaces is oven-burnt coke mixed with a small quantity of screened coal.

Mr. Pellatt illustrated the preceding paper by specimens of glass exhibiting peculiar effects of crystallization; among them were cylindrical solid pieces of flint glass, which, from being suddenly cooled by plunging them into water, had the interior entirely dislocated, and were merely held together by the exterior coating; portions of tubes showing the same effect; a portion of a vase of white glass dipped into blue glass of a greater density—in cooling, the interior white glass appeared to be crushed by the contraction of the exterior coating; a similar vase of white and blue glass of more equal density had cooled, and bore cutting without cracking; a mass of optical glass, exhibiting striæ, specks, and imperfections; which, together with the modes of manufacture, he explained.

In answer to several questions, Mr. Pellatt was not aware of any attempt having been made to cut the bulb of Prince Rupert's drops: he believed the peculiar property of the bursting of these drops or tears, on the end being broken, arose from a crack suddenly commencing and extending itself rapidly throughout the mass, causing the dislocation of the particles. Flint glass is seldom sufficiently fluid to make these drops; they are generally made from glass which does not contain lead.

Alluding to the use of plate glass in Nasmyth's Pneumatic Mirror, he observed that, owing to the absence of lead, plate glass was purer and more homogeneous than flint glass, and the equality of thickness produced by grinding and polishing enabled the curve caused by the pressure of the atmosphere to be very regular.

The use of coke as a fuel, by the regularity of its combustion, assists materially in producing good results, and prevents the injury which frequently arises from a difference in the heating powers of various coals: unfortunately, the form of the furnaces causes the greatest heat to be in the centre, thus acting most powerfully upon the backs of the pots, instead of being equally distributed around them, which would be more desirable and would insure better results.

Mr. Pellatt still continued to use nine parts of coke mingled with one part of small coal in preference to any other fuel. He had abandoned the use of gas coke, and now purchased small coal at a low price, which he converted into a moderately-hard coke, rather less dense than that used for smelting iron. In the north of England, a charge of coal generally remained in the oven during 48 hours; in London, only 36 hours; he made lighter charges and coked them in 24 hours. He still found the calorific effect of 8 or 9 lb. of coke to be equal to that of 12 lb. of coal; in his ovens, 20 cwt. of coal produced 14 cwt. of coke.

Mr. Parkes inquired, which was the best method of annealing tubes for water gauges on boilers? He generally used those prepared by Mr. Adie, of Liverpool, who annealed them by placing them in cold water and gradually raising the temperature to the boiling point, at which it was kept for 24 hours; yet, in spite of these precautions, which generally were successful, he had seen twelve of these tubes break in one day, while an apparently ill-made tube had lasted six weeks. He found thin tubes last longer than thick ones. He was in the habit of removing the stains of bog water from his boiler gauges by scouring them with emery; when reheated, they invariably broke; after many experiments, he tried the use of acid, which answered perfectly, and no tubes were subsequently broken.

Mr. Pellatt recommended boiling as a safe and good mode of annealing all kinds of glass; in the ordinary method of annealing, thick and thin ware is often subjected to the same process, and remains in the leet for the same period: this would account for the superior duration of the thin tubes. He attributed the fracture of the tubes to the tension of the exterior coating and the vibration caused by the process of cleaning: this effect was so well known that old tube could scarcely be sold, as it generally broke in cleaning.

Mr. Hawkins observed, that tubes almost invariably broke in merely removing dust from the inside, whether it was done by rubbing with a tight packing or by slightly wiping it out. In some experiments on the production of carbonic acid gas, he used glass tubes of ⅜ of an inch internal diameter and ¼ of an inch thick: they bore a pressure of 100 atmospheres. Some wrought-iron tubes into which holes of ¼ of an inch diameter were drilled and pieces of glass inserted, bore a pressure of 600 atmospheres.

REVIEWS.

Papers on Iron and Steel, Practical and Experimental. By David Mushet. London: John Weale, 1840.

In the volume before us we have the result of Mr. Mushet's labours for the last 40 years and upwards, on the investigation of the properties of iron. Most of the papers have appeared in the Philosophical Magazine, the first as long ago as 1798, they are now collected together in one volume with additional notes and remarks, occasioned by the new discoveries since the period of their first publication.

It must be most gratifying to Mr. Mushet to reprint the precept at the commencement of the present volume, which was also the prelude of the first paper which appeared in public, and one which we are sure every scientific man will read with pleasure.

It is much to be wished, that men practically versed in the various manufactures of Britain would turn their attention to the best means of disseminating a knowledge of the principles and operations which have been determined by experience as the best to be followed in the large way, according to local and other circumstances. A candid and liberal communication of individual observation, by promoting the common interest, would tend ultimately to the benefit of each manufacturer, by the increased improvement and perfection of their various articles; for the real welfare of any particular branch depends less upon the superiority of one man's article over that of another, in the same line, than upon the general superiority of a national product over that of any other country—a pre-eminence that depends entirely on the aggregate mass of industry, ingenuity and intellect exerted in the one or the other.

What I recommend is the more necessary, as inaccurate and fallacious principles are often brought forward by men of science, even the best intentioned, from a want of that practical knowledge, which can only be acquired by a long and personal acquaintance with the processes carried on in the large way of manufacture. The mischiefs hence occasioned are incredible: it tends to separate the man of science and the manufacturer; it shackles the latter with increasing prejudice; makes him view the former with a suspicious eye; is the principal reason why science has been so long excluded from our manufactories; and why the accurate results of the laboratory have so long been despised by the practical artist, and been deemed undeserving of experiment on an extended scale. The artist and the man of science should mutually inform each other: principles will then, and not till then, acquire consistence and correctness, and their value will be established on the surest foundation.

The volume before us as we have stated is not a mere reprint or collection of the original papers, but contains in addition the results of Mr. Mushet's subsequent experience, thus forming a complete and uniform work. Although confined only to one branch, that of the manufacture of pig iron, and the description of the ores and fuel necessary for producing it, it gives in a volume of 952 pages a mass of information, which is invaluable to the manufacturer and the student. It is to be hoped, however, that should this volume meet with the success, which it cannot fail to attain, if it be rewarded according to its merits, that Mr. Mushet may be induced to give a second volume, as he intimates, on malleable iron and steel, and possibly a third volume on the subject of some of the other metals. We feel certain that Mr Mushet need not delay on this account, but that in full anticipation of a successful reception, he may go on confidently to render fresh services to the public, and add new honours to those he has already received. Mr. Mushet has done much himself, but he has done more in showing how much it is in the power of an individual, by his own exertions, to benefit his fellowmen, and increase the resources of his native land. To those who know Mr. Mushet no enumeration of his labours is necessary, but those who do not cannot do better than peruse the narrative given in the preface to the present work, from which we extract that portion relating to the grand discovery, by which he conferred such a boon on Scotland and the iron trade in general.

Notwithstanding these early reproaches, I have lived to see the nomenclature of my youth furnish a vocabulary of terms in the art of iron making which is used by many of the iron masters of the present day, with freedom and effect, in communicating with each other on the subject of their respective manufactures.

Prejudices seldom outlive the generation to which they belong, when opposed by a more rational system of explanation. In this respect, indeed, "Time," as my Lord Bacon says, "is the greatest of all innovators."

In a similar manner has Time operated in my favour, in respect to the Black-band iron-stone. The discovery of this was made in 1801, when I was engaged in erecting for myself and partners the Calder Iron Works. Great prejudice was excited against me by the iron masters and others of that day in presuming to class the *wild* coals of the country with iron-stones fit and proper for the blast-furnace. Yet that discovery has elevated Scotland to a considerable rank amongst the iron making nations of Europe—with resources still in store that may be considered inexhaustible.

But such are the consolatory effects of time, that the discoverer of 1801 is no longer considered the intrusive visionary of the laboratory, but the acknowledged benefactor of his country at large, and particularly of an extensive class of coal and mine proprietors and iron masters, who have derived, and are still deriving, great wealth from this important discovery; and who, in the spirit of grateful acknowledgment, have pronounced it worthy of a crown of gold, or a monumental record upon the spot where the discovery was first made.*

At an advanced period of life, such considerations are soothing and satisfactory. Many under similar circumstances have not, in their own life-time, had that measure of justice awarded to them by their country, to which they were equally entitled. I accept it, however, as a boon justly due to me, and as an equivalent in some degree for that laborious course of investigation which I had prescribed for myself, and which, in early life, was carried on under circumstances of personal exposure and inconvenience, which nothing but a frame of iron could have supported. They atone also, in part for that disappointment sustained in early life by the speculative habits of one partner, and the constitutional nervousness of another, which eventually occasioned my separation from the Calder Iron Works, and lost me the possession of extensive tracts of the Black-band iron-stone, which I had secured while the value of the discovery was appreciated only by myself.

How gratifying must it be to Mr. Mushet to look back and contemplate these labours of his pen, which have been received by the public with so much interest. We are unable now to enter into an examination of the very many papers which the work contains, but we can assure those of our readers who desire information on this important department of our national wealth and strength, that they will find it the most valuable work on that subject yet published, one which we are sure must find its way into every scientific library throughout the world. We shall not suffer Mr. Mushet's work to escape us without another notice.

* From the Airdrie estate last year, from Black-band iron-stone alone, Sir W. Alexander derived a clear income of £16,500.

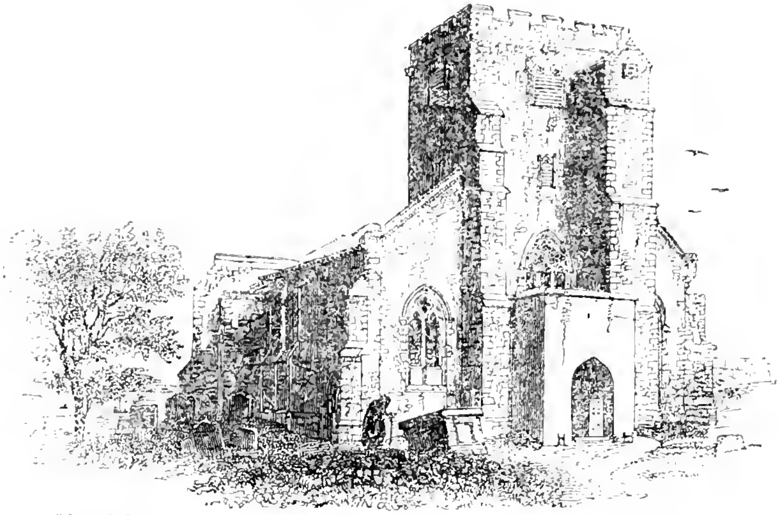
A Treatise on Engineering Field Work. By Peter Bruff, C. E. London: Simpkin, Marshall, & Co. 1840.

We noticed at some length, in the first volume of the Journal, the first edition of this work, which, we are happy to find, has arrived at a second edition with considerable additions. It contains a great deal of real practical information for the student, and even to the old practitioner it will be valuable, who will find many hints dispersed throughout the work well worth knowing. We perceive that the present volume is entirely confined to land surveying, and that the division on levelling will appear hereafter in a distinct volume. It is our intention to turn to this volume next month, when we shall give a few extracts; in the mean time, we have much pleasure in recommending the work to all those who wish to become acquainted with land surveying.

A Brief Survey of Physical and Fossil Geology. By Frederick John Francis. London: Hatchard, 1839.

This small work is a republication of two lectures delivered at Literary Institutions, and therefore well adapted for popular circulation. The object of such a performance almost places it out of the range of criticism, particularly, whereas in this instance, the work seems carefully compiled.

STONE CHURCH.



Illustrations of Stone Church, Kent, with an Historical Account. By Edward Cresy, F.S.A. Published for the Topographical Society, Trafalgar Square. London: H. Hooper, 1840.

That an active society formed of competent members, having for its object the making known those specimens of architectural, and sculptured antiquities, which from their remoteness from the capital, or other adventitious circumstances, are liable to be overlooked by the mass of observers, and thus exposed to neglect, was felt to be a great desideratum, no intelligent Englishman will deny; and to such a one it must be a subject of congratulation, that a task so replete with difficulties, and requiring so much sound knowledge, and varied talent on the part of those who engage in it, should have become the province of a topographical society, whose members possess the valuable acquirements displayed in their beautiful publication of "Stone Church."

Nothing that we can say can possibly enhance the merits of this charming volume; and in speaking of it in the highest terms of praise, we are guided by no other motive than that of indulging a feeling of gratitude, towards a society which shews such devotion, to a cause in which we, in common with all sincere lovers of art and their country, feel the deepest interest.

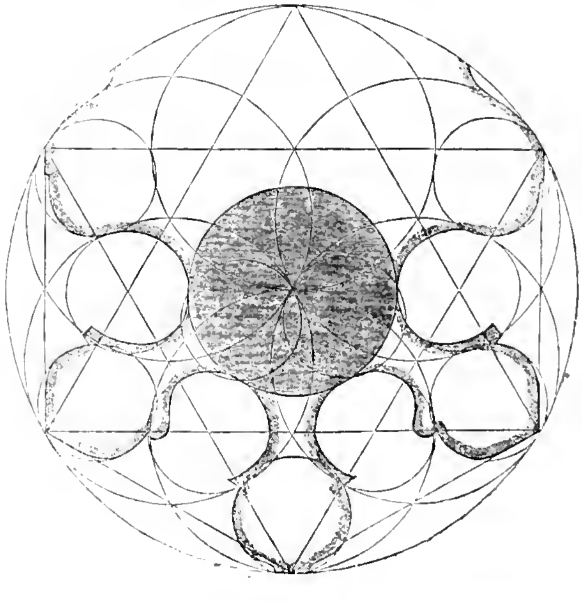
The creating among the masses an intelligent admiration of the monuments which adorn their country, has the happy effect of binding the former more and more to the land of their birth, and becomes a sure means of fostering and promoting that noble feeling, love of country; and we know of no subject more worthy of the civilized state in which we live, than that of rescuing from oblivion and decay, the numerous unpretending, but beautiful structures, left us by our ancestors, which, whilst they have thrown an irresistible charm over our country, have also given birth to that taste for the beautiful, in the exercise of which at various periods of her history, England has reaped so many unfading laurels.

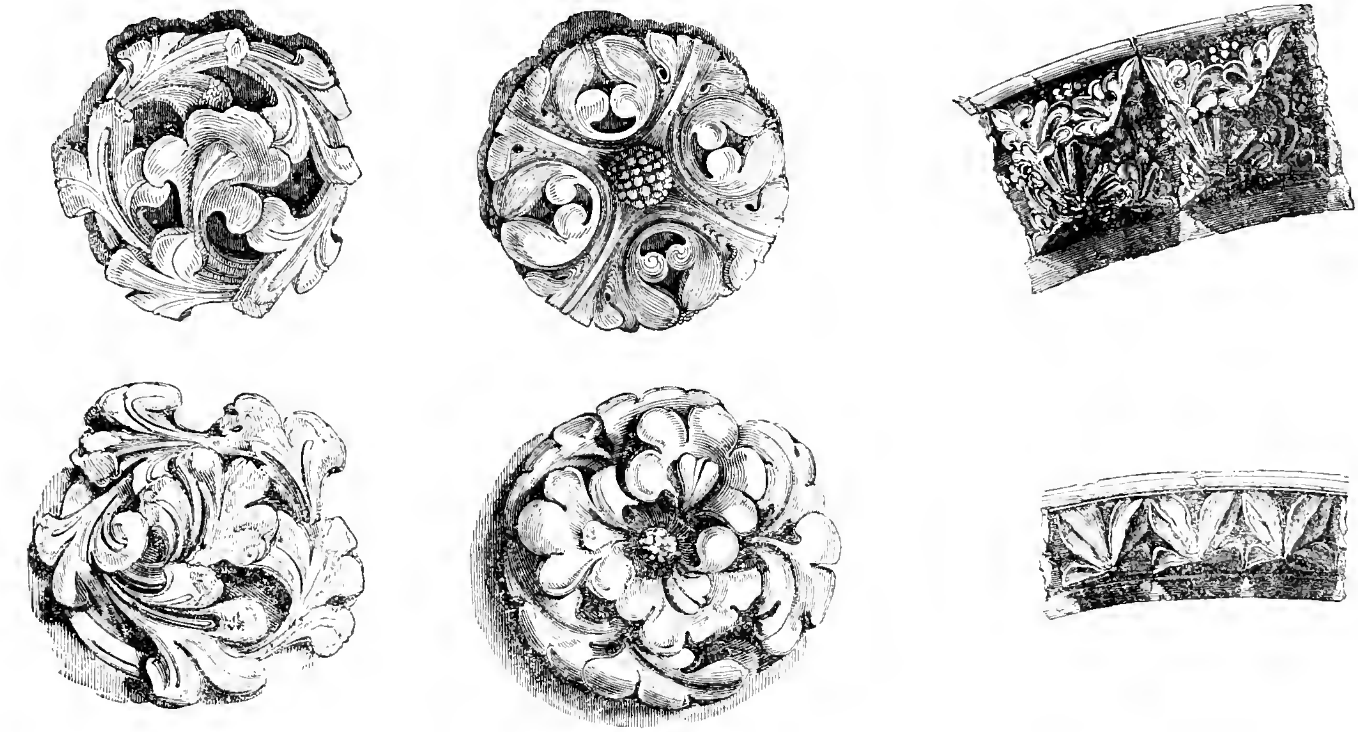
The means which it is clear the members of the topographical society possess of honourably compassing their laudable object, will we trust, insure them the willing co-operation of those who simpathising with the subject, are fortunate enough to have the power of exerting themselves usefully in a sphere yielding so much personal entertainment as well as benefit to the public, for be it remembered that the revival of that which is old and good, far from being of a merely retrospective character, has in it an active principle, that of kindling a generous emulation in the minds of the present generation, and that at no period of our history has this stimulus to mental exertion been more required than at the present, when throughout the country we find coupled with great zeal for building ecclesiastical edifices, a reckless indifference to taste, a fitness of character, degrading to our religion as well as to art.

In selecting Stone Church for publication, the society have chosen a subject well calculated to exercise the taste and antiquarian knowledge of its members. It is an elegant building, most carefully designed and executed in that pure style, which was the offspring of the 13th century, and associated with it are many interesting historical details, all of which is most clearly and scientifically set forth in the work before us; connoisseurs are unanimous in their opinion of the merits of this interesting structure, and recognise in it the standard of taste in the beautiful style in which it is designed, there being nothing to be found, not even in our cathedrals, to transcend the fine style, and masterly execution of the ornaments; this building offers a peculiarity in its system of internal decoration, viz., that of the ornaments gradually assuming a richer character as they are placed nearer the altar, this arrangement, whether the result of some fortuitous circumstance, or the original intention of the architect, is so pleasing, as to be quite worthy of imitation.

The following passage shows upon what severe principles these decorative accessories are composed, and we quote this passage the more willingly, because it advocates that important principle, the knowledge of geometry, which we believe to be the true foundation of excellence in architecture, and because it has long been our conviction, that a no more sure method could be adopted of upholding amongst us a fine taste in that sublime art, than that of an assiduous cultivation of the science of geometry, in schools destined for the education of architects; whose motto, over the threshold of their studios should ever be, "Nemo geometriæ expers, huc ingrediatur."

"Salisbury, Lincoln, Westminster, Winchester, and other buildings of this time, no longer exhibited the round arch or features borrowed by the Normans from Roman constructions, but a new style altogether, having principles essentially geometrical; and it is in vain that we attempt to imitate the tracery or mouldings belonging to this style correctly, unless we consider them to emanate from some simple figure. However numerous the mouldings, they never appear confused, which entirely arises from the order observed in their arrangement; this may be better expressed by the subjoined diagram, taken from the





BOSSES AND ENRICHMENTS FROM THE CHANCEL.

mouldings which form the trefoil arches round the chancel of Stone Church. The points of intersection of the two equilateral triangles are the centres for the hollows, and the more prominent parts of the moulding are set out with the same radius at the points of the triangles; or, in other words, four circles are encircled within a circle, and by omitting each alternate one the figure is formed. From the equilateral triangle are readily produced the hexagon and duodecagon; and the rose windows of the churches and cathedrals of France, many nearly fifty feet in diameter, and exhibiting a great varity of figures in their designs, are among the most beautiful examples which can be cited of the early and later application of the equilateral triangle to the figures of architecture. From the trefoil, sexfoil and their multiples, as shewn at St. Denis, proceeded the flowing tracery, simply produced by omission of portions of the regular geometrical figure, that which remained being so combined that the manner of its setting out was concealed, probably for the purpose of exciting wonder in the spectator, and thereby adding to that air of mystery which the craft delighted to spread around them. The system depending on the equilateral triangle for its variety of form continued in use till the beginning of 15th century in France, when it underwent a great and important change by the introduction of the isosceles triangle, and its compound the pentagon. A pupil of Alexander de Berneval, architect to the church of St. Ouon at Rouen, proved that these figures could furnish novelties in design, and that all beauty was not confined to the long used favourite triangle.

"To the common observer this theory may appear fanciful, but the writer does not hesitate to assert that the boldest mouldings, and the most delicate tracery, where gently flowing lines seem the result of a sportive fancy only, equally emanate from the same sources, and that it is to the neglect of the application of the rules of geometry that we may attribute the defects and failures wherever an imitation of this early style has been attempted in the present day, which neglect has been greatly fostered by the too prevailing opinion that all the beauty we admire is produced by art alone unaided by the science of geometry, the time devoted to line and rule being considered lost. The beautiful tracery, called by some *par excellence*, the decorated English, cannot accurately be displayed without a knowledge of these principles. Many examples have been tested to prove this fact."

In this building we also find an instance of the comprehensive view which our ancestors took of architecture, in common with other bygone nations excelling in that art, painting—not restricted to the stained glass window—entering largely into the composition.

The principle of combining painting with architecture appears to have been upheld at all periods signalized for devotion to the latter art, and that whatever be the styles which have arisen, their authors seem to have participated in the feeling that a building erected for some dignified purpose, however carefully designed and executed, might be its architectural features, would fail to fulfil its object, if it lacked the charm of color, considering the true province of architecture to be the medium of gracefully uniting the sister arts of painting and sculpture.

"Polychromy was introduced into our churches at a very early period, and became the general decoration where magnificence was aimed at, and the more costly substitute of mosaic could not be obtained. The Greek temples in the days of Pericles even had their pure white marble painted and gilt, and traces of it may still be found in the frieze of the admired Parthenon. The Egyptian as well as the Roman buildings at a very early as well as later period were all painted; and the practice seems only to have been lost in this country after the Reformation."

Until lately we believe there existed some doubt as to whether the authors of the Gothic style indulged in the art of polycromy, that they cultivated this fascinating art willingly, is however now certain—and were consequently not partial to that gloomy aspect which many of their buildings assume, when denuded of the brilliancy of their colours, introduced no doubt for the express purpose of counteracting that sombre effect incident from either the nature of the design itself or its inclosed situation. Thus the cloisters of Westminster Abbey now so repulsively gloomy, must have been most attractive when exhibiting, as they once did, all the pomp of colour. It is impossible to take leave of this subject without offering our sincere congratulations to the topographic society upon the success of their efforts, and expressing our conviction that all lovers of art will acknowledge their present volume of Stone Church to be a valuable contribution to the store of literature and art. The manner in which the work is executed deserves the highest commendation, the plates exhibiting great delicacy as well as vigour.

Specifications for Practical Architecture. By ALFRED BARTHOLOMEW, Architect. London: John Williams, 1840.

Mr. Bartholomew has produced a very valuable work, containing a vast accumulation of materials connected with the construction of buildings; he has condensed in a moderate size octavo volume a larger quantity of practical information than will be found in any other work of a similar description, we have besides 160 illustrations by wood cuts of the first character. Although we do not agree with the author in many of his remarks, particularly in some of his strictures on architecture and the use of cement, we are not disposed to find fault with him on that account, as the great variety of useful instruction which is conveyed by the many precepts, if we may be allowed to call them so, contained in this work, far outweigh the few faults we might be disposed to look into. Both professions, the architect and the engineer, will read this work with much interest, and the student by a careful study and perusal of it, will gain considerable *practical* knowledge. We have not time now to minutely examine the contents of the volume, as they are far too voluminous for us to attempt hastily, but we shall not fail, next month, examining largely, and extracting freely, from the pages of this text book, we shall, before we conclude this notice, state that we fully agree with Mr. Bartholomew in what he has said regarding specifications, particularly with the following:

Except for the mere *manner* of the work, the author can hardly think strong general clauses just; and he now never inserts them, unless he has previously included in the *particular description*, every thing which he believes the building can require: indeed he cannot think it borders upon honesty, to involve perhaps in bankruptcy, the builder, who like all labourers is worthy of his hire, by rendering him ignorantly liable to perform, to the detriment of his family and his creditors, and to the scandal of society, that work, of the nature of which, at the time of signing of the contract, the architect himself has not had a clear idea.

We have more than once, denounced the unjust sweeping clauses which are frequently inserted into specifications, particularly one, that the builder is to do all that is expressed or implied by the drawings and specifications, and also another, whereby the responsibility of the construction of the building is thrown on the builder, which is strictly belonging to the engineer or architect, by the introduction of such clauses, it allows any man to call himself an architect, for he is thus enabled to escape censure and cloak his ignorance of construction.

Architectural Remains of the Reigns of Elizabeth and James I.

As a series of historical documents, illustrating the architecture of the period referred to, and also as contributions towards topographical information, these drawings possess considerable interest, apart from the pictorial merit of several of them. Still, we must be allowed to question the propriety of taking examples of that period as models suitable for imitation, at the present day. To revert to a style of the art that was in itself merely an attempt towards one, it being superseded by another before it had time to develop itself, to get rid of its crudities, to become refined as well as matured, appears to us a rather backward, crab-like advance, and not very much less absurd than it would be for an adult to imitate the tottering steps of a child just learning to walk. There might be something like sense in going back to any *Renaissance* style for the purpose of taking it up where it had been abandoned, and applying to it those lessons in taste which we have—or ought, by this time, to have—acquired from what has since been produced or been studied. Could we, by some architectural chemistry, extract all the good qualities of the Elizabethan style, leaving all its dross and impurities behind;—could we transfer to modern designs its stateliness, its picturesque combinations and outlines, its freedom and spirit, without any of its barbarisms and deformities, without any of its uncouthness and extravagance, its puerile conceits and incongruities, without its inconsistent mixture of overdone finery in one part and poverty in another, could we accomplish this, or were we to attempt it, there would be some plausible pretext for taking the style so far into favour again. But to adopt it, as we find it to be when adopted at all, with all its vices, is surely somewhat preposterous. At present it is imitated without any discrimination; we either find it copied in all its rude and unmeaning, yet most expensive finery, or, if attempted to be simplified, reduced to naked deformity and insipid monotonousness, and deprived of all that tends to render it if extravagant, at least picturesque.

However, there is no occasion for our deprecating the imitation—the *literal imitation*, we mean, of Elizabethan architecture any further, because, we conceive, its day, as a fashion of the day, is nearly over. The recent application of it to shop fronts is likely to open people's eyes to its *vulgarity*, far sooner than all the objections of criticism. Besides which, it has lately received some tolerably staggering blows from criticism itself. Mr. Wightwick—and his book is likely enough to find its way into fashionable circles—speaks of Elizabethan as "beneath abhorring" as a style, though deserving notice as a link in the history of the art; which opinion will doubtless cause some of its fashionable admirers to stand quite aghast. Mr. Bartholomew, again, speaks of it without more respect or ceremony, denouncing it in good set terms as founded in ignorance and corruption. Nay, he goes so far as to say,

"Among the numerous" *(quære)* "architectural publications that issue from the press in these times with such rapidity, may be mentioned those which treat of buildings erected in England during the reigns of Queen Elizabeth and King James the First; but while these works, some of them so splendid in their embellishments, are so valuable as furnishing historical records, yet is it to be regretted that no works ever published ever had a more pernicious effect upon public taste; for some of those who view their embellishments feel a strange inclination to copy that in which their eye delights, although they know its corruption, in the same way as children look at dirt till they desire to handle it."

"It may be said," he afterwards observes, "to contain all the faults and corruptions of design and composition, which have ever been condemned in every style of architecture by every description of critics, of every age, and of every country in the world"!

This is a clincher! and if it does not put people out of conceit with Elizabethan architecture, and make them heartily ashamed of their fancy for it, we know not what will. Of course Bartholomew must look upon Mr. Richardson as a very great offender, one of those who have contributed to vitiate public taste by their splendid publications. To say the truth, some of the subjects contained in the part before us, are so seductive and captivating as pictures, as almost to disarm criticism;—little is it to be wondered at, therefore, if those are apt to be mislead, and have their fancy led captive by them, who either cannot or will not be at the pains to discriminate between the charm of pictorial treatment and effect, and what belongs merely to architectural design.

The view of the quadrangle at Kirby, the seat of Lord Chancellor Hatton, and now belonging to the Earl of Winchelsea, affords a striking instance to the purpose; since although a singular *mélange* as to style,—although the entrance tower and porch present a mere grotesque parody of Roman architecture, and although large fluted pilasters of the Ionic order appear in other parts between lofty and spacious windows and bays, whose openings are divided into a system of small panels, by numerous mullions and transoms,—the general effect is so imposing, picturesque, and even scenic, that we admire almost in spite of ourselves. Still we should not admire the less, were some of the mere extravagances expunged or abated. However this building—or at least a portion of it, for if not altogether so grotesque, the Garden Front is by no means so "*exciting*," is of superior quality to the generality of Elizabethan designs.

The Garden Porch at Coombe Abbey, opening upon a terrace with a rich open work parapet, is another picturesque bit, though a mere bit, of architecture; but it shows exceedingly well in the drawing, because it is given on a satisfactory scale, and the subject is confined to it. On the same plate is another drawing representing part of the Great Chamber and its fireplace, at Coombe; but although we are well satisfied with it as a picture, we have no admiration to bestow on the subject itself, for nothing can be more barbarous and uncouth, more perversely hideous in taste, than the whole of the chimney piece; however, there is very little danger of its being copied, at least not by any one who has not a terribly heavy purse, and is distressed how to lighten it.

Of that celebrated mansion Burghley House, we have here two views of the North and West Fronts, but we also desiderate a ground plan, and one, if not more elevations, notwithstanding that the character of the detail can be tolerably well made out in the perspective drawings, which show the building from a near point of view. In its general style this edifice is rather plain, and derives its air of magnificence and richness chiefly from its magnitude, and from the variety produced by its being broken into numerous parts, yet so as not to interfere too much with regularity, or with breadth of character. What decoration there is, is almost entirely confined to the summit of the structure, where the open parapets, turrets, domes and chimneys, make a "brave show." The chimney stacks, however, composed of two or more Doric columns, with a piece of entablature above them, are offensive conceits, and tend to suggest the idea of there having been originally some upper structure, of which they are the remaining fragments. Some of the parts of the parapets and their ornaments are shown at large in one of the Plates of Details, of which several are here given.

How far these latter will be found serviceable as practical studies, we pretend not to say, being inclined to suspect that the taste for the style itself, of which it may truly be affirmed that it is *vitiis imitabile*, will wear away as quickly as it arose.

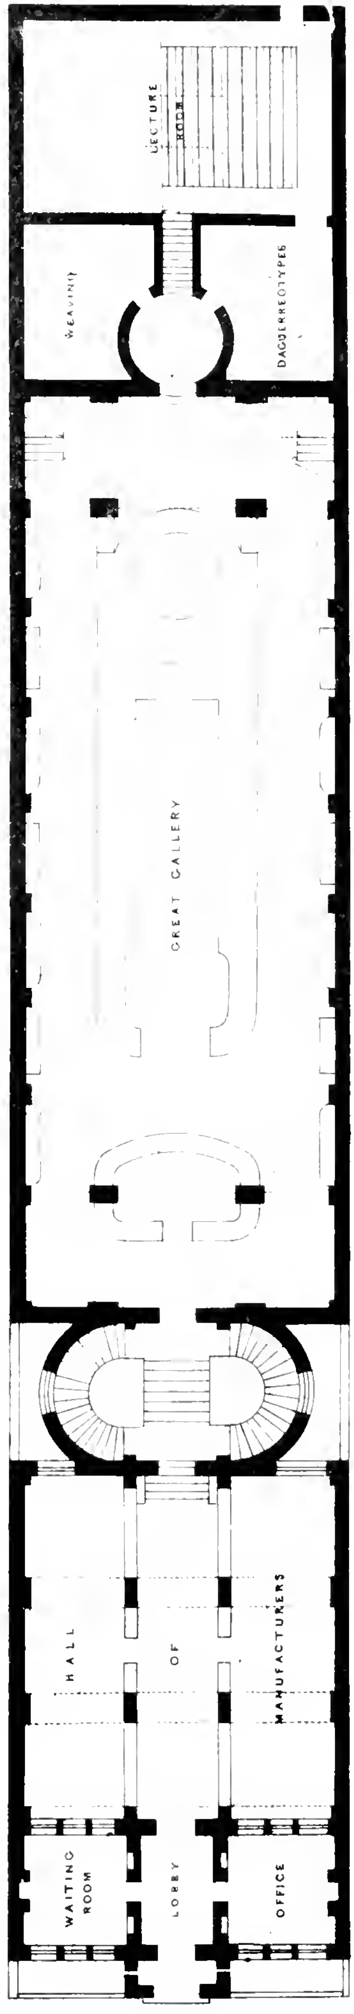
GROUND FLOOR PLAN



POLYTECHNIC INSTITUTION.

With an Engraving, Plate XV.

This institution was founded in 1838, and shortly after its opening we gave a brief description of it at page 318 of our first volume; we now present our readers with some farther details. The annexed engraving gives the elevation, transverse section, and ground plan of the building, and to these we refer our readers as a substitute for a lengthened description. What we anticipated at a former period has since been fully carried out, and this institution has become in its neighbourhood, like the Adelaide Gallery, of great utility in promoting the practical arts. If we have not like at Paris, an *Exposition des Arts et Metiers*, or Mechanics Exhibitions like our provincial towns or American cities, we have at any rate the advantage of them as regards permanent museums, by means of these institutions. The mechanical collections of Paris are now far from equalling those of London, and it wants but very little exertion to give us a decided superiority. We may observe, by the bye, on this subject, that it is much to be regretted that the museum of the Society of Arts is not made more available. We may remind our readers that these exhibitions emanated from the attempt to form a national exhibition of arts and manufactures in the King's Mews.

The design of the building does credit to Mr. Thomson, the architect, for having so skilfully adapted it to the purpose to which it is devoted, the lighting of the great hall is provided for in the coved ceiling or roof, a gallery passes all round the great hall, supported on each side by cantilevers, as shown in the section; on the ground line there is a canal formed for the exhibition of hydraulic works, steam boats, water wheels, &c., and at the end is a circular reservoir for exhibiting the diving bell, and working under water in the diving dress; at the east end is the entrance hall from Regent-street, above is a theatre for lectures, &c., and below a laboratory and other rooms for experiments. The west end of the great hall or saloon communicates with premises in Cavendish-square. The total depth of the premises is 320 feet, and 44 feet wide, and the great gallery 120 feet long, 40 feet wide, and 38 feet high in the centre.

HARBOURS OF REFUGE ON THE SOUTH EASTERN COAST.

In our last month's Journal we gave a few extracts from the Commissioners Report, pointing out some discrepancies, upon which we intended to have made remarks, but upon mature consideration we think it better, instead of contending with details, or occupying ourselves with the misconception of the Commissioners, to look at the question in a broader kind of view and on national grounds, that we may see how far the Government will be justified in recommending Parliament to grant so large a sum of money as is required for carrying out the harbours proposed. In the first place, it is generally admitted that England has not on her south eastern shores any harbours of sufficient magnitude or depth of water to receive a fleet of men-of-war, or even for our largest class steamers, and the absolute necessity of having such harbours is also admitted. It therefore only remains to examine whether the localities selected are the best, and whether there is any necessity for erecting them on the magnificent scale proposed in the report before us. With regard to the latter question, we have only to look at the artificial harbours which have been executed, and we shall generally find that they have been constructed on too small a scale, to render them of any service for shipping, such as men-of-war of the largest class, and in consequence of their contracted scale they soon silt up and bars are formed at their entrances, rendering them almost useless except to merchantmen of small tonnage. With regard to the necessity for harbours of refuge in time of war, there cannot be a doubt; it is therefore highly expedient that harbours should be constructed of sufficient capacity for a fleet of men-of-war, either to sail or be towed in or out at all times of the tide, an hour lost may be the cause of irreparable damage to our coast, a descent on our shores, or the escape of the enemies fleet, and on this account we should be prepared to recommend the construction of harbours on the boldest scale that our finances will allow, for we would rather have one on an extensive scale than we would have half a dozen of the small fry, of these descriptions of harbours we have had enough, and if they are wanted, the local authorities ought to be able to raise funds sufficient without Government aid. We have always been averse to the interference of Government for what may be justly considered private purposes.

We shall now look to the situations selected by the Commissioners, and the first to which our especial attention is required is the harbour of Dover. Here all parties must admit it is a situation that requires to be well provided and well watched; and moreover the passage of the Straits must be made our own, it must be kept at all hazards and at all costs. To allow an enemy's fleet to remain there for a day would be madness, and the only way to avoid it, is to have a good harbour, where in case of need, the largest class steamers may be able to take shelter, for which no situation is so well adapted as Dover.

The next site selected is Beachy Head, where it will be found that there is already a good anchorage, with a situation well adapted for a breakwater similar to that of Plymouth. This would afford shelter for large class vessels between Dover or the Downs and Portsmouth, at present a long line of coast without the slightest refuge for a man-of-war, and consequently without protection for the small merchantmen. The next and last situation is that of Forness, near Margate, which affords protection to the mouth of the Thames, this requires a harbour of spacious dimensions, in which vessels riding in the Downs may take shelter if required. If we view the coast from Margate to Portsmouth, there cannot, on the whole, be found more eligible sites for harbours than those selected, keeping in mind the grand object, that they must be harbours of refuge, not for merchantmen alone, but for the Queen's service also, where vessels carrying 100 or 120 guns may take shelter at all times of the tide, and the steam frigate like the Gorgon and the Cyclops may run in and out with facility, and be ready for action at a moment's notice.

We are therefore under all the circumstances disposed to support, most strongly, the recommendation of the Commissioners, and trust that Parliament when called upon for a grant, will look at the question boldly, and judge whether it be not better to grant four or five millions in the time of peace, rather than wait until war takes place, when shipping to more than that amount may be destroyed in one year.

REMARKS ON MR. TOMSON'S PAPER ON THE WORKS OF SIR JOHN VANBURGH.

The animated and lively discussion at the Institute on Monday evening, manifested in a very pleasing way, that the little citadel of taste is becoming more and more the object of zealous and vigilant scrutiny. The beautiful pourtrayal by Mr. Thomson of Sir John Vanburgh's style, (the subject of Monday evening's attention) though it requires no record of approval from a person like myself, to give it one feature of additional interest, prevents the *silence* of one insensibly attracted by any commentary upon by-gone talent, or the merits of originality. Sir John Vanburgh, recognised as a pupil of Wren, and included in the school of Palladio, seems to display, I humbly imagine, too little of ornamental sweep and the flowings of elegance, too exact a distribution of the several parts, too cool a display of effect, to rank as a disciple of Palladio, or a pupil of Wren; and yet, at the same time, too much of extended variety in bodily proportion, to present a true idea of Grecian sentiment.

Exuberance with him is never beheld in the drooping festoon or the careless sweep of foliated bands. The curves and bendings of elegant contour, deck not the façade, but the care of distribution figures in a thousand lines, in a prim exactness, in a minute attention to the rules of his art. For this he seems to stand isolated from his school, and like Soane, betrays the fretwork of a self-constituted style, connecting and harmonizing the fashion of two rival styles, the Greek and the Roman. More extended—more daring in his ideas than Soane, he seems, like him, to have studied general minuteness. But it is the proportion, the loftiness, and the general effect of magnitude, which infuses in the mind, grand impressions, whilst contemplating Blenheim. It is to this ability in outline, this arrangement of a mass, which creates the desired effect; though the rules of his style appear as licences to an admirer of the Greek or the Roman. With all the blemish of incorrect detail, (if, as to general effect, it be a blemish), Vanburgh had the feelings of an artist, and felt that poetry of sentiment, which shines in his works; though unimbued with the delicate finish of Chambers and a later day.

To comment further upon (in some respects) this Soane of the last century, would be inconsiderate; yet it is a gratification to see the merits of past days recalled—and to pluck from the thousand beds of taste some of those beauties, identified with faded talent and forgotten genius; to see a mind original and rare regaining its buried influence, and asserting it with a liberal and enlightened community of architects.

The deduction in favour of the subject, the natural effect of Vanburgh's style, is this, that the head of the student, and the heart of the poet—the enquiring mind, and the soul to admire its own researches, must unite in the same man, if that man is to be an architect. A mere knowledge in the existence of this style, or that, or that it flourished in this age, or that, cannot improve the architect, though it may the mind; and unless we can raise ourselves above that pedantry of ignorance, which covets every thing antique, be it dust or marble, we can never rival, nor even faintly imitate, the lovely relics of antiquity.

It is not enough that the column or the pedestal should be brother to some Greek or Roman model, since it is not every one whose brain can swim with the pleasures of a connoisseur. A stranger to Athens or Rome would perhaps turn from the external polish of a modern edifice, however skilfully arranged, and become lost in the strange grandeur of Blenheim.

Frederick East.

TRUSSED BEAMS.

Sir—In reference to the method of trussing beams, communicated in the 32nd number of your Journal, and said to be invented by Herr Laves of Hanover, I beg to observe that the principle is by no means new to this country. In the practice of Mr. John Brown of Norwich, I have long had occasion to describe, in specifications, precisely the same method for many purposes, but chiefly for the purlins of roofs, where the transverse trusses have, unavoidably, been at a great distance apart. In order to show you, indeed, how little the method we pursue differs from that of Mr. Laves, I will extract from a specification I have at hand the following:—"All lengths of purlins which may exceed 9 feet between the bearings, to be sawn, lengthwise, through the middle of the depth, and trussed as shown by the accompanying sketch* with a wrought iron collar at each end, and a ⅝ screw bolt with broad clasp irons in the centre.

I remain,
Your obedient servant,
William B. Colling.

Norwich,
June 6th, 1840

LOCOMOTIVE ALARUM.

Sir—Various suggestions have lately appeared in the public prints, relative to the best means of communicating an alarum to the engine-man in case of fire or other accident in a railway train.—I would suggest a steam-whistle, which should differ decidedly in sound from those used by the engine-men.—A light chain attached to the cock of the whistle would enable each guard, and (if thought desirable) the passengers in each carriage to give an alarm in case of an accident occurring, or being likely to occur.

The advantage which such an alarum would possess over any other, is, that not only the engine-man, but all the guards and attendants would be immediately on the *qui vive*, and prepared to act as circumstances might require. The disadvantage is, that passengers hearing the alarum, might lose their presence of mind, and endanger themselves by attempting to escape from the carriages, instead of doing the only thing, which can tend to ensure their safety, viz., firmly keeping their sittings.

I am, Sir, your obedient servant,
Robert Sheppard.

Horsham, Sussex, Aug. 19, 1840.

ON SCREW PILE LIGHTHOUSES.

Sir—A correspondent in your excellent Journal for July, under the signature of "One of the Old School," endeavours to institute a comparison between the patent screw pile, and the common driving pile, the latter of which it is evident enjoys his exclusive favour, on the very rational grounds of its antiquity.

In summing up its superior merits his readers might reasonably expect to have their attention directed to many lighthouses, and other buildings supported by his favourite pile, and placed upon banks of loose sand covered by the ocean.

That he has failed to do so, is for the simple reason that no such structure ever did or ever can exist.

The experiment has indeed been frequently made of driving piles in such positions, and it has happened that owing to the buoyancy of the wood and mobility, and want of tenacity in the sand, they have invariably been found extracted by, and floating on the surface of the succeeding tide.

If then the old pile or pointed stake, which has been in use for at least 20 centuries, has been always found incapable of forming a sound foundation in such positions, how can it reasonably be put in comparison with the screw pile, which within four years of its being made public, has been successfully applied in submarine sandbanks of the most infirm description, and has moreover received the unqualified approbation of the first engineers of the present day.

Of these I might furnish an ample list, but feel the impropriety of giving names of the highest respectability to be handed about in idle discussion with your nameless correspondent.

I may however mention that a screw pile lighthouse, on a sandbank off the mouth of the Thames, is at present in progress of erection, under the auspices of a gentleman who deservedly stands at the head of his profession. And, that another upon a sandbank thirty miles north of Liverpool, was erected during the past winter, at the earnest recommendation of a gentleman well known as an experienced and highly talented marine surveyor, who has no antiquated prejudices standing in the way of recent improvements. And I boldly assert, without fear of contradiction, from any *practical engineer of experience*, that, to construct such a lighthouse on either site upon common piles, would be totally impossible.

As the other objections raised by your correspondent to the screw pile lighthouse, are only supported by his marvelous gift of prophecy, I shall content myself with requesting him to visit the one at foot of Wyre, where he will have proof positive of the fallacy of his conclusions, and when there, if he will drive a common pile into the sand, so as to resist a downward pressure or upward strain, equal to that which the screw pile will bear, I shall at once relinquish the latter as a useless expense.

I am, Sir, your obliged and humble servant,
Alexander Mitchell.

Belfast, August 18, 1840.

THE SAFETY ROTATION RAILWAY.

(*A New Method of Construction in Railways, and in applying Power to propel Carriages thereon. Patented by Mr. Rangely. March*, 1840.)

FROM A CORRESPONDENT.

This invention, of which, in our present number, we can give but a brief description, aims at effecting a complete revolution in the present mode of railway construction and locomotion. In place of having the ordinary rails and wheeled carriages, two series of wheels are fixed along the whole length of the road at about two yards apart, and at an equal distance from centre to centre of each wheel. These wheels are connected throughout the whole length of the line by bands working in grooved pullies keyed on to the same axle as the wheels, but the axles of one side of the line are not connected with those of the opposite line. The axles of the wheels are raised about one foot from the ground, the top of the wheel (which is proposed to be of 3 feet diameter,) will be therefore elevated 2½ feet above the surface. On these wheels is placed a strong framing of timber, having an iron plate fastened on each side in the line of the two series of wheels. A little within this bearing frame, so as just to clear the wheels, is a luggage-box or hold, descending to within a few inches of the ground, in which it is proposed to stow all heavy commodities, for which purpose it is well adapted, opening as it does at either end, and its flooring close to the surface of the ground. At each end of the lower part of the framing of this luggage-box, are fixed horizontal guide or friction wheels working against the supports of the bearing wheels and pullies, by which arrangement curves will be traversed with little friction, and it will be impossible for the framing to quit the track. The framing of timber will be about 19 feet in length, so that it will rest alternately on six and eight wheels, but never on less than six. On this framing the passenger carriages are erected, which, in its progression forward, it is thought will be kept steady and free from lateral motion by the weight in the luggage box, assisted by the horizontal guide wheels. The method by which locomotion is produced, is by putting the wheels in motion by means of machinery at either end, which would be effected for an immense distance with a moderate power, as there would be very little more friction due to the wheels than that arising from their own weight; and the frame, bearing the carriage, would not be run on to the bearing wheels until the whole were in motion, when its weight would act almost after the manner of a fly wheel, resting, as it would, on the periphery of the bearing wheels. It will be perceived that, by this plan, the bearings of the wheels must be kept perfectly in the direction of the plane of the road, whether inclined or horizontal; otherwise serious concussions would occur. But this would not be the case by the depression of one wheel, or even by its entire removal, as the framing will be constructed sufficiently stiff as not to deflect by having the distance of the bearings doubled.

If this plan should be found to answer, it will present facilities of transport never before thought of, as carriages might be continually despatched without a chance of collision, either by stoppage or from increased speed of the last beyond the preceding. It also promises to remove the present great drawback to railway progression, viz. the being able to surmount but very slight acclivities by locomotive power with any profitable load; but by the rotative system, inclines may be surmounted of almost any steepness without the chance of accident. In case a band should break, the action of this railway would not be impeded, as the power being transmitted from either end, rotation would take place throughout its whole length, but the

* We have not given the sketch, as it is very similar in principle to those shown in page 161, excepting that in the above, at the end of the slit, there is a key of oak with an iron strap passing round the outside, and in the centre there is a block of oak with a nut and screw bolt passing through it and the top and bottom scantlings.—Ed. C. E. & A. Jour.

power would not be transmitted from either end past the disjunction. Even should two bands be destroyed at a distance from each other and on the same side of the track, its action would not be destroyed, for although the isolated portion of wheels would be dead, those on the other side of the track would be in action, which, with the horizontal guide wheels, would move forward the carriage, although, on such portion, at a diminished speed. Instead of an increased outlay being required in the formation of railways, on this system it is estimated that a very considerable saving will be effected, as a single track will be sufficient, with sidings of dead wheels at the termination of the several portions into which a long line would be divided. In crossing valleys, a framing of piles to support the bearing wheels would be quite sufficient, and the road might be left quite open between each line of wheels, as it would be impossible for the carriage to quit the track, and therefore no necessity for making a solid road for safety sake. As this system is so novel and *revolutionary* in its mode of action, it will of course meet with numerous opponents who are interested in the present state of things; such as are not wedded thereto, or can admit the possibility of a total change in the system, we would advise to pay a visit to the Polytechnic Institution in Regent Street, where working models of this invention may be inspected.

THE ELECTRIC TELEGRAPH.

From the fifth Report of the Select Committee on Railways.

As everything connected with the operations of a power the development of which is calculated in its progress to effect very great changes in our social, commercial, and perhaps political condition, must be viewed with no inconsiderable interest, we propose to give, from time to time, condensed but complete abstracts of such portions of the report as we think best calculated to arrest public attention.

The first evidence taken before the committee relative to the magnetic telegraph, for which a patent has been taken out by Messrs. Cooke and Wheatstone, and which is now in operation between West Drayton and Paddington, on the Great Western line of railroad. As it would be impossible without a representation of the dial and apparatus, to impart a distinct notion of the manner in which intelligence is conveyed from one station to another, suffice it to say that the communication is effected by metallic wires made to operate upon fine magnetic needles which point to 20 letters of the alphabet marked upon the dial, being acted upon by electrical currents passing through coils of wire placed immediately behind them.

According to the information contained in the evidence of Mr. C. Wheatstone, professor of experimental philosophy in King's College, there is no necessary connexion between this species of communication and railroads. On the contrary, it can be established on a common road, or even where no road exists, though a railroad, in consequence of the continuity of property which it possesses, is best adapted for the experiment. In answer to a question, "whether (in the event of the Great Western Railway being finished from London) the telegraph could be carried through the whole way?" Mr. Wheatstone replied, that he believed it could be done, and with but little multiplication of power, inasmuch as late experiments had shown, contrary to former opinions, that to send an electric current to any considerable extent, there was no need of a strong battery, a weak one in fact being quite sufficient, provided it consisted of a number of elements proportionate to the distance. The communication between London and Bristol might require some intermediate stations at very considerable distances, though his own opinion was that they would not be required. From experiments which he made some years since, he ascertained that electricity travelled through a copper wire at the rate of about 200,000 miles in a second, being 8,000 miles quicker than the rate at which light passes during the same period.

Mr. Wheatstone states the advantages which the electric possesses over the ordinary telegraph as follows:—"It will work day and night, but the ordinary telegraph will act only during the day. It will also work in all states of the weather, whilst the ordinary telegraph can be worked only in fine weather. There are a great many days in the year during which no communications can be given by the ordinary telegraph, and besides, a great many communications are stopped before they can be finished, on account of changes in the state of the atmosphere; no inconveniences of this kind would attend the electrical telegraph. Another advantage is, that the expense of the several stations is by no means comparable to that of the ordinary telegraph; no look-out men are required, and the apparatus may be worked in any room where there are persons to attend to it. There is another advantage which the electric possesses over the ordinary telegraph, viz., the rapidity with which the signals may be made to follow each other. 30 signals may be made in a minute, a number which could not be made by the ordinary telegraph. There is one thing I will take the opportunity to mention. I have been confining the attention of the committee to the telegraph now working on the Great Western Railroad, but having lately occupied myself in carrying into effect numerous improvements which have suggested themselves to me, I have, conjointly with Mr. Cooke, who has turned his attention greatly to the same subject, obtained a new patent for a telegraphic arrangement, which I think will present very great advantages over that which at present exists. It can be applied without entailing any additional expense of consequence to the line now laid down, it being only necessary to substitute the new for the former instruments. This new apparatus requires only a single pair of wires to effect all which the present one does with five, so that three independent telegraphs may be immediately placed on the line of the Great Western. It presents in the same place all the letters of the alphabet, according to any order of succession, and the apparatus is so extremely simple, that any person, without any previous acquaintance with it, can send a communication, and read the answer."

According to the evidence of Mr. Alexander Saunders, secretary to the Great Western Railroad Company, the expense of laying down the iron tubes through which the magnetic wires pass, and completing the telegraphic line, was from 250*l.* to 300*l.* per mile. To a question as to whether all the advantages which were expected had been derived from the magnetic telegraph, this gentleman replied, "I think we have scarcely had it in a state to say that we have derived all the advantages which were contemplated from it, because between West Drayton and Paddington we have very little inducement to work the telegraph separately for that part; it had much more reference to the more distant stations, and the communications of one line with others, or to communications between places on the line where short and long trains together are running upon the same portion of railroad. As yet we have had no practical benefit of that description, but it has enabled us to ascertain that the telegraph perfectly performs all the duty that was expected of it. As far as it goes it works perfectly true, and if it work as well when the whole line is completed, I fully anticipate all the useful results contemplated from it."

Used with a view to commercial purposes, Mr. Saunders admitted that the sole possession of the magnetic telegraph would give the Great Western company a great advantage over the rest of the public, who could not, and as he conceived ought not to have any remedy, inasmuch as the company were the sole proprietors of the land, and would be at the entire expense of laying down the line of telegraph. If the Government chose to have a line of telegraph along the Great Western Railroad, he did not see any objection, provided the company were adequately paid for the use of their land, and that the line should be used for Government purposes only. A restriction of the use of the telegraph by the company solely to matters relating to the railway, and prohibiting the transmission of other intelligence, would prevent the company from laying down the line. He also thought it would be a great hardship if an expenditure had been incurred by any company in laying down a line under the expectation that they were to derive a benefit from it, whether in transmitting railway or general information, that they should be compelled to permit another company to lay down another telegraph on their line.

Mr. Wheatstone, observing upon the expense, said the cost of the present experiment has exceeded 250*l.* per mile. We will assume that it cannot safely be reduced, though I think with more experience that it might be. If we consider that the cost of laying down the whole telegraphic line from London to Bristol will be only the cost of one mile of the railroad itself, the expenditure will not appear great, considering the benefits to be obtained; this is less than one per cent. on the original estimate of the expenditure. Now with respect to the proposed Government line. The principal expense of laying down the telegraph line is, in fact, the iron tube, and the other things connected with it. The mere cost of the wires is very little, not more than 6*l.* or 7*l.* per mile each; as many wires as you please may be put in the same tube, consequently, supposing an iron tube to be laid down hence to Portsmouth, if wires for three distinct lines were enclosed within it, the expense of each line, considered separately, would be very considerably diminished. One line might be appropriated for the railroad purposes alone, another for general commercial intercourse, and a third for the exclusive use of Government. There would be no difficulty if the Government have a telegraphic line thus associated with others to make the terminations in their own offices,—from the Admiralty in London, for instance, to any office belonging to the same department at Portsmouth, so that information might be sent without communicating with any person but their own clerks. If this plan was adopted, it would do away with every objection which has been made with regard to the injury a private company would do the public by having the conclusive means of intelligence in their own hands, and I am sure any railway company would enter willingly into an arrangement by which the Government might possess an exclusive line, at a very moderate expense—much below that at which they could lay it down themselves. If the new telegraph of which I have spoken succeeds—and it has succeeded perfectly so far as experiments have yet been tried—we might place three telegraphs in connexion with the six wires now used on the Great Western Railway; and these might be applied, as I have said before, to three specific purposes—one exclusively for railway purposes; another, to be let to any persons who choose to avail themselves of it; and another for Government objects."

In answer to some questions, Mr. Wheatstone said, that if Government feared that any third person might, by means of portable instruments, become acquainted with their messages, they should communicate in cypher, of which an extremely safe and simple mode had been devised, enabling a person to communicate with a thousand correspondents so as that it would be impossible for any one of them to read what was intended for another. With respect to the time the apparatus would continue without requiring renewal, he could not say. It depended upon the tubes being kept water-tight, as the wires in that case would remain uninjured for an indefinite period. The wear and tear of the telegraph apparatus from London to Bristol would be far less expense than the wear and tear of the railroad for one mile.

There is one suggestion with respect to the use of the telegraph for railroad purposes which should not be overlooked, being of the greatest importance, inasmuch as all danger from collision would be obviated, and more prompt assistance rendered in case of accident. Mr. Wheatstone's proposal is to have posts through which the magnetic wires can be carried up, and with an apparatus on the top placed at every quarter of a mile along the line. By this means the guard having with him a portable instrument, might communicate a message in either direction of the line at pleasure.

IMPORTANT DISCOVERY IN METALLURGY.

At a recent sitting of the *Academie des Sciences*, M. Becquerel read a paper relating to a most important discovery, namely, the application of the electro-chemical power to the art of metallurgy, especially as regards gold, silver, copper, and lead.

After a few preliminary remarks, explaining the various services which this force can render to natural sciences, to arts and manufactures, the learned academician alluded in particular to the refining of the precious metals; and it will be seen in the course of this analysis the great advantage he has derived from the new methods introduced by him into different branches of industry.

It will also be gratifying to learn, that one of the poorest departments of France possesses a gold, silver, and lead mine, and that the happy results already obtained hold out a still more flattering prospect. The following is an analysis of the memoir presented by M. Becquerel:—

The experiments relative to the application of the electro-chemical power to refining *(metallurgie)* of silver, copper, and lead, without the aid of quicksilver, and with little or no fuel, have been continued by M. Becquerel with constant success: his operations were conducted upon a large scale, and embraced considerable quantities of ores derived from Europe, Asia, and America. The object of these researches was in the first place the immediate separation *(reduction)* of the metals one from the other, and especially of silver and of lead from galena; this operation was effected with so much rapidity, that at the preparatory foundry in Paris four pounds weight of silver can now be drawn off in the metalled state from silver ore in the space of six hours; secondly, the preparation which the ore is to undergo, so as to render each metal capable of being withdrawn by the electric current. This preparation varies according to the nature of the ore, presents no obstacle when the silver is in the metallic state, or in the nature of a sulphate, as usually occurs in Mexico and Peru, but it becomes more complicated when the silver is mixed with other substances; the use of a small quantity of combustible matter is then indispensable in order to effect the roasting at a low temperature.

Ores are generally found in great quantities in those countries, but are for the most part abandoned, owing to the want of sufficient fuel for effecting their amalgamation, or to their being found at too great a distance from the sea to transport them to Europe, unless at an enormous expense.

In Columbia, where large masses of gold and silver ore are found mixed with zinc, the richest are sometimes exported to Europe to be fused, whilst the poorest and those of a medium quality are either rejected altogether, or used to so little advantage, that the mining companies lose by them. Exertions are now in progress for introducing the new methods, which are equally applicable to amalgamation and to the electro-chemical process.

The silver ores which are most difficult of amalgamation are those which contain a large portion of copper and arsenic. Ores of this description are found in considerable quantity, especially in Chili, where the inhabitants frequently offer them to Europeans, by whom they are sometimes taken for ballast for want of freight, and without any certainty of turning them to advantage.

The great difficulty was to be able to treat these substances in Europe so as to obtain, in separate portions, and at little expense, all the silver, copper, and arsenic they contained. This problem has just been solved in a satisfactory manner, and so as to ensure immense advantages to new speculators, who will no longer have to contend with the obstacles met with by their predecessors.

On inquiring into the causes of the delay experienced in working the mines in America, it will be seen that the principal ones arise from the high price of quicksilver, and the great difficulty of draining the water by which the mines are inundated. This is not the case in Asia, in the Russian possessions, which are rich in mineral productions, and yield larger profits from day to day in consequence of the introduction of the improvements lately adopted in Europe for reducing metallic ores. In the silver mines of Altaie the expenses for extracting the ore, process of reduction, and of the establishment, do not amount to a quarter of the rough produce, although the ore in general is of slight tenacity. These advantages are owing to the modern price of labour, the abundant supply of combustible matter and substances required in the fusing, and which are not to be had in America, especially in Mexico and the Cordilleras.

The electro-chemical process can be easily applied to the ores at Altaie; however, in countries where sufficient fuel is at hand, and salt cannot be procured, the fusing operation will be always preferred, except in cases of complex ores, which often exercise the ingenuity of metallurgists.

There are but few silver mines worked in Russia. The only ones of importance are those of Altaie, Nertchinsk, and those of the Caucasus and the Ural; but the great source of mineral riches in that kingdom consist principally of the gold and platina dust (sands), the washing of which engrosses the chief attention of the Government. This process, though methodically conducted, is very imperfect, for a large quantity of the gold contained in the sand is lost; the proceeds, however, are considerable; during the last year no less than 12,200lb. were obtained, upwards of 800,000*l.* value.

The argentiferous and auriferous galenæ which have been subjected to the electro-chemical process are perfectly fit for the extraction of gold and silver by washing. This method requires that the ores should be pulverized and roasted so as to separate the metal from the pyrites and other compounds which detain it. The silver and lead being removed, the ore thus reduced to about half its weight, can be washed with the greatest facility, and one man can wash several hundred pounds per day. This method was tried with the galena (very argentiferous) discovered a few years since at St. Santin Cantalés, in the department of Cantal, and which yielded not more than 2½ grains of gold in every 200lb. of ore, with 30 per cent. of lead. But, upon adopting the electro-chemical process, the same quantity of ore produced something more than three drachms of gold. From this important result it is supposed that the rocks in that part of the country are auriferous, as might also be inferred from the name of the place, Aurilac (*auri lacus*). Another great advantage of the electro-chymical method is, that it enables the metallurgist to separate those portions of ore which contain gold, silver, &c., from those which contain none.

M. Becquerel then alluded to the other uses to which electricity might be applied in the manufacture of metals, especially in the art of gilding silver and copper, as also for taking impressions in copper of medals, bassi relievi, and engravings.

The learned academician concluded by observing that this new and highly important power was only in its infancy, and that it would be impossible to foresee the immense services it was likely to render to the arts.

GRANTON PIER.

There are, perhaps, few engineering works at present in progress in Scotland that seems to attract more general interest than the magnificent pier, now in course of being erected, by His Grace the Duke of Buccleugh, on His Grace's property at Granton, a few miles northward from the city of Edinburgh.

The original object and design for a new pier at Granton, was to supply the wants of the city of Edinburgh in regard to steam-vessel conveyances, that passengers might there embark and disembark with safety, in all states of the tide and weather, without boating—the inconvenience arising from the want of which, both from there not being found a proper site, and the requisite funds for accomplishing so truly desirable an object elsewhere, has been but too long felt and acknowledged in that quarter. Accordingly Mr. Walker of London, that most talented and deservedly celebrated civil engineer, was sent for in the year 1836; and after examining the coast adjacent to the Scottish capital, without any restrictions as to locality, he pitched upon Granton as being the most eligible site for such a work; and having prepared suitable working plans, this great and useful work was forthwith commenced, and has since been unremittingly carried on at the sole expense of a single individual—that distinguished, patriotic, and benevolent nobleman the Duke of Buccleuch.

A brief description of the general plan of the pier may not prove uninteresting here. Granton Pier commences at high water mark on the shore, and runs at right angles with it into the Frith of Forth; it is intended to be about 1,700 feet in length, by about 150 feet in breadth; is to be built chiefly with stone, and founded upon shale rock; it will be so arranged as that it will have a double roadway and front wall, one on either side, with a parapet wall in the centre (with connecting openings between the sides), on each side of which will be a footpath. The sea or front walls will be exactly alike, and so divided that there will be six jetties, and one slip or inclined plane on each side of the pier, and one jetty at its outer end; these jetties will be each strongly faced with timber, and so ingeniously contrived and put together that a platform of planking will be on its top, and an intermediate one below, which will communicate with the roadway by means of an easy stone stair. Each jetty will have two cranes on an improved principle, one at each end, and a double warehouse, in the centre of which the aforesaid stair passes; the jib of each crane will swing right into one of the doors of each warehouse, and above the hatchways of vessels lying at jetty. The slips or inclined planes are faced with wooden defenders, so that vessels landing live stock, &c., may haul up or down as the state of the tide may be. The depth of water on both sides of the pier, with the lowest spring ebbs, will be twelve feet at low water at the outer end, diminishing very gradually inward; and the bottom is of a soft and fine clay. It is intended that the pier shall have an elegant approach, and a lighthouse at its extremity.

From the principle on which Granton Pier has been carried on, namely, finishing as it goes outward, it has already proved itself to answer better than was anticipated, not only as a place where steamers of the largest size can dash in and out with the lowest ebbs, where the passenger can by a few safe and simple paces step from the steamer into the cab, and drive off at full speed, and *vice versa*, but as a place of accommodation and refuge to all classes of vessels, in all kinds of weather. As a pier from which steamers can arrive and depart with ease at their respective fixed hours, it has already been fairly proved without failure; as a place for despatch, it may be mentioned that one of the large London steamers lately arrived heavily laden—she was unladen and laden again, she disembarked and embarked her passengers, and sailed, all in the course of eight hours. As a place of refuge and shelter it was lately tested, for, with a severe easterly gale of wind in April last, the steam boats plying to the stone and chain piers of Newhaven were obliged to avail themselves of the facilities afforded at Granton; and with the same gale seven or eight steamers might at once have been seen lying snug at, or departing from the western side of Granton Pier. Very shortly afterward, with a similar gale, a vessel in a sinking state, with her crew on board, run for and obtained shelter at Granton at low water, and but for this fortunate escape all hands must have perished.

In addition to carrying on the pier, which has been found to answer so admirably, His Grace the Duke of Buccleuch has formed a splendid new road between it and Edinburgh; and a magnificent hotel and warehouse, and also a pier master's house, adjoining the pier, have been finished lately. It is also in contemplation, if not already commenced, to make a road from Granton Pier to join the Cramond Road to the westward; and a water-work for supplying the pier and houses with good fresh water. Indeed, the improvements at present going forward at Granton with such gigantic strides, may justly be viewed as an era in the history of civil engineering.

It would be improper to close the present account of Granton Pier without observing the credit which it, as a novel and highly important work of engineering, reflects on its judicious and skilful principal engineer, Mr. Walker. The improvements daily going forward in its detail and parts, so ingeniously and carefully concocted by the resident engineer, Mr. Howkins, as well as the excellent arrangements in carrying on the work without in the slightest degree interrupting the extensive and growing trade of the pier, are richly deserving of praise.

The Granton Pier will yet, at no distant day, give facilities to every description of trade, and have resources which time, together with the assiduous endeavours of its noble and indefatigable proprietor, will only disclose. As far as the work has now proceeded, and in proportion as it is capable of doing good, the public are certainly deeply indebted to the Duke of Buccleuch.—*Elgin Courant.*

THE THAMES FLOATING FIRE-ENGINE.

Hitherto the London Fire Office has had its fire-engines on the Thames placed in vessels or floatse onstructed of wood, and although built exceedingly strong, yet considerable loss of engine power was sustained, through the vibratory motion of the hull, in addition to which, the bottom of the vessels or floats became soddened and foul, so that great difficulty was experienced in removing them from their moorings to the scene of action. The fire office being about to place another engine-vessel or float upon the Thames, the advantages of a wrought-iron hull were submitted to the committee of management, who decided in favour of the same, and on Thursday, 20th ult., (off Blackwall), a novel and interesting trial took place, on board the said wrought-iron float (built by Messrs. Ditchburn & Mare). The fire engines are by Mr. Tilley, of Blackfriars Road, of larger dimensions and different arrangement than those hitherto used; the handles or levers are placed parallel to the vessel's sides, leaving a convenient passage in the middle of the deck. Thirty men were placed to each handle or lever, (of which there are four,) two on each side, making 120 men; every thing being ready, the order was given to start, when one of the fire-men (holding the branch-pipe) was, by the force of the water entering the pipe, knocked on the deck; the men were instantly stopped: on starting again, it was found that it required four of the stoutest fire-men to manage the pipe, (the nozle aperture of which measures two inches in diameter,) and a column of water was discharged from it, in a direct measured distance of 200 feet. The hull of the vessel was found, under the most violent effect that could be produced upon it, perfectly free from vibration, quivering, or rolling motion; 18 men propelled her by the means of oars, at the rate of 6 miles an hour. The result was highly satisfactory to all parties concerned; but we are disposed to ask, why does not the London Fire Office avail itself of the best motive power—steam. A 10-horse engine would propel such a vessel 10 miles an hour in still water, and double the effect, they can at present produce with manual labour; would be without cessation, and under entire command; the steam could be raised at any time in 15 minutes, and all this for the trifling sum of £500.

STEAM NAVIGATION.

THE EARL OF HARDWICKE EAST INDIAMAN.

On the 8th ult. we had the pleasure of steaming down the river with a select naval and scientific party, who had met on board for the purpose of inspecting this beautiful vessel with her new improvements, which, to the great credit of her spirited and enterprising owners Messrs. Green, has several of considerable value and importance, but the one with which we were most interested was that of a steam engine of 30-horse power, manufactured by Messrs. Seawards, employed to rotate paddle-wheels placed in the usual position, but without paddle-boxes, and having a skeleton like appearance; these are to be used as auxiliaries to the vessel during light winds and calm weather, or for the purpose of keeping off a lee shore, or on any other occasion when the sail fails its duty; and in order to render these paddles less objectionable, they are constructed so as to be thrown out of gear at a minute's notice, and made to revolve upon their own axis, independently of the machinery, and prevent that resistance in sailing that they would otherwise render. They can likewise be disengaged altogether by withdrawing the several floats separately, that are attached to the shaft of the paddle by arms, similar to the levers of a capstan, and secured on their boundary by a long linked chain which is easily disconnected, and the whole of the paddle-wheel removed in case of stormy weather. The shaft and arms are of iron, and the floats of wood, the latter material being considered easier to handle than if made of iron. The engine works horizontally, and occupies but little space, being 24 feet in length, and but 10 feet wide, in that part of the vessel which is but of little consequence, namely, between the fore and main hatchway, and being entirely between decks, neither part appears above deck, nor in the hold. The boiler is jacketted with two coats of felt, over which is a thickness of two-inch deal planking, which being an excellent non-conductor, entirely retains the heat, and prevents the wood-work in the neighbourhood of the boiler being injured by excessive heat. The fuel used was that patented by Oram, made of pitch, small coal and mud, moulded into the form of bricks, which are stacked up close, and by their compact form appear to occupy but little room: the consumption was 120 bricks of 4 lb. weight each, in 2 hours 12 minutes, or at the rate of a little more than 2 cwt. per hour, burning without smoke—and, according to the patentee, with a more intense heat, and much more economically than that of its rival, coal. The Earl of Hardwicke is of 1000 tons burthen, draws 17 feet of water, bound for Bengal, and is full of passengers, troops and cargo. She left the East India Docks on the 8th ult., worked her engine down to Gravesend, but owing to a strong easterly wind was assisted by a steam-tug, accomplished the distance in two hours and a half, going at the rate of six knots, with all her yards square; upon heaving round at the end of Gravesend Reach, the tug was cast off, and she steamed to the town again by her own engines at the rate of four knots, on a strong ebb tide. On Monday at noon she weighed anchor, light airs W.S.W., steamed down to the Nore Light in three hours by her own engine, and arrived at Spithead at 3, 50 p.m. on Thursday the 13th, beating the Wellington (which she passed on Monday night) by 12 hours. The steam engine being of the most essential service, working upwards of 40 hours. She took her departure from Portsmouth for Calcutta, and is expected to perform the distance in 75 days. On the Friday previous to her departure she was visited by Admiral Bouverie, Sir E. Codrington, Mr. Blake, master shipwright of Portsmouth Dock-yard, and many other naval officers and persons connected with the navy, who expressed themselves highly pleased with the plan.

The "Vernon," a sister ship, upon which the experiment of auxiliary steam was first tried, made the voyage from Calcutta to Spithead, in a very bad season, in 86 days, notwithstanding she had calms and light airs all the way down the Bay of Bengal, when she used her steam consecutively for eight days and nights, and she came from the Cape to Spithead in 42 days, being, we believe, the shortest voyage upon record, during which time she used her steam nine days. Mr. Green, the spirited proprietor of a fleet of these splendid East Indiamen, intends to apply generally auxiliary steam, and there can be little doubt but it must soon be adopted in our men-of-war. The space occupied by the machinery being the same amount as that formerly occupied for a cable tier.

It is a rather curious coincidence that the day on which the Vernon will sail for India, the 10th instant, is also the day fixed for the sailing of the "India" steam vessel of 320-horse power, thus an excellent opportunity will be afforded for ascertaining the comparative advantages of the two plans. Many bets have already been made at Lloyds, that both the "Vernon" (which is the only steamer that has ever made the voyage to India and back), and the "Hardwicke," of 30-horse power each, will make the passage out in less time than the "India" of 320-horse power. Should this prove to be the case, it will satisfactorily establish the superiority of steam applied as an auxiliary over large steam power applied in the usual way.

Iron Boats.—On the 15th ult. there were launched from the building yard of Messrs. Ditchburn and Mare, Blackwall, *two* wrought iron steam vessels *at the same time*, an occurrence we believe never before witnessed on the Thames; one was named the "Swallow," intended for the Baltic, the other "Elberfeld," for the Rhine. Messrs. Penn and Son, of Greenwich, are the engineers for the former, Messrs. Miller and Ravenhill, Blackwall, for the latter; the engines in both vessels are oscillating.

British Steamers on the Nile.—The Oriental Steam Company have purchased the iron steamer Dahlia, which is on the point of starting for Egypt to ply on the Nile, under license of the Pasha, to convey the East India mails and passengers through Egypt.

The British Queen steam ship, which sailed from Portsmouth on the afternoon of the 1st July, arrived at New York on the morning of the 18th, having made the passage in 16½ days. The Britannia steam-ship, the first of Mr. Cunard's Royal mail steamers, which sailed from Liverpool on the afternoon of the 4th July, for Halifax and Boston, reached the latter place on the evening of the 18th, having accomplished the passage, including a stoppage at Halifax, in 14 days and a half.

The Oriental, built for the Peninsula and Oriental Steam Navigation Company, is believed to be one of the finest specimens of naval architecture. She is frigate built; her engines are equal to 450 horse power, and appear to be of the best construction. The elegance with which she is fitted up, and the accommodation which she offers in every department, must render her acceptable to the most fastidious passengers. She is stated to be of 1,673 tons burden. The great cabin is beautifully ornamented with panels of *papier mache*. There are 48 tablets on the doors and sides of the compartment, made of the material by Messrs. Jennens and Bettridge, of Birmingham, prepared in a manner that renders them more durable than oak: they never can decay from dry rot, or become worm-eaten, nor are they combustible, or capable of being broken. The tablets are ornamented in *arabesques a l'orient*, in bronze scrolls of the acanthus, with gold tendrils and leaves, with sea-weed on a primrose ground, which supplementary colours accord well with the black moulding, which is richly covered with burnished gold matted tracery work, that has the appearance of being raised from the ground, and produces an effect alike beautiful by day or lamp light. The makers are entitled to great praise for the introduction of a material capable of admitting so much elegance and taste in decoration.

The Archimedes.—This vessel reached Oporto from Plymouth in 70 hours, being supposed to be the quickest steam communication that has ever been made between these places; and this was effected without her having once had occasion to stop her engines. The distance is about 800 miles.

PROGRESS OF RAILWAYS.

The Queen Dowager's Trip on the Railway.—Extraordinary Speed.—On the recent occasion of the return of the Queen Dowager from Lancaster, a special train was provided for the conveyance of her Majesty and suite, from Lancaster and Preston and North Union Railway Companies, and thence to Stafford, being the nearest point to Alton Towers, the seat of the Earl of Shrewsbury, which was her Majesty's destination, by the Grand Junction Railway Company. The train, consisting of three railway carriages, one of which had been handsomely fitted up by the London and Birmingham Company for her Majesty's use, and five private carriages on trucks, making eight in all—

Started from Lancaster, at	10h. 12m., A.M.
Arrived at Preston Station	11h. 15m.
Stopped there	13m.
And on the Viaduct over the Ribble Valley	6m.
Time at Preston	19m.
Arrived at Parkside	12h. 11m.

Where it was attached to an engine of the Grand Junction Railway. The latter part of the journey, viz., from Newton Junction to Stafford, a distance of fifty-four miles, was performed, exclusive of a stoppage of five minutes, at Crewe, for water, in one hour and thirty-one minutes, or at the rate of upwards of 35½ miles per hour. Her Majesty, on her arrival at Stafford, personally expressed to Captain Cleather, the manager of the Grand Junction Company, who was in attendance, her satisfaction at the rapidity of the passage, and the uncommon smoothness of the line. The engine, the Vandal, on its return, brought back from Birmingham a train occupied by the directors and chief officers of the company, who had been inspecting the line, and holding a board at Birmingham on that day. It left Birmingham at 6 30 P.M., and arrived at Edgehill at 9 2 P.M., having made three stoppages of five, four, and three minutes; thus running the distance in two hours and thirty-two minutes, or at the rate of thirty-eight miles an hour including stoppages, or forty-one miles an hour exclusive of them. This is believed to be the most remarkable performance, for a continued distance of this extent, that has yet taken place on this or any other railway in the kingdom. This engine, in both its trips, was under the direction of Mr. Buddicom, the superintendent of the locomotive department of the company.

THE NORTH UNION RAILWAY.

ENGINEER'S REPORT TO THE DIRECTORS.

GENTLEMEN—In drawing to a close the construction of the North Union Railway, I consider it will be satisfactory to the Directors and Proprietors to have the detailed cost of the several great heads of expenditure brought into one view before them. It is due to myself and the other officers of the Company, that the quantity of work executed for the money should be set forth; and without any thing beyond a simple statement of facts in this respect I shall be content, should this report be promulgated, to leave the Shareholders in this concern and the public to form their judgment. I likewise conceive that, as the first authentic detailed document of the kind, it may be taken as the commencement of similar statements which will hereafter be brought forward, and thereby be the means of collecting that statistical information on the Railway system, which has naturally, and of late, been so much sought after.

It should be noted that the total length of line embraced herein is 25 miles; the main line from Parkside through Wigan to Preston being 22 miles, and the New Springs Branch 3 miles; and it should be observed, that from the peculiar nature of this railway, the total extent of sidings, extra lines, &c. is very much above the usual proportion.

In the total sum of £578,931 16*s.* 2*d.* (say in round numbers £580,000.) is included the cost of re-laying the old line between Parkside and Wigan; the Cottages now building along the line; the maintenance of the Railway by the Contractors, for two years, from the respective openings; and not only all that has been already expended on the several items, but that which is now in progress, or contemplated to be done, to make the railway complete, and to draw the line at the foot of capital account.

From a consideration of the nature of the works on this line, many of them of a gigantic character, particularly the Ribble Viaduct, and including the various slips and accidents, I hope I may be permitted to consider the average cost of £23,157 per mile as a moderate amount, including, as it does, stations, carrying establishments, interest, and management.

The actual cost of the Railway itself has been only £15,793 per mile, exclusive of land; and if the peculiarly heavy expense of the Ribble Viaduct (consisting of five arches of 120 feet span each, erected at a cost of about £44,885, including all contingent extras) be excluded, as it fairly might, for comparative results, the cost of the works alone is £13,998 per mile; the purchase of land for the railway is £1,974 per mile additional; £3,517 is the cost per mile for the stations and carrying establishments; and £1,872 per mile for interest and management. Separating the latter item from the interest, it will be seen that the whole expense of the superintendance of the North Union Railway, over a period of ten years of greater or less activity has scarcely exceeded 7 per cent. This item is, of course, not in the engineer's department, but it is due to the managing officer of the Company to state the circumstance: it will also be found that the average quantities per mile are—of earth work, 116,120 cubic yards, averaging under 10¾*d.* per yard; of masonry, 4000 cubic yards, averaging 22*s.* 7*d.* per yard; and of iron, 287 tons, averaging something below 9*l.* 15*s.* per ton.

In respect to the mode in which the difficulties presented by the physical obstructions on the face of the country have been surmounted, by the adoption of gradients of 1 in 100 to a considerable extent, and thereby a vast saving effected in the construction of the railway, I hope to be able to demonstrate, at the close of the first two years' entire working of the line in October next, that, with the exception of some very little addition to the quantity of fuel, the cost of working the North Union Railway, reduced to a rate per mile per train, is *below* that of other lines with superior gradients, while the trains and rate of travelling are at least equal to the averages elsewhere; and I feel confident of being able shortly to give a very close approximation of what that average expense is per mile per train, including all the deductions from the gross receipts, before declaring a dividend.

There being then but little difference, as far as observation and experience have hitherto gone, in the working trains of passengers and light goods on railways, differing considerably in gradient, at velocities and with loads such as usually occur, the high importance of economy in the first construction is self-evident. It has thus told effectively on the Grand Junction Railway, and I trust will be equally felt on the Midland Counties Railway, each of which lines, with similar equipments to those on the North Union Railway, will be found to have cost at about the same rate, or but little exceeding it, say certainly within £25,000 per mile. Reducing the whole expenses on the North Union Railway to round numbers and to a per centage, the account will stand as follows:

		Total.	Per cent.	Per mile.
	Earth Work	£126,000	22	£5000
	Masonry	120,000	21	4800
	Fencing	21,000	3½	800
Upper Works.	Railway laid complete	61,000	$10\frac{1}{2}$	2400
	Iron	67,000	$11\frac{1}{2}$	2700
	Land and Damages	50,000	$8\frac{1}{2}$	2000
	Stations	44,000	$7\frac{1}{2}$	1800
	Carrying Establishment	44,000	$7\frac{1}{2}$	1800
	Interest	5,000	$\frac{4}{5}$	200
	Management	42,000	$7\frac{1}{3}$	1700
		£580,000	100	£23,200

But to enable a more critical examination to be made, I shall subjoin the following abstract:

Abstract of the Cost of the Works upon the Line of the North Union Railway—25 miles—with the General Heads of Expenditure in the various Departments.

	£ s. d.	£ s. d.
EARTH WORK........ 2,903,028 cubic yards, (average 10¾*d.*) per yard	£125,676 3 11	
MASONRY and BRIDGES.—100,265 cubic yards		
Masonry	£113,096 0 5	
325 tons Iron Work	3,875 0 0	
25,022 cubic feet Timber	3 277 14 8	
FENCING and DRAINS.—87,712 lineal yards. —*N.B. This includes Road Diversions, &c., Gates, &c. &c.*	20,533 2 7	
UPPER WORKS.—6,885 tons of Iron Rails and Chairs	66,833 17 7	
91,545 lineal yards of Railway, laid on Blocks and Sleepers, including Ballast, Drains, Walling, Bolts, Keys, Felt, Plugs, and small Materials and Labour	61,538 0 2	
		£394,826 19 4
LAND and DAMAGES.—320 acres for Railway		49,342 3 10
STATIONS.—Land for Stations	£17,257 15 5	
Station Buildings	13,589 8 1	
Warehouses	9,266 0 0	
Fixtures, Turnplates, and Sundries	4,164 16 6	
CARRYING ESTABLISHMENT.—Repairing Shops, Tools, and Fixtures	11,884 0 0	
Locomotive Engines, Tenders, &c.	18,863 6 7	
Carriages, Horse Boxes, Trucks, &c.	12,934 17 10	
		88,960 4 5
INTEREST.—Interest Account, Rates, Taxes, &c.	4,746 15 8	
MANAGEMENT.—Parliamentary and Law Expenses	17,147 8 0	
Engineering and Surveying	6,193 5 9	
Office Expenses, Travelling, Advertising, &c.	3,134 19 2	
Salaries	15,580 0 0	
		46,802 8 7
TOTAL COST . . £23,157 5 6 per mile.—or—		£578,931 16 2

It should also be mentioned that, of the above land there remains to the value of about four or five thousand pounds available for re-sale; and, in conclusion, I trust that the dividend of nearly 7 per cent. per annum out of the clear profits of the Railway, since its entire completion and opening throughout, in October, 1838, to the present time, with a prospect of a steady increase, is a sufficient proof of the soundness of the concern; and with my grateful acknowledgments to the Directors for their invariable kind support amidst many trying difficulties, now happily surmounted,

I have the honour to subscribe myself,

Their very faithful servant,

CHARLES VIGNOLES,

Engineer-in-Chief.

4, *Trafalgar-square, London,*
August 4, 1840.

PUBLIC BUILDINGS, AND IMPROVEMENTS.

New Church at Golden Hill.—On Monday, 3rd ult., the first stone was laid of a new church about to be erected at Golden Hill, a populous village situated at the northern extremity of the Potteries. The church will contain 500 sittings, one-half of which will be free. Mr. Stanley is the architect, and Mr. Shufflebotham is the builder, and it is expected that the building will be ready for consecration in the month of July next year.

New Church at Hill Top, West Bromwich.—On Tuesday, 4th ult., the first stone of this church was laid. The architect is Mr. Robert Ebbells.

The Nelson Pillar.—On Friday, 7th ult., the Duke of Northumberland, Sir George Cockburn, Mr. Herries, Sir Peter Laurie, and other members of the Nelson Testimonial Committee, met at the National Gallery on the subject of the magnificent pillar now rapidly rising in Trafalgar-square. The brickwork appears above the hoarding, and will soon be very conspicuous, and the committee expressed their warm approbation of the energy manifested by the contractors, Messrs. Grissell and Peto. It appears from what has recently taken place before the members, that the altitude of the pillar is not to be so great by 30 feet as was at first contemplated. Mr. Bailey is at work upon the figure of the naval warrior, which is to be of Portland stone, and for the execution of which the sculptor is to receive 1000 guineas. It is calculated that Portland stone will retain its colour and polish upon being strongly saturated, better than bronze; and Mr. Croker instanced the Nelson statue of Dublin as a proof of the superiority of the former. Mr. Lough is to execute "the lions" at the pedestal; but they are not to be commenced until the near approach of spring, when it is expected the subscription will receive numerous additions. A committee of the House of Commons reported a little while ago that the Nelson pillar ought not to be raised in Trafalgar-square, but the house having taken no notice of the suggestion, the work will proceed without a check to completion. The project of a new site would not, it is conjectured, be very kindly received, as government gave the ground, and contributors gave their money, expressly for the purpose of raising the testimonial on that spot to the great naval hero of England.—*Daily paper.*

Blackfriars Bridge.—We are requested to call the attention of the public and especially of the different paving committees, to the paving of the carriage way now in progress on Blackfriars Bridge. It is the first time the narrow paving has been tried in this metropolis, and it is considered a very great improvement, as a horse will not be so liable to slip as on wider stones. The blocks are principally of Guernsey granite, 9 inches long, only 3 inches wide, and square at the top and bottom. The substratum is formed of a concrete 12 inches thick, of stone-lime and Thames ballast. The contractor is Mr. John Mowlem, of Paddington, who has, we hear, met with very great difficulty in obtaining the granite from Guernsey. It is considered the best piece of paving in London, and it is supposed that the bridge will be open in about a week.—*Times, Aug.* 27.

Chard Canal.—This undertaking, which has now occupied six years, is fast approaching to completion. The whole extent of the line, with the exception of a mile and a half of its basin, is almost finished. The principal and only hazardous point is now the reservoir in Chard Common; here the attempts to make a bank have once or twice already failed, but increased labour and perseverance will, we trust, overcome the obstacle, and within a period of six months we trust the reservoir may present an immense sheet of water, occupying a space of 70 acres. The expenditure on the works has been very great; during the last year £20,759 4*s.* 9*d.* has been expended, and the whole expenses have been £26,479 16*s.* 9*d.* Of the 1,140 new shares created by the committee in April last, 992 have been taken. The proprietors have now a very cheering prospect, as the committee hope and expect the canal will be completed in the early part of next year.—*Western paper.*

Napoleon Monument.—A model of the monument proposed to be executed to the memory of Napoleon, has been erected beneath the dome of the Invalides, under the direction of M. Marochetti, for the purpose of ascertaining its effect; from the description, it seems to combine simplicity with grandeur. It stands in the centre of the mosaic work, beneath the dome, and is composed of four parts. The first is a vast base, surrounded by columns and bas reliefs, supporting, at its corners, four statues, one of which holds the globe, another the sceptre, a third the emblem of justice, and the fourth the imperial crown. On this base rests another, half the height of the first, two-thirds smaller in extent, also adorned with bas reliefs, and having, at its angles, four eagles, with outspread wings. From this second base rises a pedestal 8 feet in height, likewise enriched witth bas reliefs, having in its centre the single word "Napoleon." And finally, on this pedestal, stands the colossal equestrian statue of the Emperor, wearing the imperial mantle, and having the laurel crown upon his brow. His left hand holds the bridle, and in his raised right hand is the sceptre of empire. The two bases and pedestal are 40 feet in height, and the equestrian statue is 15; the eagles are 6 feet high, and the four figures on the lower base of the same proportions as the imperial figure. The colossal and pyramidal form of the monument gives us the impression of being well adapted to its site beneath the vast dome of the Invalides. It will be entirely of bronze, and three years are assigned for its execution.—*Athenæum.*

Draining the Haerlem Lake.—M. Dietz, a celebrated Dutch engineer, has invented a machine which it is supposed will be adopted for this purpose, and by means of which he calculates that 100,000 cubic ells of water may be drained off daily. This ingenious person estimates the body of water contained in the Haarlem Sea at 770,000,000 of cubic feet, to empty which it would require 10 of his machines of 30 horse power each, the quantity drained off by them daily being 1,000,000 of cubic feet, thus making the period required for its entire removal 800 days. The estimated expenditure of this work, second only in grandeur and importance to the Thames Tunnel, is as follows:—

	Florins.
10 machines, at 30,000 florins for each	300,000
Coals, &c., 500 florins per diem for 800 days	400,000
60 workmen at 1½f. each per diem for 800 days ..	72,000
Superintendence, plans, &c.	25,000
Total	797,000
About	£66,416

MISCELLANEA.

ELECTRO-CHEMICAL GILDING.—M. De la Rive, of Paris, has been very successful in gilding by electricity. This kind of gilding is thicker and firmer, as has been proved by the experiments to which it has been subjected by a Parisian goldsmith, who was requested to examine it. A vase, gilt by this process, was heated in a fire to a red heat, and then thrown into cold water, and when taken out was found to have lost nothing of its lustre.

Steam Boiler.—Lieutenant Janvier, of the French navy, is said to have discovered the means of getting up the steam of engines with such rapidity, that in ten minutes from the first lighting of the fire, and although the water in the boiler be quite cold, a vessel may be set in motion. This is, it is added, to be accomplished without any additional apparatus, and at very little expense.

Government School of Architecture.—The Lords Commissioners of the Admiralty having come to the determination that a civil architect's department shall be established at each of Her Majesty's dockyards, the whole to be under the superintendence of Captain Brandreth, of the Royal Engineers, the following are the names of officers who will be attached to the department at Woolwich dockyard:—Lieutenant William Dennison, Royal Engineers; Mr. William Scamp, Clerk of Works; Messrs. Colborne and Young, Assistants; Mr. John Hopkins, superintendent of bricklayers; Mr. William Reed, superintendent of carpenters.

An Iron Express Coach, for crossing Sandy Deserts.—The want of a vehicle of this description has long been considered a desideratum by European travellers, in their toilsome journeyings across the arid and scorching deserts of Egypt and Arabia. Hitherto the means of conveying travellers or merchandise over these extensive and barren sands has been by camels and dromedaries, for wooden carriages of any construction were utterly useless, as it was found impossible to discover any species of timber that could resist the intense heat of those districts, which soon splits and rends the best seasoned timber. British ingenuity has, however, found out a mode of overcoming the difficulty, by substituting *iron* for *wood*. In fact a carriage has been constructed, under the direction of Mr. Waghorn, by Messrs. Theodore, Jones, and Co., of Spitalfields, the patent iron wheel manufacturers. This vehicle, which is calculated to hold six persons, their stores, water, &c., has not the smallest portion of wood in its construction. The frame-work, the wheels, shafts, flooring, benches, &c., are all of wrought iron bars, either flat or round according to purpose required, the bottom being open like a net work to allow the temperate air to come up freely, and drive out the hot air as it generates through the top valves. There are hair cushions placed on the benches, which form seats quite as comfortable as those of any other coach. The machine is hung on the eentrical spring principle, which discharges the weight from the horse, and throws it on the wheels—this is another great advantage in a hot country. It will thus afford, when brought fully into operation, a safe and comfortable conveyance for travellers, despatches, and the lighter articles of commerce, and is likely to be the means of opening extensively that easy intercourse between Palestine, Persia, Arabia, and Egypt, which is greatly wanted, and would vastly extend the bounds of human knowledge, commerce, and civilisation.—*Morning Herald.*

Improvements in the construction of furnaces and in boilers; patented by Philippe Marie Moindron, Bedford Place, Russel Square, July 31.—These improvements are with a view to bring into action, more fully than is now practised, the useful properties of caloric, by the combined using of polished reflecting surfaces and non-conducting materials, by which means the heat evolved is reflected on to the surface of a boiler or other apparatus. The heat is prevented from passing away without fulfilling the duties to which it is applied. First, to envelop the boiler or other apparatus with a reflecting surface, at such a distance that the heat can pass between the reflecting surfaces and the surfaces to be heated, but in so applying reflecting surfaces, care is to be observed in arranging the same, that they may be conveniently got at from time to time to be polished. The materials employed for obtaining heat, when working the invention, are combustible gases and spirits, or fatty matters, which are consumed by burners or lamps. The boiler is placed on a frame that will allow the gas flame, from three or more concentrical and perforated rings, to pass round; the outer casing is made of any non-conducting material, and the lining nearest to the boiler consists of polished steel; the draft of air below supports combustion. Tea-kettles, or other culinary articles, may be encased with this reflecting surface and non-conducting material, whereby is obtained great economy of fuel and heat.—*Inventors' Advocate.*

Apparatus for regulating the supply of water to steam boilers: patented by James Knowles, Little Bolton, Lancashire, July 10.—Claims the use of a self-acting apparatus, the working parts of which are within the boiler, and communicate to the supply-valve from without. A lever or rod is placed longitudinally on a fulcrum within the boiler, the longer end of which is an upright rod, with a float attached thereon, passing to the outside of the boiler; at the shorter end of the lever is another upright rod connected with the supply valve, working in a tube. As long as there is plenty of water in the boiler, the float will continue to press up the long end of the lever, and, consequently, cause the valve on the upright rod of the short end of the lever to press down on its bearing, and prevent the admission of water from the tank. But when the height of the water in the boiler diminishes, the float lowers with it, and thereby forces up the rod with the valve, thus admitting a further supply of water until the float again rises to close down the valve. —*Inventor's Advocate.*

Preserving Wood from decay: patented by Arthur Howe Holdsworth, Brookill, Devonshire, July 21.—The object of this invention is to preserve wood or timber from decay by immersing it in certain liquids, having the properties of receiving a temperature capable of charring or searing the surface of wood that has been exposed to their action, and of concreting or hardening more or less by subsequent cooling, so as to remain in those pores into which they have previously entered, as well as to cover the surface of the wood, and thus prevent it from the injurious effects of air and moisture. The liquid employed is composed of tar, pitch, resin, or tallow, or that of its products, where it has been subsequently inspissated. This liquid, which can be brought to a higher degree of temperature than water, is placed into a suitable receiver, into which the wood is immersed, and allowed to remain until all bubbling ceases, occasioned by the air passing from the wood. When the wood is required for flexible purposes, such as the decks of vessels, &c., then it is only allowed to remain in the liquid while at a temperature ranging from 212° to 120°—but for charring or searing the wood, the liquid must be brought to the boiling point. The receiver has a cover with ascending pipes, to take off the inflammable vapour rising from the tallow, tar, pitch or resin. When the wood is removed from the liquid, it must be dried in suitable ovens.—*Ibid.*

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 30TH JULY TO 27TH AUGUST, 1840.

JOHN LOUIS BACHELARD, of Saint Martin's Lane, Gentleman, for "*improvements in the manufacture of beds, mattresses, chairs, sofas, cushions, pads, and other articles of a similar nature.*" Communicated by a foreigner residing abroad.—Sealed July 30; six months for enrolment.

FELIX TROUBAT, of Mark Lane, London, Merchant, for "*improvements in the manufacture of vinegar.*"—August 1; six months.

WILLIAM DAUBNEY HOLMES, of Lambeth Square, Surrey, Civil Engineer, for "*certain improvements in steam engines, and in generating and applying steam as motive power.*"—August 1; six months.

THOMAS BARNABAS DAFT, of Birmingham, Gentleman, for "*improvements in inkstands or inkholders.*"—August 1; six months.

JAMES TAAFFE, of Shaw Street, Dublin, Slater and Builder, for "*improvements in roofing and slating houses and other buildings.*"—August 1; six months.

JAMES HODGSON, of Liverpool, Engineer, for "*a new mode of combining and applying machinery for the purpose of cutting and planing wood, so as to produce plane or moulded surfaces.*"—August 3; six months.

JOHN SANDERS and WILLIAM WILLIAMS, of Bedford, Iron Founders, and SAMUEL LAURENCE TAYLOR, of Old Warden, in Bedford, aforesaid, Machine Maker, for "*improvements in ploughs.*"—August 3; six months.

GEORGE EDWARD NOON, of High Holborn, Engineer, for "*improvements in pumps and in engines for drawing beer, cyder, and other fluids.*"—August 3; six months.

WILLIAM SAUNDERS, of China Terrace, Lambeth, Chemist, for "*certain improvements in paving streets, roads, and ways.*"—August 3; six months.

WILLIAM BEETSON, of Brick Lane, Old Street, Brass Founder, for "*improvements in water closets and stuffing boxes, applicable to pumps and cocks.*" —August 5; six months.

COLIN MACRAE, of Cornhill, Perthshire, Gentleman, for "*improvements in rotary engines, worked by steam, smoke, gasses, or heated air, and in the mode of applying such engines to useful purposes.*" Communicated by a foreigner residing abroad.—August 5; six months.

THEOPHILUS RICHARDS, of Birmingham, Merchant, for "*improvements in cutting or sawing wood.*" Communicated by a foreigner residing abroad. —August 5; six months.

HENRY TREWHITT, of Newcastle-on-Tyne, Esquire, for "*improvements in applying the power of steam engines to paddle-shafts used in propelling vessels.*" Communicated by a foreigner residing abroad.—August 7; six months.

ROBERT STIRLING NEWALL, of Dundee, Gentleman, for "*improvements in wire ropes, and in machinery for making such ropes.*" Partly communicated by a foreigner residing abroad.—August 7; six months.

ANDREW SMITH, of Princes Street, Leicester Square, Engineer, for "*certain improvements in carriage wheels, rails, and chairs, for railways.*"—August 7; six months.

THOMAS JOHN DAVIS, of 5, Bloomsbury Square, Esquire, for "*certain improvements in the form and combination of blocks of such materials as are now used, or hereafter may be used, in building, or, for paving public and private roads, and court yards, or public and private causeways and subways, or any other purposes to which the said form and combination of blocks may be applied.*"—August 8; six months.

DOWNES EDWARDS, of Surbiton Hill, Kingston, Farmer, for "*improvements in preserving potatoes and other vegetable substances.*"—August 8; six months.

JOHN ISAAC HAWKINS, of College Place, Camden Town, Civil Engineer, for "*an improvement or improvements in buttons, and in the modes of affixing them to clothes.*" Communicated by a foreigner residing abroad.—August 8; six months.

FRANCIS WILLIAM GERISH, of East Road, Ironmonger, for "*improvements in apparatus to be used as a fire escape, also applicable to other purposes where ladders are used.*"—August 8; six months.

SAMUEL HOWARD, of Manchester, Engineer, for "*certain improvements in boilers and furnaces,*"—August 8; two months.

BARON CHARLES WETTERSTEDT, of Limehouse, for "*improvements in preserving vegetable, animal, and other substances, from ignition and decay.*" August 11; six months.

JOHN PETER ISAIE PONCY, of Well Street, Oxford Street, Watch Dealer, for "*improvements in clocks and chronometers.*" Communicated by a foreigner residing abroad.—August 13; six months.

MILES BERRY, of Chancery Lane, Patent Agent, for "*certain improvements in the arrangement, construction, and mode of applying certain apparatus for propelling ships and other vessels.*" Communicated by a foreigner residing abroad.—August 14; six months.

PIERRE ARMAND LE COMTE DE FONTAINEMOREAU, of Skinners Place, Size Lane, Gentleman, "*certain improvements in covering and coating metals, and alloys of metals.*"—August 15; six months.

JOHN YOUNG, of Wolverhampton, Ironmaster, for "*improvements in the manufacture or construction of knobs, handles, frames, tablets, boxes, and other ornamental articles, applicable to the decoration of houses and domestic furniture.*"—August 17; six months.

LUKE HEBERT, of Birmingham, Civil Engineer, for "*improvements in the manufacture of needles.*"—August 17; six months.

JOSEPH LOCKETT, of Manchester, Engineer, for "*certain improvements in manufacturing, preparing, and engraving cylinders, rollers, or other surfaces, for printing or embossing calicoes, or other fabrics.*"—August 27; six months.

CHARLES SMITH, of Exeter, Builder, for "*improvements in the manufacture of lime and cements, or compositions.*"—August 27; six months.

WILLIAM CHURCH, of Birmingham, Civil Engineer, for "*improvements in fastenings applicable to wearing apparel, and in apparatus for making the same and like articles, and also in the method or methods of preparing the said articles for sale.*"—August 27; six months.

HUGH UNSWORTH, of Blackood, Lancaster, Bleacher, for "*certain improvements in machinery or apparatus for mangling, drying, damping, and finishing woven goods or fabrics.*"—August 27; six months.

THOMAS ROBINSON WILLIAMS, of Cheapside, Gentleman, for "*certain improvements in measuring the velocities with which ships or other vessels or bodies move in fluids, and also for ascertaining the velocities of fluids in motion.*"—August 27; six months.

BENJAMIN HICK, Junior, of Bolton-le-Moors, Lancaster, Engineer, for "*certain improvements in regulators or governors for regulating or adjusting the speed or rotary motion of steam-engines, water-wheels, and other machinery.*"—August 27; six months.

HENRY WATERTON, of Fulmer Place, Gerards Cross, Buckingham, Esquire, for "*improvements in the manufacture of sal ammoniac.*"—August 27; six months.

TO CORRESPONDENTS.

Communications received from Mr. Francis; J. H. *on Felling of Timber and* "A Lover of the Beautiful," *will appear next month.*

New Town Hall at Ashton-under-Lyne will appear in a future number.

The Reform Club next month.

Reports for the Improvement of Lough Erne; Steam Navigation in France; Anthracite Pig Iron, and some others; also The Architecture of Liverpool; will appear in the next Journal.

Mr. Pinkus' *communication was received too late for insertion in this month's Journal; it shall appear, if he wishes it, with some slight modification next month.*

"A Lover of Machinery." *We have before alluded to the ingenious Traversing Crane adopted by Messrs. Grissel & Peto at their works at the Reform Club, and since introduced at the building of the New Houses of Parliament.*

"Robertus" *could not have seen our two last numbers when he sent his communication respecting the "Atmospheric Railway."*

"Anagnostes" *on Railway Curves, must stand over with others on the same subject.*

Mr. Wightwick's *new work,* "*Palace of Architecture,*" *will be noticed in the next Journal.*

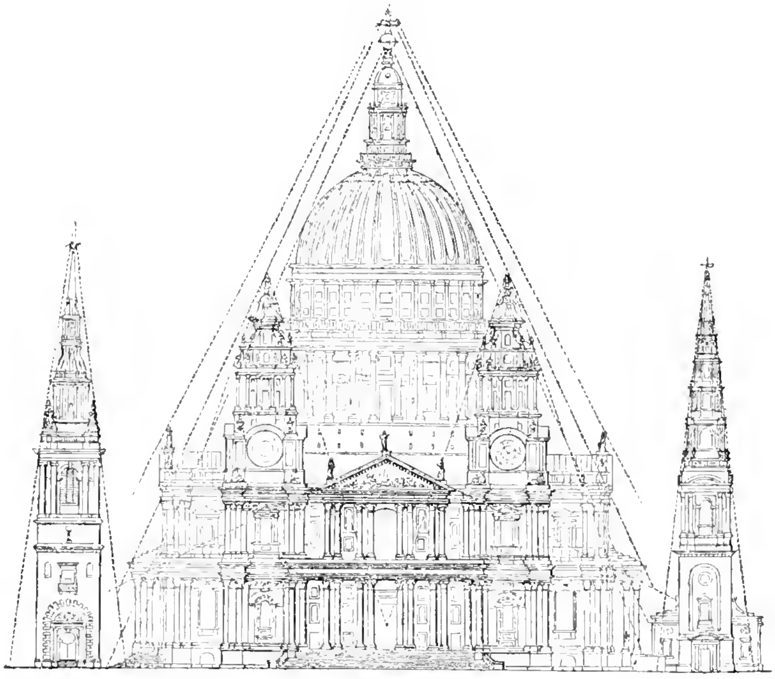
Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," *No. 11, Parliament Street, Westminster.*

Books for review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

THE FIRST VOLUME MAY BE HAD, BOUND IN CLOTH AND LETTERED IN GOLD PRICE 17*s.*

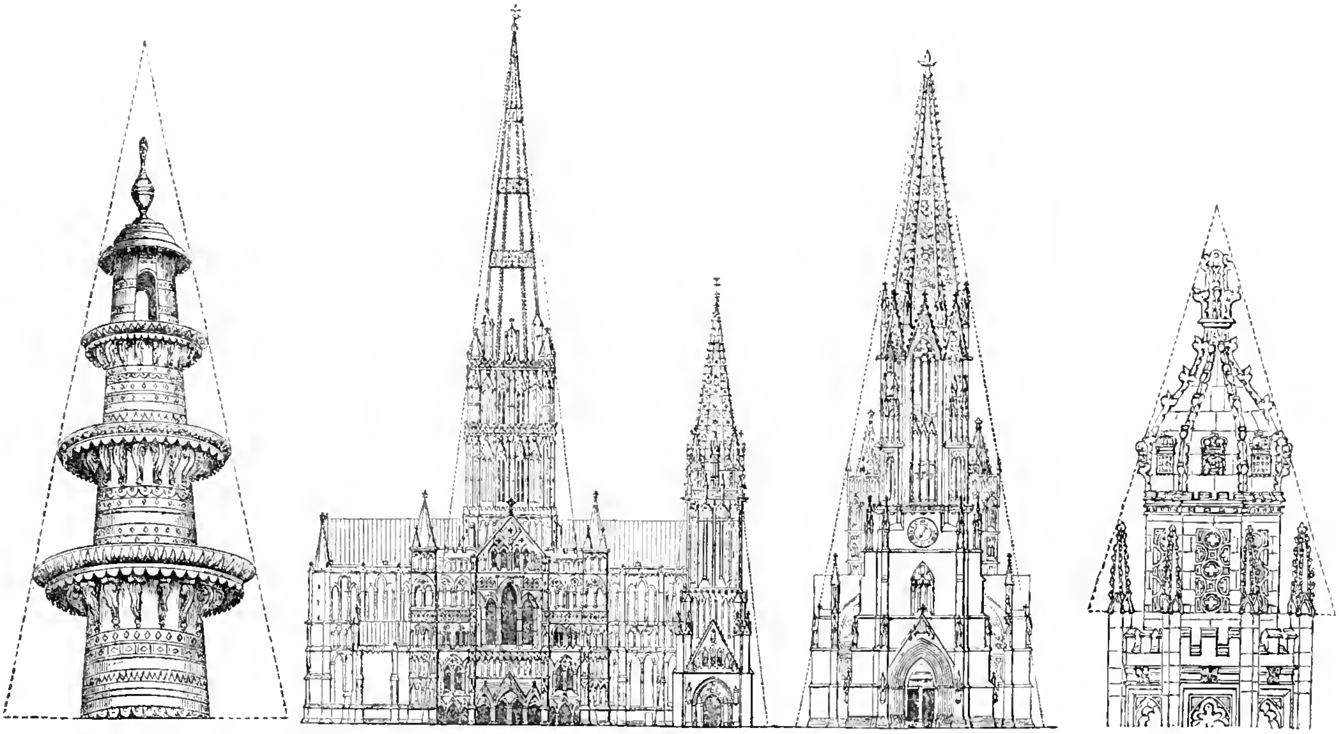
*** THE SECOND VOLUME MAY ALSO BE HAD, PRICE 20*s.*

ON BEAUTY OF OUTLINE IN BUILDING.



SCALE. FEET.

BOW — ST. PAUL'S FACADE. — ST. BRIDE'S.



SCALE 100 200 300 FEET.

Shaking Minarets of the Mosque at Armedabad. — SALISBURY. — ST. PETER'S, CAEN. — FREIBOURG. — Four great angle turrets of King's College Chapel, Cambridge.

*Of Beauty of Outline in Buildings; of the Inferiority of the Moderns, compared in this respect with the Ancient Masters; and of the inutility of Decoration, without goodness of Outline.**

By Alfred Bartholomew, Architect.

But that for which the ancient masters are so eminently superior to the modern architects, is elegance of outline: almost every one of the old buildings, however exceptionable in point of details, has a grand, a neat, and a picturesque outline. The Gothic steeples of all countries, the dome of Saint Paul's, and the bell-towers of Wren, and numerous other old buildings both in England and abroad, whether viewed from afar or near, they all have almost universally, an imposing and agreeable appearance; their considerate architects, seem at once to have designed the elegant outward shells of buildings, so as to contain amply all the internal requisites, without unsightly additions; or if from any necessity, enlargement of a pile afterwards became necessary, the picturesque massing and grouping together of the buildings was never lost sight of.

But what is the mode now pursued? In most instances very different. A debased exterior copy of some old building, is made on a small scale, in base materials; this pretended economical crust, in nine cases out of ten, is discovered eventually, to be neither high enough, long enough, nor broad enough, to contain properly all the accommodations and internal details of the building: hence are added the external incumbrances of lantern-lights, ugly dormers, chimneys, and other deforming excrescences, for which modern buildings are so celebrated.

Nature, always contrives to place every necessary apparatus, within the compass of the general outline; but most modern buildings, exhibit the same contrivance, as birds would, if their giblets being omitted within, were afterwards skewered upon their backs.

If a building at a distance, appear ugly, it is in vain that it have delicate enrichments, and that it be composed of rich materials; it cannot please either the vulgar or the tasteful, nor can the scientific give it commendation.

The qualities of form and outline, stand apart from all the petty quarrels about orders and styles, by which unskilful professors have pestered and lowered a once-noble art.

The most picturesque edifices of all countries, have a wonderful similarity in their outline. The most perfect architectural composition is that which forms one immense Pyramid of Decoration consisting of many minor subservient pyramidal masses:—such are the celebrated Indo-moslem Tombs of Akbar at Secundra, Shere Sha at Sosseram, Humaioon at Delhi, and the Tāj Mahal at Agra: such are St. Paul's Cathedral, the steeples of St. Mary-le-Bow, St. Bride's, and those of all the others of Wren's churches.

The same principle is to be found governing all Gothic steeples.

The same delicate and refined principle pervades Gothic turrets and moslem minarets.

While upon the subject of outline, the author cannot refrain from contradicting, as far as in him lies, the opinion put forth with regard to spires by Mr. Britton, in his exquisite work upon '*The History and Antiquities of the Cathedral Church of Salisbury*,' (p. 74). 'Although this spire is an object of popular and scientific curiosity, it cannot be properly regarded as beautiful or elegant, either in itself, or as a member of the edifice to which it belongs. A May pole or a poplar tree, a pyramid or a plain single column, can never satisfy the eye of an artist, or be viewed with pleasure by the man of taste. Either may be a beautiful accessory, or be pleasing in association with other forms. The tall thin spire is also far from being an elegant object. Divest it of its ornamental bands, crockets, and pinnacles, it will be tasteless and formal, as we may see exemplified in the pitiful obelisk in the centre of Queen Square, Bath; but associate it with proportionate pinnacles, or other appropriate forms, and like the spire of St. Mary's Church in Ox ord, and that of the south-western tower of Peterborough Cathedral, we are then gratified.'

Very odd reasoning this, and quite at variance with the in-born feelings of nearly every native of Christian lands. The author would have deemed it unnecessary to refute such a passage if it had been put forth by any other than an antiquarian gentleman to whose taste and perseverance we owe so much.

By the denuding process mentioned by Mr. Britton, every thing accounted beautiful in the world might be rendered both uncouth and ugly: thus, take away the features of the finest head and face, you have remaining a raw skull: take away the sauce garniture and cookery of a feast, and you leave but crude flesh, raw vegetables, and a few other things equally untempting.

The builders of the Christian steeples, those outward beacons of a religious country, so caught from the true sublime one of the chords holding mastership over the human heart and feelings, that the tottering child and the snowy-headed old man, the religionist, and the scoffer, the churchman and the sectarian, alike pay the tribute of admiration to the beauty of form of the Church spires built by our forefathers on principles the mechanism of which, perhaps, they cannot understand, and from feelings, which though some of them cannot possess, yet cannot but revere.

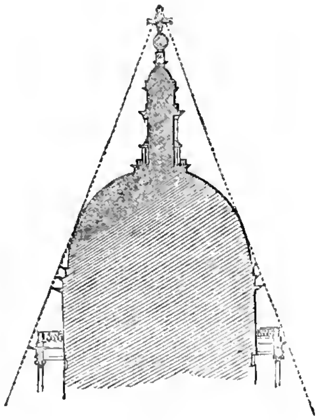
But the truth is, the myriads of these glorious outward church adornments which told at every step the alien as he came to Europe, in this land Christ is great, now deemed useless though sublime, employed industriously and profitably that portion of our Christian population which from the want of employment now begs or tenants the workhouse and the gaol.

No object exists more sublime than the steeple of St. Peters' Church at Caen, unless it be that of St. Michael's Church at Coventry,—none more sublime than St. Michael's, unless it be that of Louth,—none more sublime than Louth, unless it be that of Chichester Cathedral,—none more sublime than the steeple of Chichester Cathedral, unless it be that of Antwerp Cathedral,—none more so than Antwerp steeple, unless it be that of Strasbourg Cathedral,—none more so than Strasbourgh steeple, unless it be that of Freibourg in the Breisgau,—none more sublime than Freibourg steeple, unless it be that of Salisbury Cathedral, which tapering up to heaven in beauteous proportion till it seems more lofty than it really is, appears as though it had drawn down the very angels to work over its grand and feeling simplicity the gems and embroidery of Paradise itself; and, indeed, the most gorgeous of the English florid works of architecture always retain such a peculiar character of sacredness that they always unfold a truly religious appearance.

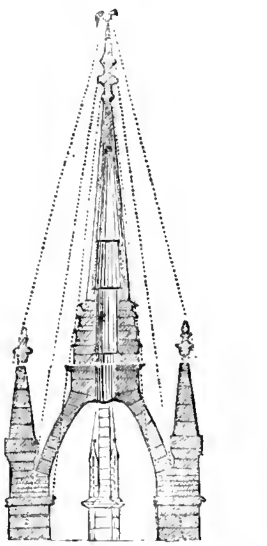
The pyramid is Nature's own form; her mountains, the grandest of earthly masses, diminish to heaven; architectural science requires that a building to endure should end in a pointed summ t: a mere heap of sand will by its own gravity assume a pyramidal form, and so endure for thousands of years, and long outlive a wall of granite reared perpendicularly.

The feeling of love for the scientific and picturesque form of the pyramid is so inherent in man, that any modern steeple which is erected, is immediately universally condemned if its outline be not strictly pyramidal, and the most illiterate, who knows not why he condemns it, is strictly correct in his condemnation.

A pyramidal outline is of such importance, that if even a dome do not conform to it, ungraceful clumsiness, and disgust to every class of beholders, are the sure results. In this may be seen the wonderful art of Wren, in proportioning the dome of St. Paul's Cathedral. The cupola is placed a great distance within the tambour, so as at once to suit the particular scheme of its construction, and to form a pyramid.



Outline of St. Paul's Cupola.



Diagonal outline of the spire of St. Dunstan's in the East, London.

* We have through the kind permission of the author, taken this paper from a work recently published by him, entitled "Specifications for Practical Architecture; preceded by an Essay on the decline of excellence in the Structure and in the Science of Modern English Buildings."

De Quincy says it appears very harmonious, notwithstanding this peculiarity; but the truth is, that the perfection of its form emanates from this diminution. Indeed, many of the modern cupolas built by Sir John Soane and others, being almost as large in diameter as their tambours, show as little mastery of the picturesque as of construction, and violating the principles of *natural* taste, have become so unpopular as to have obtained for themselves the cognomen of 'Pepper-boxes;' and the same title, but too often applies to bad copies of the ogive domes of King's College Chapel, from their not being built with the graceful and spiring elegance of their prototypes.

The principle of the picturesque in architecture, absolutely requires that if a mass have not a plain square outline, it should appear to be hewn out of an exact pyramidal or conical block.

The principle appears to have been first discovered in Egypt, and to have spread over all nations from China to the farthest extremity of Europe.

The same principle pervades the Egyptian pyramid, the Egyptian needle, and those vast moles of masonry which ascend to an enormous elevation before the Egyptian temples: it pervades the Grecian and the Roman Temple, the Athenian Choragic monument, the Pagoda of China, the mysterious edifices of Mexico, the temple of ancient Hindoostan, the Mosque and the Tomb of the Moslem, and the Christian steeple.

The Greeks, whose several states were inconsiderable, and therefore incapable of raising such ample funds as powerful kingdoms like ancient Egypt or modern Britain, never erected buildings which were not small and low: most of their edifices, therefore, not breaking above the general altitude of their dwellings, they did not require that strict attention to perfect pyramidal outline which was always attended to in the lofty buildings of other nations. They made no advances whatever in the more lofty departments of science which were requisite, and which were of necessity called into use in the construction of such gigantic edifices, they contented themselves with a mere triangular façade.

Both Greeks and Romans, however, appear to have been well aware of the upward diminution requisite in order to correct the otherwise overhanging appearance of the upper part of a building, whether from optical illusion, or from the projection of a cornice; hence we find many of their finest edifices were formed with the plain faces of their architraves receding, as if to continue the upward diminution of their columns. But the proper display of sculpture in the Frieze of an order, in general forbade that member to recede, except in small buildings, such as the Choragic monuments of Lysicrates and Thrasyllus, which were fully taken into the eye at one view. Of the following ancient buildings the faces of the architraves recede: at Athens, the Parthenon, the temples of Theseus and Erectheus, and the arch of Adrian,—at Salonica, the 'Incantada,'—at Rome, the external and internal orders of the Panthenon, the temples of Jupiter-Tonans and Bacchus, the reputed frontispiece of Nero, the reputed temple of Pallas in the forum of Nerva, the arch of Constantine, and the Ionic and Composite orders of the Coliseum: at Tivoli, the reputed Temple of Vesta: all these examples show the possession of the same knowledge, but different degrees of skill in making use of it; and there is at Agrigentum a remarkable monument, shown by Mr. Wilkins in his 'Magna Græca,' the order, entablature, and other members of which, all converge upwardly in a very peculiar manner, not altogether unlike some of the spires of Norman architecture, as at Rochester Cathedral. This structure is reputed to be the tomb of Theron, Tyrant of Agrigentum.

In buildings to be viewed from a great distance, the great art consists in making them appear pleasing from every point of view. Wren was in this as great a master as in geometry and construction: not only do his steeples bear the test in a front view; but when viewed diagonally and in various other ways they still conform to pyramidal outlines whether passed down their utmost breadth, or through the distended open parts of them which appear in a side view.

How ill the moderns have succeeded in steeple building by piling one discordant heap upon another, may be gathered from the almost universal contempt with which the architect, the architectural critic, and the public in general, view our modern steeples: to raise upon each other, to coarse broken outlines, imitations of delicate small works of ancient architecture which stood on the ground, cannot satisfy the mind or the eye: these things all require to be designed on purpose: the higher the stages of the work ascend they are more and more restricted in general magnitude by the outlines of the pyramid, yet from their superior altitude they require to be designed in a larger and simpler style, otherwise, not being read by the eye, they become confused and thence tasteless. The steeple of the new church at Shadwell, from being formed with a good outline, has received almost general praise, although its details are coarse and its materials are mean and fragile: the easy labour of drawing two pencil boundary lines, meeting at its summit, gained for its designer this praise, and saved him from the reprehension given to many works, the details of which would rank higher if placed in proper situations. The author always knew that good steeples were formed on this principle, and he has been much pleased by finding the boundary lines remaining in pencil upon ancient drawings of them.

ARCHITECTURAL COMPETITION.

Sir—I admire exceedingly the bitter complaints which the members of the profession never cease to pour forth, upon the manifold wrongs and indignities to which they are exposed in architectural competitions—as if the fault were attributable to any one but themselves.

I am not going to waste the time of your readers upon any new version of the lamentations of the architects—they may be heard wherever architects most do congregate, and will continue to be heard until the profession take the remedy for their grievances into their own hands, a course they have never yet attempted to any good purpose, because they have never attempted it in earnest. The Institute of British Architects, indeed, have published a report in which they profess to denounce the present system of competition, but they roar you as gently as any sucking dove. They are polite enough to assume that if any unfairness ever attaches itself to competitions, it is only now and then by mistake. They make no endeavour to fix the position of the profession with regard to the competition-monger, and they shrink from the only probable remedy for injustice on the one side, and meanness on the other—exposure. If the profession really seek for justice in competitions, let them ascertain their due and demand it, let them sift every unsatisfactory proceeding and expose it, regardless of the regulation sneer at "disappointed candidates," and let them, O let them acquire a little honest pride, and not persist in snapping at every paltry bait dangled before them, without even a decent concealment of the hook.

In the mean time, until the profession think it worth while to rouse and shake themselves, it may be of some use to collect *facts*, and a pretty collection we might have if every one would but speak out who could. I consider the profession greatly indebted to Messrs. Wyatt and Brandon for the example they set of this course of proceeding in your number for February last, but it is most discouraging that so long an interval should have elapsed without any one having stepped forward to second these gentlemen. I now offer myself in the absence of a better supporter, and beg the favour of you to afford me a place in your pages.

In the month of October, 1839, the following letter was issued:—

Bury St. Edmund's, 29th October, 1839.

"Sir—The subscribers to a new Church to be built in Bury, having agreed to propose to six architects to give designs and estimates of the building, beg respectfully to invite you to do so, and to call your attention to the general nature of the building they require, and to the mode of proceeding which they intend to adopt. The subscribers wish that the church be capable of containing 800 persons upon the floor of it, with an end gallery to contain not less than 150; provision also to be made for side galleries if it shall be found expedient at any time to erect them. That it be faced with white Woolpit bricks with stone quoins, and they wish the architect to specify the materials proposed to be used in the several parts of the fabric, the thickness of the walls, the dimensions of the timbers, and the mode of fitting up the interior.

"The expense of the whole work, after being completed in every respect, must not exceed the sum of £3000.

"Upon the receipt of the designs and estimates from the six architects, the subscribers will arrange the designs in the order which they shall consider the order of merit, and their adaptation to the peculiar circumstances of the case, marking that which they shall most approve No. 1, the next No. 2, and so on. If the subscribers shall think fit themselves to employ a builder to erect the church according to the design No. 1, the architect who has supplied such design shall provide all the necessary specifications and working drawings, and shall employ and pay a clerk of the works, who shall be constantly on the spot, and the architect himself shall as often as may be necessary visit the building, and direct and superintend the work himself, being allowed for the designs, specifications, and working drawings; for his time, trouble and services,—for his journeys, and other expenses, and for the wages of the Clerk of the Works, ten per cent. upon the sum for which the builder shall have contracted to complete the church.—]

"If the subscribers shall call upon the person whose design shall be marked No. 1, to carry it into effect, he shall give security for the execution of his design within months, making the church complete both externally and internally for the sum at which he may have estimated the cost,—such sum not to exceed £3000, and in this case the subscribers will appoint and pay their own surveyor; and an addition of 5 per cent. as architect's commission.

"In case of failure to give such security as may be satisfactory to the subscribers, if called upon by them to do so; he shall have no claim of any kind upon them for any payment or remuneration whatever, and they shall be at liberty to carry into effect any other plan they may select.

"[The subscribers will present to the gentleman whose design is marked No. 2, £15, and to No. 3, £10.

"Should you, Sir, be desirous upon these terms to send a design, &c., for the Church, you will be pleased to inform the subscribers of your intention to do so, by a letter addressed to me on or before the 30th of November next, and you will send the designs and estimates to me on or before the 30th of December next.

"I am, Sir, your's, obediently,
James Sparke, Hon. Sec."

"P.S.—The architect is requested to conform as nearly as may be in the details of the work, to the printed instructions of the Incorporated Society for promoting the building, &c. of Churches."

I wish to lay the facts of this case before the public with as few remarks upon them as possible, but it is necessary here to observe, that it has been stated, by way of apology for the most offensive clauses in this most offensive letter, that they were considered requisite in order to protect the subscribers against a fraud to which other parties, in similar circumstances, had been recently exposed, by a notorious falsification of estimates—but this excuse can by no means be admitted. The subscribers* selected the competitors, and were not justified in assuming that all architects are of the stamp alluded to. I should like to ask the respectable legal gentleman who signs this document on behalf of the subscribers, (begging his pardon for using the *argumentum ad hominem*,) how he would like to be sorted with such vermin as might be raked out of *his* profession?

Whatever opinion the subscribers may have thought fit to hold concerning the parties to whom this letter was addressed, it is certain that the terms it offered were peremptorily rejected by the majority, or by the whole of them for any thing I know to the contrary. It may be presumed, also, that somebody took the trouble to enlighten the subscribers upon some little miscalculations into which they had fallen with regard to the sort of building which £3000 might be expected to produce, since they shortly favoured the same parties with two other letters.

The first of these communications, dated the 18th Nov. 1839, is nearly word for word the same as that dated in October, to the end of the passage marked]. It then proceeds as follows:—

"*If the subscribers shall be unable to find a respectable builder willing to execute the design of any architect for the sum of £3000, such architect shall have no claim of any kind upon the subscribers for any payment or remuneration whatever, and they shall be at liberty to carry into effect any other design they may think fit to select.*

"The plans to be drawn to the scale of ⅛ of an inch to a foot.

"No colouring or shading to any of the drawings except the plans and sections.

"No perspective views will be admitted.

"One-third of the sittings in the body of the church to be in pews 2 ft. 10 in. by 1 ft. 8 in.

"One-third in pews 2 ft. 7 in. by 1 ft. 7 in.

"One-third ditto 2 ft. 6 in. by 1 ft. 6 in.

"The west gallery to be fitted up with open seats with back rails."

The letter then concluded as before from the passage marked [to the end. To the postcript was added,

"Your opinion is requested whether it is desirable that any part of the timber be Kyanized, and if so, what part?

"Your opinion is requested whether 800 persons be too great a number to be accommodated on the floor of the Church, considering that £3000 is the sum to be expended on the whole building, which it is wished to be of an ecclesiastical character, though not of a rich or highly ornamented style."

The last is as follows:—

"*Bury St. Edmund's, Nov. 30. 1839.*

"Sir—I have to inform you of the alterations the subscribers have determined upon, and shall feel obliged by your attention thereto.

"To contain 650 on the ground floor.

"The West gallery 200 children, and a staircase at each end, to be serviceable for the side galleries when built.

"A Tower is indispensable.

"£3000 to be expended on the building exclusive of architect's commission, and of any drawback for duty on the materials.

"Pulpit and desk to be included, but not the furniture of the Church, enclosure of same, or bells.

"The price of Woolpit bricks is about £3 per thousand delivered, but it is presumed allowance will be made for duty.

"It is guaranteed that the building shall be open for public competition.

"The question of Kyanizing is left open.

"Colouring of the elevation to be allowed.

"I am, &c.
James Sparke, Hon Sec."

Upon the faith of the conditions set forth in these three letters, five designs were sent in, three of them by members of the Institute of British Architects. How these gentlemen reconciled it to themselves or to the principles laid down in the report on competitions published in their name, and deal on any terms with parties who had shown by their first letter the sort of *temper* in which they might be expected to meet the competitors, and so gross a misapprehension of the practice and duties of their profession, is best known to themselves. Perhaps they imagined that the passage in italics, in the second letter, was inserted for the purpose of being acted upon, and if so, they are greatly to be commended for the purity of their minds. The other two designs were by gentlemen not known as architects to the profession in London, and these two were the designs preferred. And not without reason; that selected as No. 1, presented the striking feature of *a spire one hundred and sixty feet high*, and was not adopted without certain reflections, anything but flattering, upon the incompetency of the "London Architects," none of whom had been able to produce any thing to compare with it.

Having selected the design, the subscribers proceeded to receive tenders for its execution; but it having been whispered that the estimates of the builders greatly exceeded the stipulated sum, the result was—not that the subscribers rejected the design and chose another—but that the tenders were returned to the builders unopened, and the design referred back to the architect, for the purpose of being altered so as to bring it within the means of the subscribers. Certain alterations having been effected, tenders were received a second time, a contract was made, and the building is now in progress. How the subscribers have fulfilled the conditions they dictated, may be seen by the following statement:

The accepted tender amounted to £3550 (in round numbers).

In addition to this, extra foundations, to the amount of £150 to £200, were found to be necessary, not in consequence of any unforeseen difficulty, such as might arise from the nature of the soil, but because it was discovered that the section, (a copy of which lies before me,) represented the foundations to be *one foot below the surface of the ground!*

The cost of the building is therefore to be from £3,700 to £3,750; nor is this all, for neither plastering nor painting are included in the contract.

Instead of 650 sittings in pews on the ground floor, there are but 360; 180 more are in open seats, and the remainder on benches.

Instead of stone quoins there is not an atom of stone in the building but what may be indispensable. The window jambs, &c., are of moulded brick, not gauged brick, gentle reader, but bricks from the kiln, with good ¾ joints between them.

The side walls are 2½ bricks thick, but, to save materials, are built *hollow*, the construction of the rest of the building being in strict keeping; the side roofs are to be covered with zinc. Whether all this is quite acting up either to the letter or the spirit of the instructions of the Incorporated Society, may admit of a doubt at least; also whether a building with bare walls of ordinary brick, and fittings of naked deal inside, can be exactly said to maintain an ecclesiastical character.

Now these be truths. I offer no commentary upon them, for the case is neither sufficiently novel nor peculiar to call for it. If any thing should be mis-stated, I hope somebody better informed will be so obliging as to correct it, and I am sure your columns will be open, either for that purpose, or for an explanation of the proceedings of the subscribers, which I should exceedingly like to see, that is to say, made upon honourable and equitable grounds. The misfortune is, (to drop now the particular case and pursue the question generally,) that subscribers and committees, possessing the privilege of impersonality, and, as Lord Erskine once said of a corporation, having neither a body to be kicked nor a soul to be d——d, are apt to consider that they have fulfilled every obligation incumbent upon them, when they have squared their moral sense by the Law—and who is to blame them? They have a right to suppose that the architects, in a matter in which they are so much interested, are as well informed both upon the law and the practice as themselves, and content to abide by both, since they send their designs. Lest, however, any professional gentleman should chance to be in ignorance of his legal position, or should

* I beg to observe, that the term "subscribers" is used throughout in the same sense in which it is used by the Hon. Sec. Mr. Sparke, and in no other. The business was of course conducted by a Committee.

be tempted to plead it in extenuation of having offered his back to the saddle, I beg leave to make public the following case and opinion for the benefit of all whom it may concern, and especially of the architectural profession, to whom it is dedicated with the profoundest sentiments of regard.

Case.

Six architects were invited to offer designs and estimates for building a new church. The conditions proposed by the parties making the application are, that the cost of the church shall not exceed £3000, and that it shall be sufficiently capacious to seat 650 persons in pews of given dimensions on the ground floor, and certain other requisitions, and they engage to employ the architect whose design shall be most approved.

From the designs sent in to the parties in consequence of this application, one is selected by them which they consider the best; but the cost of carrying this design into execution will be £3750, and only a part of the sittings is provided for in pews of the required dimensions, the remainder being on benches occupying less space.

It is to be observed, that in the present day it is a common practice to invite architects to make designs, &c., for public buildings, on terms similar to those here stated, and architects of the first eminence have tendered designs accordingly.

In making a design for a particular building, conformable with certain stipulations, and to be limited to a certain cost, an architect has to bestow much careful consideration, in order to make the accommodation required as complete as possible, and, whilst employing the cost to the best advantage, not to exceed it. To effect this, he is obliged to curtail embellishments, which he otherwise might have considered desirable: but another, not restraining himself by the stipulations or the limited cost, makes a design much more ornamental and likely to be accepted. The one who faithfully follows his instructions is, therefore, unfairly treated if the parties who lay down the instructions do not themselves act upon them in making their selection.

In this present case, the design which will cost £3750 in its erection, will have less area than one in which all the seats were to be in pews, and consequently, not only the extra £750, but also the difference in the quantity of building tend to increase an outlay in the decoration, which it could not have had if the author had followed the instructions issued to the candidates. Besides this, the design varies considerably in other particulars from the written instructions.

Mr. Serjeant Talfourd's opinion is requested.

1st. Whether this application to the six architects created an implied contract on the part of those who made it, that if the architects would send in designs, they would select from them one which could be built for £3000, and which should be conformable with the instructions?

2nd. Whether the parties, having selected one which they are carrying into execution at a cost of £3750, and which is not conformable with the instructions in various particulars, are not liable to the other architects to remunerate them for their professional labours?

3rd. Whether such liability to remunerate would depend upon the other architects being able to prove that their designs could be severally executed for the £3000, and were conformable with the instructions?

Opinion.

Although the application to the six architects created an honourable obligation to accept the design of one in accordance with its terms, I regret to be compelled to express my opinion that it did not create an implied contract binding in point of law, and capable of being enforced by action. Regarded as a several contract with *each*, its enforcement would be attended with this difficulty, that no one could prove that *his* plan would have been accepted, if the other plan had not been preferred, without which *he* could show no damage—and if regarded as a joint contract, it must include as a complaining party the architect *preferred*, who has no grievance, and will not of course join in complaining of his own success.

2nd. Unless there is some evidence, whence it can be inferred, that the architects were entitled to expect remuneration in the event which has happened, beyond the mere invitation, I am of opinion that they cannot make any legal claim for payment in respect of exertions, which have been rendered abortive by the bad faith of the proposers.

3rd. Supposing any claim to remuneration existing, as it could only be founded on the failure of the parties inviting the plans to perform the terms of their proposal, it is clear that it must depend upon the ability of the claimant to show his own compliance with those terms. But, for the reason already given, I think the claim, even if made by an architect who is able to prove that his design was within the estimate, and conformable to the instructions, cannot be supported.

(Signed) T. N. Talfourd.

August 15, 1840.

I have nothing more to add except that I inclose my name and address in case any thing in this communication should be construed into a personality.

I am, Sir, your most obedient servant,

K. P. S.

Sept. 15, 1840.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XIX.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. In an article on the Fine Arts in Scotland, (Edinburgh Monthly Review, vol. 5,) the writer says, with reference to some of the recent buildings: "although we cannot but applaud the public spirit with which these undertakings have been projected, we are compelled to speak in less favourable terms of the taste which they display. It unfortunately happens that some of them which offend us most, occupy very conspicuous stations, namely, Nelson's Monument, the new Jail, and the new buildings on the North Bridge; to which, were we to enter into a minute examination, we should feel ourselves under the necessity of making sundry serious objections. But we prefer *to draw a veil* over the subject, sincerely wishing that the next undertakings of this kind may be conducted with more judgment and in better taste."—This is certainly the very pink of good nature in criticism, but as for the judgment displayed in it—it would not be amiss *to draw a veil* over that also. To be sure, the passage just quoted, sounds very prettily, and bespeaks a delicate forbearance on the part of criticism, well calculated to render its writer popular with those who expected a castigation from it. Yet if we *draw aside* the *flimsy veil* of words, what is the writer's naked meaning?—why this: he is perfectly aware that reproof is richly merited, yet instead of showing up the offenders, he prefers *screening* them; instead of holding up errors and blunders, and failures, by way of wholesome warning for the future,—which, perhaps, he felt would be venturing beyond his depth,—he contents himself, good, easy creature, with "sincerely wishing that the next undertakings of this kind may be conducted with more judgment and on better taste"!—which amiable phrase may be handed down to the very end of the chapter of architectural blunders and failures. Really I prefer the motto of "Old Blue and Brimstone," Judex damnatur cum *nocens* absolvitur; and I'm sure there is *no-sense* or nonsense enough in some one of the works mentioned in the paper referred to.

II. Let us, however, try another slice of it. "In examining the various public buildings which have been erected in Edinburgh, within the last forty years, no very favourable view of the progress of our taste is afforded in the circumstance of the first in point of time, namely, the Register Office, being so much superior in design to those which have followed it; and the recent improvements betraying, while they profess to be formed on the style of the ancients, a strange neglect of the principles of composition, and even of the details which come within the grasp of ordinary talent." This is well observed, and if for 'Edinburgh,' we substitute the word 'London,' all the rest will still hold good. Yes we have imitated the ancients after a very strange fashion indeed, or rather have deluded ourselves into the notion that we were actually running a race with them, while we were only hobbling after them on classical crutches. Which reminds me of what was once said to one of the Servum Pecus who piqued himself on his classical exactness: your portico may, as you observe, be *after* the Parthenon, but it lags a confounded way *behind* it."

III. The next slice of this criticism may not be to every one's taste —more likely, perhaps, to turn some folks' stomachs: "We have also to regret the *mania now so prevalent for the Gothic style*, which we cannot help thinking to be inconsistent in every respect, with the manners and the means of the age, and with the great principles of beauty which have been recognized in civilized Europe, as the basis of excellence in architectural composition,"—For this opinion we consign the writer over to Welby Pugin, he being one of those who are desperately far gone indeed in the Gothic *mania*, and therefore likely to take the writer to task to some purpose.

IV. Perhaps John Britton may fall foul upon the writer too, for John has told us in his 'Modern Athens,' that at Edinburgh, "public and private edifices of the most splendid description crowd on our notice"! although there is nothing whatever in his book to confirm—or even give decent colouring to that piece of puff. He assures us, indeed, that that most horribly dowdy building the new Edinburgh Academy, is "a handsome structure, *illustrated* by a beautiful portico *supported* by Grecian Doric columns." But such handsome structures and such "beautiful porticos," are almost enough to make us sicken at the very name of architecture. At beholding them, one is tempted to pray that an earthquake may swallow them up.—And yet after praising that balderdash, Britton actually snubbed the poor Queen on the subject of Buckingham Palace,—though he had previously spoken of it as something prodigiously grand!

V. By very far the greater part of Edinburgh architecture, as regards modern buildings, is even when not censurable for positive faults, of that mawkishly insipid, bald, cold, tame sort, as to be utterly valueless in regard to æsthetic quality. When you have said that the builders employ stone instead of brick and cement, you have gone to the utmost extent of the eulogium they merit. As to architecture properly so called, the Scottish capital is a perfect desert: and should the gude folk of Auld Reikie take this character of it in dudgeon, they ought at least to keep some of their anger for themselves; for if they have not thought it worth while at the time to produce something really deserving praise, they ought not now to be scandalized at finding themselves reproached with want of taste. At all events they may feast upon the flowery flummery with which a certain Doctor has dosed them,—to wit, Dibdin, describing Edinburgh as "a city of palaces, the *Genoa of the North*." Surely there, the Doctor drew most largely upon his imagination; or else must have mistaken some architectural mirage, for a reality, and the plain homespun buildings around him for so many palaces, after the same fashion that Don Quixote mistook the frowsy Moritornes for a lovely princess.—Happy mortals those who like the Don and the Doctor can conjure up princesses and palaces as they please!

VI. "I do not understand what you mean by Feeling: what has feeling to do with architecture?" This was once said to me by one who was by no means the greatest dunce in his profession; whereupon I was tempted almost to reply: "if you rap that thick head of yours against the wall, you will perhaps understand what feeling is—I mean the only kind of it you are capable of comprehending."

VII. 'Effect' is another word that seems banished from the architect's vocabulary: or if the term be occasionally employed, that which it expresses is very rarely considered or aimed at. Instead of being studied and purposely introduced, it appears rather to be shunned. Not but that I have seen effects and singularly striking and beautiful ones too. No thanks for them, however, to the architect; for I have almost invariably found that the most beautiful effects of all, have been entirely the result of sheer accident; and never contemplated beforehand in the design; and further, that where any originality of plan has been adopted—any deviation from the wearisome monotony and insipidity which prevail in the forms and arrangement of rooms, it has in almost every instance been occasioned by some peculiar and *untoward* circumstance in the building that has compelled the architect to fling away his *secundum artem* recipes and prescriptions, and resort to some expedient and contrivance—not of the ready "cut and dried" school, therefore, I suppose, *illegitimate*—and to be more or less original in spite of himself.—It was a marvellous mercy for Sir Jeffry Wyatville that, instead of being ordered to raze Windsor Castle to the ground, and prepare an entirely new plan, he was left to contend with the difficulties imposed by the old one. The consequence is that there are now many piquant parts in the interior, and much variety in the plan, that would else, in all probability, not have occurred.

VIII. It would not be amiss, if, instead of proposing as architectural prize-subjects to students such high flown things as palaces, and senate houses, which are not wanted, the Academy were to require of them ideas, for that which none of our palace-builders have been able to design—to wit, a sentry-box. Those at Windsor Castle and Buckingham Palace, are most beggarly things, literally wooden boxes, not only homely in material, but barbarous in taste. Surely if it were worth while to erect a marble arch before the palace in St. James' Park, it would also have been worth while to erect sentry-boxes that should accord with it; whether they were detached from the arch itself, or made to form part of its design. The perversity of taste displayed in such matters is all the more unaccountable, because one seldom finds similar contrasts of shabbiness and finery in any others. One does not see common earthenware and plate on the same table, or deal chairs and rosewood tables in the same room.—I should certainly like to be informed, wherefore, if there must be sentry-boxes at all in front of a palace, they must invariably be shabby eyesores. Yet, I believe, I might inquire for some time before any one could give me a satisfactory reason. It might possibly be alleged that it would be quite *infra dig* for any architect to attempt to design aught of the kind. Nevertheless I apprehend that a Greek architect would not have scrupled to do so, or have thought it derogatory either to his talent or his art to invent even a sentry-box—if there was occasion for one, with elegance of form. Nay, do we not find among the structures of Athens itself, one that affords a very strong hint—almost a direct model, for such purpose? Would not that example be more consistently adopted by being so transferred than after the manner in which we now behold it copied, without any modification to adapt it for the modern application of it? Scarcely shall I be asked what is the example I allude to, for no doubt, every one will now instantly discover it. As for those who cannot, it matters little to them whether I say what it is now, or a month hence. I am therefore determined not to satisfy their curiosity this time.

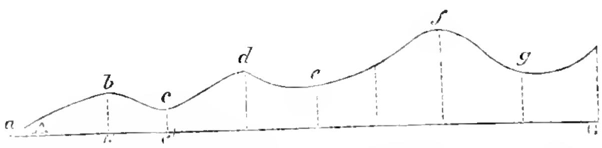
ON THE METHODS OF COMPUTING THE QUANTITIES OF EARTHWORK IN CUTTINGS AND EMBANKMENTS.

By S. Hughes, C.E.

Although the prismoidal formula of Dr. Hutton, by means of which are found the contents of the figures composing cuttings and embankments, is now well understood, and although great facilities for computing these contents are given by Mr. Macneil's tables, and by a tabular sheet more lately published by Mr. Bidder, yet it seems that a ready method of calculating separately the slopes, and the middle part of the excavation or embankment is still wanting.

Mr. Macneil has one table in his book giving areas for a base of 1, and a slope of 1 to 1, from which by simple multiplication the contents for any slope and for any base may be found. Mr. Bidder's table also gives the contents for slopes of 1 to 1, and base of 1, but for lengths of one chain or 22 yards. These tables are useful only for calculating sections where the scale is very small, and where the heights cannot be taken otherwise than in feet, because the tables are only computed for whole numbers. In the process of calculating from working sections however, where the scale is sufficiently large to show the heights in feet, and decimals of a foot, the tables will be of no use, and the following simple formulæ derived from that of Dr. Hutton, mentioned above, are intended to supply the deficiency of more extensive tables, and it is believed they may be used with so much ease as entirely to supersede the use of any tables.

Fig. 1.



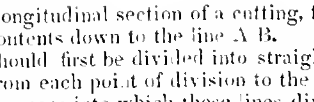
Let *a b c d* be the longitudinal section of a cutting, from which it is required to find the contents down to the line A B.

The surface line should first be divided into straight portions, and vertical lines drawn from each point of division to the line A B. Then the contents of all the spaces into which these lines divide the section being added into one sum, will be the content of the whole cutting. It is required therefore, independently of tables, to adopt a ready method of ascertaining the cubical capacity of a portion of the cutting whose vertical area is represented by one of the before mentioned spaces, as $b\,b'\,c\,c'$.

For this purpose let the two depths of the cutting at the greater and smaller ends, or $b\,b'$, $c\,c'$, be respectively $=$ D and d; let the breadth be $= b$, the ratio of slopes $= r$, and the distance between the two ends $= l$.

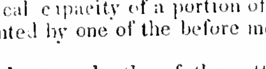
The area of this piece of cutting at the greater end will be

Fig. 2.



And at the smaller end

Fig. 3.



so that the solid figure comprised between these two end areas is composed of a middle part or core which is the frustrum of a wedge, and of two side pieces, which together form the frustrum of a pyramid.

It is evident that the content of the core is simply $l\,b.\,\frac{D+d}{2}$ and by the prismoidal formula the content of the side pieces is also readily

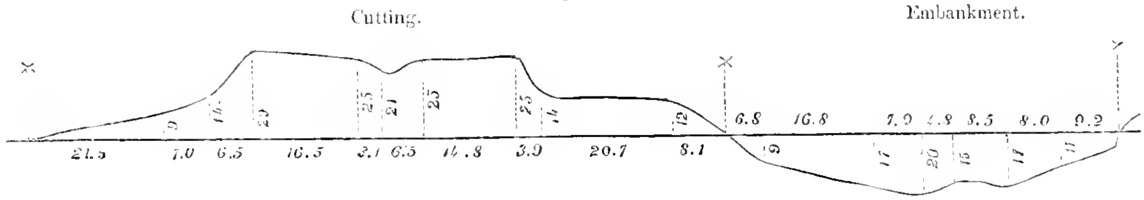
$$\text{found} = l.\;\frac{D^2 r + d^2 r + 4\,\frac{(D^2 r + d^2 r + 2\,r\,D\,d)}{4}}{6}$$

which reduced becomes $= l.\,\frac{r}{3}\,(D^2 + d^2 + D\,d)$.

This expression appears to be so simple as scarcely to require any table by way of aid in the calculation. It is obvious, however, that the only table which can at all be necessary in using this method of computing sections is one of squares, such as may be found in the Engineer's Pocket Book, and many other works of reference.

The following example will show the manner in which the formulæ should be used.

Fig. 4.



Let the above be a part of the section to be computed then the calculation will be as under.

EXCAVATION, No. 1.

Lengths in chains.	Depths in feet.		Middle $(D+d)\,l$	Sides $l\,(D^2+d^2+Dd)$
21·5	0	9	193·5	1741
7·0	9	14	161·	2821
6·5	14	29	279·5	9380
16·3	29	25	880·2	35713
3·7	25	21	170·2	5887
6·5	21	25	299·	10341
14·8	25	25	740·	27750
3·9	25	14	152·1	4567
20·7	14	12	538·2	10516
8·1	12	0	97·2	1166
			3510·9	109882

Middle $3510{\cdot}9 \times \frac{22}{9 \times 2} = 4291$ cube yards for base of 1 foot.

Sides $109882 \times \frac{22}{9 \times 6} = 44767$ cube yards for slopes of ½ to 1.

EMBANKMENT No. 1.

6·8	0	9	61·2	551
16·8	9	17	436·8	8786
7·9	17	20	292·3	8129
4·8	20	15	168·	4440
8·5	15	17	272·	6536
8·0	17	11	224·	4776
9·2	11	6	156·4	2052
			1610·7	35270

Middle $1610{\cdot}7 \times \frac{22}{9 \times 2} = 1969$ cube yards for base of 1 foot.

Sides $35270 \times \frac{22}{9 \times 6} = 14369$ cube yards for slopes of ½ to 1.

Very little explanation will be required to render the preceding calculation understood. It is evident that the multiplication by the fraction $\frac{22}{9 \times 2}$ or $\frac{11}{9}$ is necessary (in consequence of the lengths being in chains, and the depths in feet,) to reduce the first results into cube yards.

And it will also be clear that as the numbers in the column headed "sides," are determined without multiplication by the fraction $\frac{r}{3}$, that is for a slope of 3 to 1, the further division by 6 is necessary to reduce them to a slope of ½ to 1. The quantities may be determined with equal readiness for any slope, integral or fractional, by simply multiplying the numbers found as above, by the fraction $\frac{r}{3}$, where r is the rate of slope required.

It will be found extremely convenient for engineers and others consulting the sections of new lines of railways, or comparing together two or more sections of the same line, to know the quantities for different slopes, and these may be readily exhibited by simple addition, thus:

(For a base of 30 feet.)

EXCAVATION 1.		EMBANKMENT 1.	
	Cube yards.		Cube yards.
Upright sides.	128,730	Upright sides.	59,070
Slopes of ½ to 1	173,497	Slopes of ½ to 1	73,439
" 1 to 1	218,264	" 1 to 1	87,808
" 1½ to 1	263,031	" 1½ to 1	102,177
" 2 to 1	307,798	" 2 to 1	116,546
" 2½ to 1	352,565	" 2½ to 1	130,915
" 3 to 1	397,332	" 3 to 1	145,284

It may be useful now to glance at certain erroneous methods of calculating earthwork which were at one time exceedingly prevalent. These methods have often been the occasion of serious loss and disappointment to contractors and others, by some of whom they are not abandoned even at the present day. It will be shown that calculations of earthwork made according to the common erroneous rules may be readily altered so as to give a correct result. Hence the investigation of these errors will furnish us with new and distinct rules for finding the contents of earthwork sections, each rule being correct and giving the same result as the formula already derived.

I. Let it be required to determine the error occasioned by taking the mean of the two *end areas*, and multiplying this mean by the length for the solid contents of a prismoid. This method may be expressed thus:—$l\,\frac{D\,b + D^2 r + d\,b + d^2 r}{2} = l\,b.\,\frac{D+d}{2} + l\,\frac{r}{2}(D^2 + d^2)$ from which it appears that the difference between this and the correct expression exists only in the side pieces, and is equal to $\frac{r}{2}\,(D^2 + d^2) - \frac{r}{3}\,(D^2 + d^2 + D\,d) = \frac{r}{2}\,D^2 + \frac{r}{3}\,d^2 - \frac{r}{3}\,D^2 + \frac{r}{2}\,d^2 + \frac{r}{3}\,D\,d = \frac{3\,r}{6}\,D^2 + \frac{3\,r}{6}\,d^2 - \frac{2\,r}{6}\,D^2 + \frac{2\,r}{6}\,d^2 + \frac{2\,r}{6^2}\,D\,d = \frac{r}{6}\,(D^2 + d - 2\,D\,d)$. Excess above the correct area. Now this excess is equal to *one-sixth* the square of the difference of the depths multiplied by the ratio of the slopes.

II. The other erroneous method is more commonly in practice than the preceding, and gives a result nearer to the correct one, but the difference here is one of defect, not excess, that is on the wrong side for the contractor. According to this method, an area is calculated for the arithmetical mean of the depths, and this area is used as the one which being multiplied by the length, is to give the content of the figure.

Thus $b\,\frac{D+d}{2} + r\left(\frac{D+d}{2}\right)^2$ is the area corresponding to the mean of the depths from which it is seen that the difference here also between this and the correct area exists only in the side pieces. This difference is readily obtained thus: $\frac{r}{3}D^2 + \frac{r}{3}d^2 + \frac{r}{3}Dd - \frac{r}{4}D^2 + \frac{r}{4}d^2 + \frac{r}{2}Dd = \frac{4r}{12}D^2 + \frac{4r}{12}d^2 + \frac{4r}{12}Dd - \frac{3r}{12}D^2 + \frac{3r}{12}d^2 + \frac{6r}{12}Dd = \frac{r}{12}(D^2 + d^2 - 2Dd)$, which is equal to *one-twelfth* the square of the difference of the depths multiplied by the ratio of the slopes.

We have now examined three different methods of calculating earthwork, the two latter of which require certain corrections; and combining these corrections with the original erroneous rules, in order to render them perfect, the whole three methods may be correctly expressed as follows.

I. Square the sum of the depths and deduct their product, multiply the remainder by one-third the ratio of slopes. To this add the half sum of the depths multiplied by the breadth.

Or,

II. From the half sum of the two end areas deduct one-sixth the square of the difference of the depths, multiplied by the ratio of the slopes, the remainder is the correct area.

Or,

III. To the area corresponding to the half sum of the depths, add one-twelfth the square of the difference of the depths, multiplied by the ratio of the slopes, the sum is the correct area.

EXAMPLE.

Suppose a piece of cutting or embankment 39·8 feet deep at one end, and 24·6 at the other end, the base or top 30 feet, and slopes 2 to 1, required the area, which being multiplied by the length, shall give the true content.

I.

39·8
24·6

64·4 × 64·4 = 4147·36
39·8 × 24·6 = 979·08

3168.28
2

6336·56
3)
2112·19
32·2 × 30 = 966

correct area 3078·19

II.

(39·8 × 2 + 30) 39·8 = 4362·08
(24·6 × 2 + 30) 24·6 = 1948·32

2)6310·40

3155.20

$\frac{2(39\cdot8 - 24\cdot6)^2}{6} =$ 77·01

correct area 3078·19

III.

(39·8 + 24·6 + 30) 32·2 = 3039·68

$\frac{2(39\cdot8 - 24\cdot6)^2}{12} =$ 38·51

correct area 3078·19

The first and third of these methods are recommended to practical men in preference to any of the common tables.

The writer having both calculated himself, and superintended others, while calculating some thousands of miles in length of sections, can speak very positively as to the saving of time which is effected by the simple calculations here pointed out. The mode of applying the first method to extensive sections has been already shown, and the application of the third is equally simple. The labour of calculation is nearly balanced between these two.

12, *University-street*, *Sept.* 12, 1840.

THE REFORM CLUBHOUSE.

(With 2 Engravings, Plates 16 & 17.)

HARDLY shall we be censured for bestowing farther notice on the exterior of this edifice, because, although the Wood-cut view of it in our May number, served very well to convey a general idea of the design and style of architecture, the details and admeasurements could only be guessed at, whereas it is highly desirable that they should be correctly represented on an intelligible scale, similarly to those given of the Travellers' Club-house in the series of "Studies and Examples of the English School of Architecture." We hope that the last-mentioned building, this new production of Mr. Barry's will be fully illustrated by the same artists: in the mean while we shall show in this and our following number, as much as will enable our readers to understand both the external elevations, and the leading arrangement, &c. of the interior; which last we intend to explain by a Section as well as Ground Plan.

Whether there be any who do not admire this piece of architecture, we cannot positively say; yet if any there are at all, we conceive that they are very few. Neither can we be certain that there are none, who do not regret that the style here adopted is likely to supplant that *pure* Greek architecture which, till very lately, was in such repute and request among us. It happens curiously enough, however, that the Reform and Conservative Club-houses, almost inevitably force a comparison between their respective styles. While the contrast they present is most striking in itself; it is evidently enough, in favour of Mr. Barry's building: yet whether the two styles are thus fairly tested is a different question, for it may be said that we have here the very choicest Italian confronted not with any example of Grecian architecture, nor with what is considered a skilful and artist-like modification of it, but with what exhibits only the poverty and defectiveness of that style without any of its redeeming qualities. At all events, therefore, the admirers of the latter must now be as little satisfied with that specimen of Sir R. Smirke's taste and ideas of classical design, as those who give their unqualified preference to the Italian style. In no respect is the contrast between the two designs more striking than as to those particulars which exhibit similary of purpose in both. In the one case, we perceive that so far from at all detracting from the beauty or character of the rest, the *area* is so treated as to be exceedingly ornamental, and to give additional dignity to the whole design, being enclosed by a terrace-like screen consisting of a balustrade, upon a deep socle of elegant rustic work; while that of the Conservative Club-house is no better than the area of a common house, and the railing is as poor in effect, and as un-Grecian in design, as it was possible to make it. No less strongly marked is the contrast between these two façades as regards the character they derive from their crowning members: though somewhat less plain and scanty than in some other examples of the same school, the entablature and cornice of the Conservative, tame and meagre enough at the best, now appears utterly insignificant in comparison with the cornicione one of its neighbour the Reform Club-house:—which latter may in fact be considered as the entablature to the whole structure, therefore not at all excessive as to bulk. The same remarkable disparity of character pervades the two designs generally: in Sir R. Smirke's building, almost every part is left chillingly bare and poor, and at the best, shows certain Grecian forms stripped of all their beauty, whereas in Mr. Barry's all the lesser members and details, such as string courses, &c. are made to conduce to architectural elegance and expression. The "Conservative" may be compared to a picture mere *dead-coloured*, the "Reform" to one consistently worked up and carefully finished in all its accessories.

If it be objected that the *microstyle* application of columns to the windows of the Reform Club-house, is not strictly legitimate, inasmuch as those parts are thereby converted into mere decorative appendages; we think that so applied they are less faulty than either *microstyle* orders affecting to be somewhat more than decoration, or than such apology for an order as a few large antæ gratuitously stuck on here and there to the front of a building, and which are allowed to contribute as little towards decoration as they do.

Either Greek architecture does not by any possible modification of it, admit of the variety and richness which the Italian style affords,—at least not where columns are excluded; or else no one has as yet thought it worth while so to mould the former as to render it quite as suitable as the other for buildings of this class. Be that as it may, the example of the Reform Club-house most assuredly is not calculated to obtain much favour for the style of its neighbour; but neither, on the other hand, is it likely to recommend the petty Palladian manner, which has hitherto been generally received as the quintessence of Italian art.

In our account of the interior of Mr. Barry's building we shall have occasion to enter into description, but on the present occasion the elevation given in the plate renders description unnecessary, those of the south and west sides being perfectly similar, except that there the pediments to the windows are alternately segmental and triangular. Besides the elevation, the details of the exterior, viz. Cornicione, windows, &c. are shown in a separate plate, so that the design is perfectly intelligible.

ON THE DISTINCTIVE CAUSES WHICH OPERATED IN PROMOTING THE RISE AND PROGRESS OF GREEK AND ROMAN ART.

By Frederick J. Francis, Architect.

Among all those nations the records of whose history reach to the present time, those of Greece and Rome stand out the most conspicuous and illustrious. Every thing which relates to them, is by common consent, invested with a sustained and continuous interest, which the annals of no other countries are able to produce. The very mention of their names calls up in the mind a thousand noble and spirit-moving recollections, the dynasties of the present age seem to shrink abashed, when placed in comparison with their ancient national grandeur; and we have but to let our thoughts sweep in the range of their contemplations, over the successive epochs of their history to discern at one period or another the ascendancy of every thing great or excellent, whether in political constitution—in national and individual virtue—in the refinements of literature, or the peaceful glories of art.

And yet, great—eminently great, as were both those countries in politics, philosophy and art, no one can doubt that the circumstances which attended the highest national altitude of the one nation, were singularly contrasted with those which attended the other. In Greece, as we shall hereafter see more particularly, the period of purest political freedom was contemporaneous with the development of the sublimest philosophy, and the most exalted art: while in Rome, it is unhappily notorious, that at the time when their literature and arts were at their meridian, the subjects of merited astonishment to foreign and surrounding states, extorting the homage, and compelling the admiration of all—the essential freedom of their political system was totally undermined—the roots of that despotism which was subsequently the wreck of every thing illustrious among them, had firmly implanted themselves, and their successes in art did not so much result from the combined efforts of a people collectively imbued with a thorough passion for, and appreciation of, the sublime and beautiful, as from the effects of a few accomplished but tyrannic emperors, who, by means of a gorgeous display of the beauties of art, hoped to blind the once free born citizens of Rome, to the disastrous consequences which must inevitably accrue to the nation, from the establishment of eastern absolutism; and to amuse them with the tinsel trappings of national prosperity, when they were, all the while, forging for them, manacles, the most degrading that ever weighed down the energy, and annihilated the spirit of the noble and the free.

But to confine our remarks strictly to the subject we have undertaken briefly to examine. It will not be imagined from what we have already stated, that there was any similarity in the principles which gave to the arts of the two countries their leading impulse, or contributed to their final success. As there was a great difference in the period, so was there a marked contrast in the causes, immediate as well as secondary, which induced their consummation among the one people and the other: and a steady consideration of this unquestioned fact, will help to make us duly estimate the relative claims of the two to the higher and more illustrious place in our esteem. In both countries we cannot fail to recognise a state of things wherein the arts were loved, cherished and venerated: but still, Greece in the meridian of her arts, under the sway of Pericles, and Rome, correspondently great, under the dominion of Augustus Cæsar, present far more numerous features of contrast, than analogy; the whole current of the public mind of the one nation ran in a different channel from that of the other; and we contemplate with far greater satisfaction the intellectual eminence of the one, than the splendid, but withal treacherous distinctions of the other.

But it will be necessary for the right elucidation of the subject, that we should glance with some minuteness at the various isolated and connected chain of circumstances which attended the rise of Grecian art, in order that it may the more clearly appear that all analogies to it, are wanting in the correspondent progression of art in Rome.

The rise of Grecian art took place under circumstances singularly striking. Like other nations in their infant state, the country of Greece was originally inhabited by a wild race of hardy mountaineers, men to whom the fortresses of nature were dwelling places, and the pursuits of the chase, a subsistence. Gradually consolidating themselves into societies, settled laws took the place of that uncertain authority founded only on might: the savage barbarism of aboriginal life was laid aside, from being predatory wanderers they became civilized settlers; and progressively advanced in mental and moral acquirement. At a very early period of their existence as an independent people, many of the inhabitants emigrated to the neighbouring coasts, and long antecedent to the parent state, reached to great national eminence and distinction.

The great Ionic migration to the fertile and beautiful settlements of Asia Minor, was the most illustrious of them all; and it was among these celebrated and voluptuous colonies that the real and inherent genius of the Grecian people originally manifested itself. Here philosophy, poetry, history and art first found a home; while the parent state had scarcely emerged from the long pupilage of nations, they had attained the summit of their intellectual development, and were even giving unequivocal symptoms of prostration and decline. They struggled and fell, to rise no more; but as if by their dissolution an additional impetus was given to the efforts of continental Greece, it was only subsequent to the protracted war with Persia, which had been the ruin of her colonies, that Athens, the metropolis and heart of Greece, took the van in the department of art: she then vindicated her claim to that superiority which of right belonged to her, as the capital of a free and manly race; and although formerly she had produced no artists, and possessed no genius equal to those Sicyon, Egina, and Miletus, she now as far outstripped them in the peaceful glories of art, as she had done in the deeds of military and naval valour. She soon reached to her proudest intellectual eminence, and under the fostering sway of the renowned Pericles, showed marvellous proofs that the really sublime and beautiful in material objects were thoroughly appreciated and understood.

But here we pause for a moment to mark the causes which induced these extraordinary triumphs. How was it that among these small, independent, and comparatively insignificant states, the human mind, as if relieved from a burden which formerly oppressed it, and visited with an elastic and buoyant energy, previously unknown, should so signally assert its appropriate dignity, and display its brightest efflorescence.

How was it, that although empires, mighty and illustrious, had preceded even the commencement of her national individuality, who had wielded the sceptres of well nigh universal monarchy, and in whose hands were lodged, treasures the most unlimited, they had never evidenced the possession of aught, but a narrow and contracted intellect—had never been able to achieve anything remarkable in the region of intellectual superiority, nor were even at the summit of their glory, a tenth part so really and truly great, as were those comparatively small and insignificant states.

Are we to look at the nations by whom Greece was surrounded, for the germ of that architectural beauty—that sculptural grace—that artistic excellence, which pre-eminently distinguished them? Did they derive from a source extensive to themselves, as we shall presently find to be the case with Rome, those principles of the beautiful and the sublime, which they so exquisitely carried out and acted upon? Was there ought in the arts of Egypt or the Eastern world, which can be referred to, as giving to the gifted children of Greece, any of the original ideas of that mingled grandeur, simplicity and grace, which are acknowledged so thoroughly to pervade their unrivalled productions? We answer, assuredly not. We think it is doing great injustice to the striking originality of the Grecian mind, to contend that as Rome derived her arts from Greece, so Greece derived her arts from Egypt or Asia. There may be, and there doubtless are, distant and obscure analogies between the architecture of the Nile, cumbrous as it was, and the symmetrical productions of Greece; but still, whatever the Greeks borrowed in this branch of art, was only incidental and subordinate, and became so essentially changed by its tranmission, as to well nigh the product of their own independent and unaided genius. And then, whatever differences of opinion may exist upon this point, it must be admitted by all, that in sculpture and painting they owe to the Egyptians, absolutely nothing. Look at the ideal beauty of their immortal creations, that god-like expression of majesty which pervades one—that manly grace, or matronly dignity which distinguishes another; that winning tenderness which beams forth in a third; and in the whole range of either Egyptian or Asiatic art, can there be adduced one single group or figure, by the contemplation of which a Grecian artist might have caught one additional ray of inspiration, or been enabled so to guide his chisel or his pencil as to convey to his works one previously unimagined lineament of grace, expression or beauty. Emphatically we answer, assuredly not. The Egyptians, a severe people—hard as their own granite—only reached a certain point in the region of art, and attained to no progressive and advancing excellence. In their thorough hatred of reform, and scrupulous attachment to the miscalled wisdom of their ancestors, they laid equally an interdict upon novelties in art, as upon novelties in political affairs; and consequently, in architecture, were never able to reach that singular combination of the sublime and beautiful which pervades the works of Greece: in sculpture, were ignorant of that true ideal beauty founded in the abstract upon nature, yet soaring above any individual instance of it: and in painting, they were, we are competently informed, destitute of all knowledge of expression and grace, and the fascinations of varying lights and shadows.

If then the Greeks did not owe the superiority of their attainments in art, to the extrinsic aid of foreign states, if through the entire range of Egyptian and Asiatic productions, we see, speaking comparatively, absolutely nothing of that mingled grandeur, grace and beauty, which is stamped in almost every creation of the pure Greek mind: we are driven to the conclusion that they derived their excellence from their own direct and inherent genius; that they had, what no other nation possessed before, the elements of pure and exalted art, within the precincts of their own national mind: and were able, moreover, to refine and purify all that they saw around them; bringing about, in short, an entirely new epoch in the history of art. It was their leading aim, and they accomplished it, to raise architecture from the unmeaning and the colossal, into the simple, the grand, and the graceful; to transform the emblematic ugliness which pervaded all the efforts of the earlier sculptors, into the beauty and majesty of the perfect ideal; and to transform into the formerly cold and lifeless productions of the Egyptian painters that perfection of form, outline, and expression, which shines forth for instance in the Venus Anadyomene.

Now who does not perceive at once, from this brief detail, that the rise of the arts in Rome, stands remarkably contrasted with that in the country we have been reviewing. Greece, we have seen, was preceded by no people who had any clear or definite conception of what was really and expressively beautiful, and evolved all that we most admire and venerate from the recesses of her own national intellect: Rome, on the contrary, was in the infancy of her existence, while Greece was perfect and efflorescent, and had, in living in the midst of such mental greatness, just that advantage which a gifted individual has, on being born in an age of intellectual eminence.

In the rise of art in Greece, and in the correspondent rise of art in Rome, there is just this difference, that while with the former nation it was *original*, with the latter it was *derivative;* it is beyond cavil that till the treasures of Greece were disclosed by conquest to the eyes of the ambitious and aspiring Romans, there were no advances made in art among them, worthy distinctive mention—nothing which at all equalled, or can be regarded even as a forerunner to the eminence they subsequently attained.

The Romans in the first ages of their power, under the dominion of the kings, and in the earlier periods of the republic, were practically speaking, unacquainted with the liberal arts. Simple, frugal, and hardy, renowned for wisdom in the senate, and valour in the field, their minds were more engrossed with constant endeavours to preserve unimpaired the political institutions of their country, than to produce ought great or noble in architecture, sculpture, and painting. The severity of their manners forbade all unnecessary display,—they seemed entirely destitute of all love for the beautiful, and all taste to appreciate it: the great men of the time were neglectful of their city, and careless to adorn it. They passed the principal part of their time, says Sallust, in the retirement of the country, practising the frugality which prevailed in the age, attending to the cultivation of their farms, taking no pride in the outward decoration of their capital, and only visiting it upon occasions of religious and judicial solemnity. Everything in short, combines to prove that, unlike their celebrated predecessors, they achieved nothing—unaided and alone, in exalted art. The commencement of their artistic excellence, must be dated from the period when the conquering legions of Scylla, laid siege to the elegant and luxurious Athens; and as the very extreme of refinement to which she had arrived, proved a self-destroying power in her constitution, and, co-operating with other causes, sapped the vitals of her strength, she fell an easy prey to the fury of the relentless dictator; under his revolutionary violence the city of Athens was sacked, pilaged, and destroyed: her matchless monuments of art were rudely transferred from their legitimate resting places—were seized as trophies of Roman valour, and sent to the capital to grace a Roman triumph. Unsparing indeed and merciless was the hand of the conqueror upon the once glorious and sacred city; every thing of value was removed, even to the ornaments which decorated the friezes of the temples, and the basso relievos on the walls. Syracuse, Carthage, and Corinth shared a similar fate; spoliation and pillage marked universally the progress of the Roman arms; and the once proud states of Greece were, one and all, compelled to own the superiority and bow to the power of the foe.

Thenceforward, Rome presented a different aspect from what she had done formerly; no longer severely great, and nationally simple, she had laid aside the just, and equitable spirit of her ancestors, and by embarking in an unprincipled war, became, by her conquest of Greece, possessed of some of the proudest memorials of human genius. Italy was at once inundated with the productions of Greek talent; men stood astonished at the perfection of works—the similitudes to which they had never before witnessed. Grecian artists were everywhere caressed and sought after, and although this, in some respects was desirable, yet, at the same time, it had the effect of putting a complete extinguisher upon whatever rising talent the Roman artists might have possessed. When the grand, the majestic, and the beautiful from Attica was exposed to the eyes of the proud citizens of the imperial city, they were charmed, fascinated, and spell bound; they regarded what they saw, as evidencing consummate excellence, and despairing of equalling that which they deemed unapproachable; the spirit of emulation died within them.*

The influx of foreign productions entirely suffocated native Italian genius, Greek productions became matters of property, and dealers sprung up who manufactured originals to supply the market of the rich collector; galleries were formed to produce genius, which had sprung up, from national demand, without a single gallery, or a single collection of any works, except the productions of their native soil. The most celebrated works were copied and re-copied by the Greeks in all parts of the Mediterranean. Horace alludes to this, and there can be no doubt whatever that the effect was to render all native attempts of the Romans and Etruscans no longer available. For not one great artist is named during the whole period of progressive decay, from the Cæsars to Constantine; and the Romans or Latins never produced any talent worth consideration, till the revival of art in Italy, after so many ages, in the 15th century.†

It is, therefore, abundantly clear from this comparison, that great abatement on the score of originality must be made when reflecting on the peculiar causes, which contributed to the full development of art in ancient Rome. While among the gifted inhabitants of Greece, its principles and its practice seem thoroughly indigenous; while we search in vain, the arts of preceding and contemporaneous nations for any traces of these manifold excellences which distinguish their immortal productions; while, in short, the eminence they attained, mainly resulted from a creative, an ever active self energising influence possessed by the national intellect; with the people of Rome it was as we have seen, entirely and emphatically otherwise. They of themselves evolved, not the material elements of the expressive and the beautiful; they derived all their notions of them from their prostrate rivals, the Greeks. Their architecture, their sculpture, and their painting, all breathes of Attica. It was constantly the aim of the Italian artists to cultivate the Attic taste, they laboured not to produce a distinctive style of art, but endeavoured simply to travel in the path, previously followed by the people of Greece.

To do them, however, justice, it should be remarked that they appear less fettered in their architectural productions. In this branch of art, we discern characteristics more strictly national, and less slavishly imitative than these which distinguish their sculpture or their painting. For although we are aware that before the conquest of Greece, the structures of Rome were both rude and inelegant, and that to the Greeks, the Romans were especially indebted for the more polished forms of columnar architecture, yet as it has been judiciously observed by Mr. Hosking, "the difference between the Greek and Roman styles of architecture is not merely in the preference given to one, over another peculiar mode of columnar arrangement and composition, but a different taste pervades even the details;" and a wide departure is frequently to be traced from the primitive forms of the ancient models.

By their discovery of the arch, which undoubtedly was unknown to the Greeks, the principles of their architecture became more flexible and less unbending; and they were enabled thereby, we do not say to render their productions more strictly beautiful, but more decorative and profusely ornate. The simplicity of the Greek forms could not be excelled by any additional decorative embellishment, the outline of their purest edifices was in perfect harmony with all the acknowledged principles of exalted art. But still, the Romans, whom unbounded military success had swelled with the workings of the most ambitious pride, anxious to erect edifices of corresponding majesty with their achievements in the field, which should be fit memorials of the victories they had won, and appropriate receptacles of the trophies they had captured, threw around the architecture of their city all the fascinations of gorgeous and elaborate decoration, and that violation of the principles of pure taste observable in their works, which if extended to painting and sculpture, would have appeared ridiculous—was in architecture redeemed, by the vastness of the objects to which it was applied, and the nature of the ends it was intended to serve. In all their buildings they certainly show a less refined taste than the people of Greece: it will be seen that they relied for effect less on the sim-

* We intend these remarks to apply chiefly to sculpture and painting, they cannot be extended to architecture, as we shall hereafter see, without considerable modification.

† See Art. Painting. Ency. Britannia.

plicity of form and outline, than on the multiplicity of detail, and glittering profusion of ornament. At the same time let us not deny that splendid were the structures, and magnificent the edifices which, under the sway of the Cæsars, adorned the Imperial city.

> "Not Babylon,
> Nor great Alcairo, such magnificence
> Equalled in all their glories, to enshrine
> Belus or Serapis, their gods, or seat
> Their kings, when Egypt with Assyria strove
> In wealth and luxury."

But, even with this ready acknowledgment of the distinctive excellence attained by the Romans in this branch of art, a reflection presses immediately upon our minds, which detracts from the glory of the nation itself, and gives us humiliating thoughts of their condition, even while we admire the splendour of their city. With the people of Greece the period of greatest architectural triumph was contemporaneously with their possession of the purest political freedom. The enthusiasm in favour of art was not confined to a few, but pervaded the minds of the whole people; Pericles was but the instrument of the national will—merely acted in conformity with the national spirit; but in Rome there was unquestionably magnificence, yet it was the magnificence not of popular enthusiasm, not as the result of any love for the beautiful pervading the mind of the nation, but rather of a few accomplished, but withal tyrannic emperors. The liberty which had distinguished the nation in the purer ages of the republic, which had been at once the consolidation of their political system, and the secret of their military success, was fast vanishing away. Under the domination first of dictators and then of emperors, the people lost, one after another, the principles of pure and exalted liberty: tyranny usurped the place of freedom, and while there was thrown around their declining dynasty all the splendour which characterizes an Eastern empire, it was at the same time in near connection with that slavish and degrading prostration of the nation's mind, which is its inseparable concomitant.

Architecture then, with all its multiform resources of grandeur and beauty was resorted to, and diligently encouraged by the Roman emperors; not, as was the case with the rulers of Greece, with a view of rousing the minds of the nation at large to an appreciation of the varied forms of material beauty, as contributing thereby to the formation of an elevated and dignified character, but rather from the desire to render the people unconscious of the value of those privileges they were snatching from their grasp. The city was everywhere adorned with emblems of their valour, and trophies of their military success—temples, columns, triumphal arches and fora, were raised in honour of individual emperors, and the mighty deeds for which they were said to be conspicuous, just to cast a false glare around the real condition of the nation, and to blind them to any sense of that thraldom, as degrading, as it should have been felt to be galling, of which they were diligently forging the chains. Instead of the severe manners and stern morality which marked the times of a Brutus and a Scippio, there was introduced that extreme luxury, which comports well with the establishment of an Eastern absolutism, and which invariably weakens, enervates, and eventually destroys the people among whom it takes root.

Under the continual agency of such an influence, even architecture itself gradually declined—all taste was corrupted, and art consequently soon felt into utter extinction. The empire itself fell by an act of suicide, and dragged into the chasm, literature, science and art, and for many ages the slumber of primitive barbarism enwrapped the face of Europe. Unlike, however, other nations who, when once ruined, have been ruined utterly, she "has conquered and been conquered—and again has conquered her conquerors." After her ancient fall, she was destined once more to rise again,—"when her carnal empire had been stripped off from her, she came forth as the queen of a spiritual empire, and within her walls, the dead seem to stand side by side with the living, in awful and most indisguisable communion." Her arts again revived in the 15th century, Italy vindicated to herself the possession of that originality she had not evidenced in ancient time—she came forth like a giant refreshed with sleep, and reared up men of the profoundest genius, such as Michael Angelo, Raffaelle, Leonardi, Titian, and others, who have shed a halo of glory around the age they adorned, and rendered it memorable and illustrious in the annals of art.

Here then it is time to close—we have traced the rise of the arts in the two countries, and have seen that while with the one they were original, with the other they were derivative: we have traced their progressive advancement, and have seen the different characteristics of the two nations, at the period when they were in their highest excellence; we have shown that while in Greece they were conjoined with free political institutions, in Rome they, in far too great a degree were the handmaids and attendants on tyranny. Finally, we have glanced at their downfall, and while we have perceived the dominion of death over Greece to be total, as far as all real greatness is concerned; we have marked the re-vivifying energy exhibited by Rome, and the marvellous display of genius which she has produced in modern times. We have endeavoured in all we have written to do full justice to the claims which the arts of the two countries have, for preference and superiority, and while firm in the opinion that Greece must unquestionably bear the palm, have striven not to forget what was due to Imperial Rome, as the once proud mistress of the world.

PUBLIC BUILDINGS IN LONDON.

A Critical Review of the Public Buildings, Statues and Ornaments in and about London and Westminster—1734.

By Ralph.

(Concluded from page 304.)

Gray's Inn is certainly too considerable a place to be passed over unobserved: but the notice we shall take of it, will be rather in compliment to what it might have been made, not what it is at present; it is no more than a confused heap of ugly buildings that have neither order, regularity or connection, and yet the ground they stand on was capable of all: they might have had a fine open front to the street, and another to the gardens, and that too with as little expence: but the taste of our ancestors did not seem to be altogether fixed on beauty, and we ourselves make but very slow advances towards a reformation. As to the gardens belonging to this Inn, they are certainly an advantage to the students there, and a convenience to the town in general; and if they have not many beauties to entertain you, they have few absurdities to disgust you: it is true indeed they might be made much better than they are, by keeping the vistas full of trees, the walks smooth, and the borders even. The mount and summer-house upon the top of it, might be made quite delightful, and if the two porticos at the ends of the terrace, had been in taste, they would have given an air of magnificence, which at present is much wanting. I could wish too that the piece of ground between the two terraces and the road, was made better use of by the society, than turning it into a kitchen garden, as well as that next Gray's-inn-lane: these two spots might have been covered with trees, in the most beautiful manner, and supplied with fountains, which would make this place one of the most delightful spots about town.

It will be impossible to pass by the new church of St. George, Bloomsbury, without giving it a very particular survey; it is built all of stone, is adorned with a pompous portico, can boast many other decorations, has been stinted in no expense, and yet, upon the whole, is ridiculous and absurd, even to a proverb. The reason is this; the builder mistook whim for genius, and ornament for taste: he has even erred so much, that the very portico does not seem to be in the middle of the church, and as to the steeple, it is stuck on like a wen to the rest of the building; then the execrable conceit of setting up the king on the top of it, excites nothing but laughter in the ignorant, and contempt in the judge. In short, it is a lasting reflexion on the fame of the architect, and the understanding of those who employed him.

The new church of St. Giles's is one of the most simple and elegant of the modern structures; it is raised at very little expence, has very few ornaments, and little beside the propriety of its parts, and the harmony of the whole, to excite attention and challenge applause; yet still it pleases, and justly too; the east end is both plain and majestic, and there is nothing in the west to object to but the smallness of the doors, and the poverty of appearance that must necessarily follow. The steeple is light, airy, and genteel, argues a good deal of genius in the architect, and looks very well both in comparison with the body of the church, and when it is considered as a building by itself, in a distant prospect. Yet, after all I have confessed in favour of this edifice, I cannot help again arraigning the superstition of situating churches due east and west; for, in complaisance to this folly, the building before us has lost a great advantage it might have otherwise enjoyed; I mean the making the east end the front, and placing it in such a manner as to have ended the vista of what is called Broad St. Giles's; whereas, now, it is nowhere to be seen with ease to the eye, or so as justly to comprehend the symmetry and connexion of the whole.

There is nothing in the whole prodigious length of the two Bond Streets, or in any of the adjacent places, though almost all erected within our memories, that has any thing worth our attention; several little, wretched attempts there are at foppery in building, but they are even too inconsiderable for censure.

There is something particular in the manner of George Street, which deserves our attention, it being laid out so considerably wider at the upper end, towards Hanover Square, that it quite reverses the perspective, and shows the end of the vista broader than the beginning, which was calculated to give a nobler view of the square itself at the entrance, and a better prospect down the street from the other side; both ways the effect answers the intention, and we have only to lament that the buildings themselves are not more worthy this pains to show them to advantage. The west side of Hanover Square is uniform, argues a very tolerable taste in the architect, and deserves a good deal of approbation: but all the rest are intolerable, and deserve no attention at all.

I must own this, however, that the view down George Street, from the upper side of the square, is one of the most entertaining in the whole city: the sides of the square, the area in the middle, the breaks of building that form the entrance of the vista, the vista itself, but, above all, the beautiful projection of the portico of St. George's Church, are all circumstances that unite in beauty, and make the scene perfect.

If any thing is wanting, it is a graced building at the end of the vista; and the chapel which now stands there afforded a handsome opportunity even for adding this too, if the undertakers had taste or generosity enough to make the best use of it.

The church of St. George's is, at least, one of the most elegant in London; the portico is stately and august, the steeple handsome and well proportioned, and the north and east prospects very well worth a sincere approbation: but even this structure is nowhere to be seen but in profile, as mentioned above, though situated in the very centre of the vista that leads to Grosvenor Square, and were it not for two or three intervening houses, would be seen in the noblest point of light in the world. In short, it would fill the eye quite from the other side of that square in all its perfection; and I leave any one to judge to what superior advantage it would then appear, and how many more beauties it would add to the prospect.

We must now cross the road to Oxford, or Cavendish Square, I am uncertain by which of those names it is most properly distinguished, and there we shall see the folly of attempting great things, before we are sure we can accomplish little ones. Here it is, the modern plague of building was first stayed, and I think the rude unfinished figure of this project should deter others from a like infatuation. When we see any thing like grandeur or beauty going forward, we are uneasy till it is finished, but when we see it interrupted, or entirely laid aside, we are not only angry with the disappointment, but the author too; I am morally assured that more people are displeased at seeing this square lie in its present neglected condition, than are entertained with what was meant for elegance or ornament in it. To be free, nobody should undertake things of this public nature, without resolving to go through with them; for the declining it afterwards is so notorious, that the whole world has occasion to blame it, though few or none can be sufficiently acquainted with the motives, so as either to defend or absolve.

It is said the imperfect side of this square was laid out for a certain nobleman's palace, which was to have extended the whole length; and that the two detached houses which now stand at each end of the line, were to have been the wings; I am apt to believe this can be no other than a vulgar mistake, for these structures, though exactly alike, could have been no way of a piece with any regular or stately building; and it is to be presumed this nobleman would have as little attempted any other, as he would have left any attempt unfinished.

The house of the late Lord Bingley, on the west side of the square, is one of the most singular pieces of architecture about town; in my opinion it is rather like a convent than the residence of a man of quality, and seems more a copy of some of Poussin's landscape ornaments, than a design to imitate any of the genuine beauties of building. I may be mistaken, perhaps, in my opinion, and what I esteem Gothic, heavy and fantastic, may really be harmonious, light and elegant; so I leave the determination of it to better judges.

I have now brought this painful survey almost to an end, and am not a little pleased on that account; it was not so easy a task as I at first imagined, and whoever will make it their guide to measure the same ground, will be of the same opinion; huge, indeed, as this city is, the toil of examining it from place to place is the least; for a building ought to be viewed several times before we come to a conclusion, either with regard to its faults or beauties: part of that trouble this Review was designed to save, and if it will not polish the taste, or reform the judgment, it will serve, however, as an index to the public buildings, &c., and point out to the stranger whatever is worthy of his attention.

Grosvenor Square is not only the last addition which has been made to the town, but the last in situation too; and as it is generally understood to be the finest of all our squares, I am sorry I have the opportunity to say it has so few advantages to recommend it, and that the public is disposed to like these few so well; I have frequently observed already, that magnificence should never be attempted; it ought always to be perfect and complete, or else the very essay mocks the builder, and excites ridicule instead of admiration. This is the case of Grosvenor Square; it was meant to be very fine, but has miscarried very unfortunately in the execution; there is no harmony or agreement in the parts which compose it, neither is there one of those parts which can make us any thing like amends for the irregularity of the whole. The triple house, of the north side, is a wretched attempt at something extraordinary; but I hope not many people, beside the purchasers, are deceived in their opinions of its merits; for it is not only bad in itself, but in its situation too; had it been in the centre of the line, there would have been some excuse for the project, but as it is almost in one extreme, there can be no plea remaining; unless the view of taking in some young heir to buy it, at a great rate, may be allowed one.

The east side is the only regular one of the four, and is undoubtedly much the most elegant for that reason; but then even this is not in taste, and neither the house in the middle, nor the two which serve as wings, have anything remarkable to recommend them, though the builder seems to design they should; the pediment over that in the middle, particularly, is proportioned only to the breadth of that house, and not the entire line; whereby it appears that the artist forgot his first design, of making this the main body to the whole.

The other two sides are little better than a collection of whims and frolics in building, without anything like order or beauty, and therefore deserving no farther consideration.

I have often wondered that, in the number of squares which adorn this city, no builder ever thought of an octangular one; I am fully persuaded that it would make a nobler figure than any we have seen yet, and is capable of greater beauties; it is to be observed, though, that I would not have it broken at the angles, for the sake of the streets or entrances, because that would spoil the theatrical appearance of the whole; I would rather choose to have all those inlets under an arch, in the centre of each particular side, and if the superstructure was elevated proportionably, in a grand and noble stile, what was principally meant as a conveniency, would prove one of the most magnificent ornaments in the world.

I would not be understood here as recommending any farther additions to this mighty metropolis; no, I am of opinion the head is already much too big for the body, and therefore its farther growth cannot be checked too soon. But this I leave to the determination of wiser heads than mine.

STONE FOR THE NEW HOUSES OF PARLIAMENT.

Sir—It is much to be wished that anonymous writers would endeavour to give more practical proof of their candour, love of fair play, and other good qualities and dispositions which their signatures profess. In the letter in your last number on the "Stone for the new Houses of Parliament," by "A Lover of Fair Play," though there are some just and reasonable complaints, there is still so much that is unjust and ungenerous, that I think few who have taken an impartial view of the subject will think he has any claim to the honourable title he has assumed.

I am far from thinking that Mr. Barry and the Commissioners are altogether free from censure, and I am decidedly of opinion, that after deviating from their first recommendation, they should be called upon to lay before the public a second report explanatory of the changes which have taken place; and till this is done, I think every body has a right to give his own opinion on the subject. At the same time, however, I think that the tone in which the subject has been treated in many public prints, and which is echoed by your correspondent, cannot be too strongly deprecated. When men of science and reputation are engaged on a public object, their conduct is certainly open to public discussion, but such discussions should be conducted in the spirit of cool and impartial inquiry; the correctness of the judgment of the parties in question should be carefully investigated, but the correctness of their intentions should not for a moment be called in question. Had this been the course pursued on the present subject, there can be no doubt that a satisfactory explanation would have been given by the Commissioners; but when every kind of abuse and brutal insult has been heaped upon them by the lowest political prints, I think no one need wonder that men of science and integrity would not stoop to defend themselves from such impotent attacks.

The following appear to me to be (*primâ facie*) the complaints which may be reasonably brought against the commissioners :—

1. That having been commissioned to make a survey of the quarries throughout the United Kingdom, they omitted to examine those of Ireland.

2. That a very superior Irish stone having been offered to them, without charge for royalty, they declined the offer.

3. That they recommended (among other reasons), "for facility and economy of conversion," a stone which could not be procured either in sufficient quantity, or in blocks of a sufficient size.

4. That on the failure of this quarry, they did not go to another which might be considered to stand next in their report, but to a new quarry, which has also proved insufficient to supply the required quantity.

5. That this deficiency of supply has not been made good by application to the quarry at first so strongly recommended, which is said to contain stone exactly similar to that of the new quarry, and which might be expected to be at the least capable of supplying *some* stone; but that two other quarries have been applied to which are not mentioned in the Commissioners' report. In short, that after all the parade of the commission, the supply of stone has been obtained from three several quarries, not one of which was recommended, nor even its existence hinted at. in the report of the Commissioners.

This seems a strong case against them, and certainly evinces a want of care in the first survey, and some inconsistency in their subsequent conduct, but I have no doubt that many of the objections are capable of satisfactory explanation.

The first charge, I think, a very dubious one, and rests upon the simple question of whether they were commissioned to visit the Irish quarries or not.

The second is entirely refuted by the very judicious remarks with which you have favoured your readers, and by the fact that in colour and general appearance the stone in question was altogether unsuitable to the purpose.

The third certainly evinces some want of care. As to the beauty and probable durability of the Bolsover stone, there can be no doubt, but the thinness of the majority of the beds, which is the great objection, is obvious on a slight examination of the quarry; though the Commissioners, in their just admiration of the quality, might have flattered themselves that by sinking deeper or opening new quarries in the neighbourhood, better blocks could be obtained. It should also be borne in mind that they do not distinctly specify the quarry, but recommend the stone of Bolsover Moor *and its neighbourhood.*

The fourth objection at first sight appears reasonable, but on consideration I think no one will deny that the stone first recommended having proved insufficient in quantity, Mr. Barry was quite right in adopting that which most resembled it in quality, though he had not seen it when acting on the commission; being also within a few miles of Bolsover, it may (though by a little stretch of the meaning of the words) be considered to be in "its neighbourhood."

The fifth objection I am unable satisfactorily to answer. I do not see why the Bolsover stone should not have been used, so far as it would go, in supplying the deficiency (which I believe to be only temporary) in the supply of the other quarry. The quality of the Bolsover appears to me to be far superior to the Anston and infinitely better than the Steetley (which latter, however, I think is only used internally), and there certainly is stone at Bolsover of sufficient size, though not in large quantities. The circumstance of the Woodhouse quarry being only lately discovered (or rather *re*-discovered), removes the objection of its not being in the report; but the Steetley and Anston being old and well-known quarries, it certainly looks like negligence not to have reported on them, and like inconsistency to have selected them though not mentioned in the report. One would certainly have expected that before going to these quarries, consistency would have prompted strong measures, such as sinking shafts, opening new quarries, &c., for ascertaining whether suitable stone was not to be obtained on Bolsover Moor. Such measures may have been taken—I only mention this as one of the points which require clearing up for the sake of satisfying the public.

The most important question, however, after all, is, whether the stone now using is of suitable quality. On this question I am not capable of giving an opinion, but will state a few points which have struck me on an examination of the different varieties of stone, with a view to call forth the remarks of more competent judges.

1. The stone from Mansfield-wood House is not, as has been stated, *exactly* like the Bolsover. It very strongly resembles it, but differs in having a browner and less brilliant colour, and in having a far greater proportion of black metallic specks, which in some blocks are minute and clearly defined, in others large and diffused. This difference appears to be a great cause of the difference of colour which is observed among the blocks. On the whole, I think the Mansfield-wood House a darker coloured and less beautiful stone than the Bolsover, but still a very beautiful stone.

2. The question may be asked, what proof have we of the durability of this stone? In answer to this, I think it may be safely said, that there is every reason to believe that the stone used in the Norman parts of Southwell Minster, and which was supposed to be the Bolsover stone, was, in fact, procured from Mansfield-wood House. A comparison of the stone from the two quarries with that at Southwell would, I think, satisfy any careful observer on this head.

3. The Anston stone does not appear equal to either the Mansfield-wood House or the Bolsover, but is still a good and probably a very durable stone.

4. The Steetley appears to be a very friable stone, certainly semi-crystalline, but the crystals detached and ill-cemented. It is, I believe, only used internally, but I much wonder that the infinitely more beautiful stone of Roche Abbey, which is so eminently suited to internal work, was not preferred.

What your correspondent can have discovered in Mr. Bald's very interesting papers, to confirm so decidedly the superiority of the Irish limestones, I am at a loss to discover. Mr. Bald's papers only treat of the white limestone of Antrim, which no one even dreamed of recommending for the Houses of Parliament, and which Mr. Bald says should never be used for any buildings where durability is an object. Your correspondent is, perhaps, not aware that Dr. Smith, of whom Mr. Bald speaks with veneration as the father of English geology, and who, he says, has carefully examined the Antrim limestone, is himself one of the Commissioners who have been so much vilified.

I have the honour to be, Sir,
Your most obedient servant,

London,
September 3rd, 1840.

ANOTHER LOVER OF FAIR PLAY.

P.S.—It is a question worthy of being investigated, whether magnesian limestones have not a tendency to acquire a dark and gloomy colour by age. The old churches and other buildings on that formation have certainly a gloomy appearance compared with those in some parts of Northamptonshire and Lincolnshire, which are of oolite. May it not be the case that the lichens which grow on the magnesian limestone are of a dark disagreeable colour, while those which thrive on the oolites are of a white livelier hue? This is rather an important question.

ON FIRING BLASTS UNDER WATER.

MR. EDITOR,—It occurs to me that a much more simple, and much more efficient method for firing blasts under water, may be obtained, than the method used to break up the Royal George, and a method so simple that it would not require a colonel to superintend. A percussion cap is all that is necessary to fire 10,000 lb. of powder as easily as an ounce. Suppose that an air-tight compartment at the top of the powder cylinder, to be fitted up with an apparatus similar to the lock of a gun. and a strong spring carrying 4 or 5 hammers, to strike as many caps. The cock to set the spring being ground into the side of the box, and fitted with a leather collar; the trigger should also pass into the box in a similar manner. What would be more easily for the diver after having secured the cylinder strongly to its place, than to raise the spring and fasten a strong line to the trigger; the line might be of any length, and when strongly pulled would as effectually fire the blast as a dozen batteries. The caps being inside the air-tight box would be protected from the water and kept dry.

Mines might thus be fired at the exact instant when they would do the greatest mischief to the enemy.

It is a fact well known to engineers and miners, that when it is desirous to detach a large mass of rock by means of several blasts, a great part of the effect is lost by not being able to explode them at the same instant; but by means of percussion caps a hundred blasts might be fired at the same instant, a very simple arrangement would be sufficient for this purpose.

Would not cannon be also very easily fired by large percussion caps, and struck by a small hammer held in the hand of the person appointed to discharge the gun?

Those lucifer matches which explode by friction I have used without failure to fire trains of gunpowder, by merely placing two or three in the slit end of a stick (kept down by a large stone), which on being bent sideways and detained in that position by another stick, to which a long line is fastened, on pulling the line the latter stick is withdrawn, and the first carrying the matches, springs straight, the matches scrubbing on the ground or dry stone, explode, and fire the train.

Should you think these desultory remarks worth a place in your Journal, you will oblige,

Your's, respectfully,

C. L. DRESSER.

Commercial Buildings, Leeds, Sept. 4, 1840.

FELLING TIMBER.

SIR—Should the enclosed be of sufficient value in your estimation, to entitle it to a place in the Journal, it is at your service. I cut it out of the "New York Albion" a few years ago, while residing in America. The subject of felling timber is of more consequence to engineers and architects than many of them have supposed, as few would feel desirous of knowing that their labours are not destined in many instances to endure longer than the brief period of their own life, should the dry-rot allow it even that extent of duration.

I was told by a very skilful mechanic in the city of Philadelphia, that he had observed in his own experience that timber cut in the winter was invariably more thoroughly impregnated with sap than at any other time. That as soon as the new wood was at its full growth, say in August, he had found was the best time for felling the timber.

I have myself seen thousands of trees lying in the woods of America, in the state denominated "logged," (that is cut into lengths for the mills) which, were rapidly hastening to decay, and in almost all these cases it was owing to their having been cut in the winter, as there all the logs are left after being cut, till they are needed for the mill, and many are so left for months, nor is it uncommon to see timber under the saw, of which at least one-third is at the time in a state of absolute decay.

Your's, very respectfully,

J. HOLDEN.

36, All Saints Place, Ormond Street, Manchester, August 22, 1840.

"Mr. Rainey, of Middletown, Conn., a ship-builder of considerable experience, having become convinced that the sap was the cause of the decay of wood, instituted a series of experiments to ascertain its place in different seasons of the year, and found that in the winter, the heart wood contained much more than the sap wood, while in the summer it seemed concentrated in the alburnum or outside layers of wood. It has been generally supposed that the sap of the tree was principally in the roots during the winter, and acting on this supposition, Mr. Rainey had preferred for ship building, timber cut in the winter; some cases, however, in which timber cut in the summer was used with that cut in the winter, and remained sound while the latter decayed, induced an investigation as to the cause, and resulted as stated. Mr. R. now uses timber cut as far from December as possible, and finds much less cause for complaint than formerly. The following was one of the experiments that led Mr. R. to doubt the propriety of cutting timber in winter:—

"'Having cut a small oak staddle, on or about the 20th of June, I placed several pieces of it in the fire place, and put a fire under them; after a little while there appeared at the end of the sticks a wet circle describing the exact thickness of the alburnum, or sap wood, and when they became considerably heated, the steam rushed with violence from the tubes of the sap wood, while there was but a small appearance of vapour from the heart wood. About the same day of December, of the same year, I had another small oak cut, and went through with the same process of heating several pieces of the wood; and when they began to be heated, the whole surface of the heart wood, except a small circle enclosing the pith, was wet, but the alburnum was dry, and when they were fairly heated through, the steam rushed with violence from the heart wood, though the whole quantity that escaped, was not so large as in the former case. The results of these experiments accord with a well known fact in regard to the sugar maple, namely, that no sap can be obtained from the tubes of the alburnum of the tree, and therefore they are obliged to bore a hole for the tube through the alburnum, into the heart wood before it will run.'

"Mr. Rainey's inference as to the position of the sap during the severe weather of winter, is probably correct, as we have observed many appearances that would go to confirm it; but, that at the time of making sugar, the sap is found in the heart wood of the maple, is decidedly incorrect, as every person acquainted with the manufacture well knows. In many cases in tapping the trees, the heart wood is not touched at all, and it is deemed desirable to avoid it when practicable.—The sap of the maple will not, however, flow until the temperature of the earth and air has been raised by the sun of spring, and the circulation, which is partially or totally suspended in the alburnum during the severe frosts, is restored.—The relative position of the sap is consequently changed from what it was a few weeks previous, having passed from the centre to the surface through the lateral pores, or what is called the silver grain, as well as commenced its flow upwards to the expanding leaves and branches.

"Farmers find the cutting of timber for posts and rails an important item in their profit or loss account; and if Mr. Rainey's experiments as to the duration of timber can be fully relied upon, or substantiated by further experience, a very great point in domestic farming economy would be gained. We think the early settlers of Western New York could throw much light on this subject, by ascertaining the relative duration of their rail fences made from timber cut in the winter, or midsummer, as most farms must have had specimens of both kinds; and any notices of this nature, furnished us, shall be inserted with pleasure."

TIDE GAUGE.

SIR—My attention was directed by a friend, who is a Civil Engineer, to a paragraph in "The Civil Engineer and Architect's Journal," for May 1838, under the head of "Proceedings of Scientific Societies," Royal Society, giving a description of a new Tide Gauge, constructed by T. G. Bunt, and erected on the eastern bank of the river Avon, in front of the Hotwell House, Bristol, in 1837. At this I was astonished, as I was on a visit at Mr. Mitchell's, at Sheerness Dock-yard, three or four years since, when Mr. T. G. Bunt was carrying on a *self-established* correspondence with Mr. Mitchell, *who was a stranger to him*, and Mr. Mitchell, to my knowledge, actually sent him a drawing of his tide gauge with a description, which so *singularly* and *so nicely agrees* with that given by Mr. Bunt of his *new tide gauge*; and Mr. M. showed me at the time, some of the letters that he had received from Mr. Bunt, which had they come to me from a stranger as they did Mr. Mitchell, I should have thought it great impudence. I have since shown this paragraph to Mr. Mitchell, who, like the immortal Watt, with "dirty" Prony, was too inoffensive a man to attack the person when the injustice done was mentioned to him. I have since this again asked Mr. Mitchell if he had known Mr. Bunt before? He replied, no; nor have I ever seen him. I asked Mr. M. why he ever answered the first letter? He said (and should this meet his Mr. M.'s eye, I hope he will forgive me publishing private conversation), "why, really I thought the person Mr. Bunt, might have a family like myself, and might be striving to gain something by working out his own ideas, at seeing mine in its complete state, but I had no idea of such as you have shown me."

Mr. M. then again showed me his "tide gauge," which as aforesaid, was erected in all her Majesty's Dock-yards, and has answered admirably for years; he also showed me that of Mr. Lloyds, which is quite different.

A description of Mr. Mitchell's tide gauge may be seen in the "Nautical Magazine," for one of the months in the year, I think, of 1835, and which was inserted by a friend of Mr. M.'s, at *that friend's very kind request*.

Now these facts, for the good of the community at large, especially the various scientific gentlemen that read your Journal, whose protection is of importance, I lay at your disposal, and as it is the duty of every person to crush "plagiarism," I have forwarded this, which I would thank you to give insertion in your valuable scientific and interesting Journal, as a "beacon" to warn persons from being unexpectedly similar passive objects.

I am, Sir, your obedient servant,

JAMES INGLIS.

London, Sept. 2, 1840.

P.S.—Since writing the foregoing, I have seen Mr. Mitchell's son who made the drawings and wrote the description that was sent to Mr. Bunt of Mr. Mitchell's tide gauge, who says that the correspondence could doubtless be produced.

[We have omitted the first part of Mr. Inglis's communication, as it only relates to the invention of a tide gauge which has failed, there is no charge of plagiarism against the party.—EDITOR.]

YSTALYFERA ANTHRACITE IRON.

Mr. Evans, of Manchester, has given a report upon the *strength* of the Ystalyfera Anthracite Pig Iron, of the several qualities, Nos. 1, 2, and 3, with a view to ascertain its properties, particularly in relation to other irons, being the result of about 280 experiments upon rectangular transverse bars. The experiments were made by breaking the bars between supports of their distances; namely, of 4 ft. 6 in. and 2 ft. 3 in. apart.

The trials were confined to the transverse strength of 1-inch rectangular bars, with their several values, as under:—

1st. Specific gravity.—2nd. Modulus of elasticity.—3rd. Transverse strength of 1-inch rectangular bars, 4 ft. 6 in. apart.—4th. Transverse strength of 1-inch rectangular bars, 2 ft. 3 in. apart.*—5th. Ultimate deflections.—6th. Power to resist impact, of which the tables† are divided into, and contain bars broken from

72 specimens of No. 1,
65 ditto of No. 2.
61 ditto of No. 3.

all cast horizontally in stand, melted by coke from the cupola in the usual way;—

44 specimens of bars melted as above, of equal mixtures of Nos. 1, 2, & 3;—

24 specimens ditto, of the same melting and mixture, but afterwards planed down to a perfect 1-inch square gauge; and—

16 specimens ditto, of the same mixture, but melted in the crucible.

The area of breaking section is calculated as the square of the depth, into the breadth, and inversely as the length; an example of which is subjoined, for the bars requiring reduction to 1·00 inch square from excess of area at the fracture or otherwise: thus, No. 12 measured, depth 1·002, breadth 1·005, which, reduced, stands 499 5 lb. in the table, under the head of 4 ft. 6 in. bars.

RULE.—To find from the above table the breaking weight in rectangular bars. calling b and d the breadth and depth in inches, and l the distance between the supports in feet, and putting 4·5 for 4 ft. 6 in., we have $\frac{4\cdot5 + b\,d^2\,S}{l}$ = breaking weights in lbs.—The value of S being taken from the above tables.

For example: What weight would be necessary to break the bar, No. 21, in No. 1 table, 2 inches broad, 3 inches deep, and 6 feet between the supports? According to the rule given above, we have $b = 2$ inches, $d = 3$ inches, $l = 6$ feet, $S = 484$ from the table. Then $\frac{4\cdot5 \times b\ d^2\ S}{l} = \frac{4\cdot5 \times 2 \times 3^2 \times 484}{6} =$ 6534 lb.‡

* The 2 ft. 3 in. bars are reduced to 4 ft. 6 in., as being a fair method of obtaining a more correct mean; a separate column in the tabulated form being set apart for them.

† The report contains six tables of experiments made by Mr. Evans, we have given the table only containing the *mean* result of all the experiments. —[Ed.]

‡ The modulus of elasticity is taken from the deflection caused by 112 lb. on the 4 ft. 6 in. bars.

Elasticity calculated from the deflection caused by 112 lb. on inch square

We will briefly take the mean values of each table, together with a summary of comparison of the whole, &c. §*The specific gravity* of No. 1 Iron at 7·093, is rather under the standard 7·207, as given by Tredgold, but above the mean of the No. 1 in Messrs. Fairbairn and Hodgkinson's list, which give 7·032 for twelve different irons of this number. As Tredgold's is a *general* one, and not the result of any particular number; and as it will be found in Anthracite Iron, as well as in Messrs. F. and H.'s results, that the No. 1 is usually a lighter iron than either of the Nos., the above may be considered a near approximation to the usual irons of the same No. or quality made from coke.

Its modulus of elasticity, the mean of which is 13970644 shows the comparative stiffness of the metal, and is given in pounds per square inch.

The *breaking weights* are given in three separate tables, the mean of which makes 444 lb., 445 lb., and 444·5 lb. respectively, which approximate in rather a singular manner to each other, and must be taken as the best proof of *uniformity of strength* and texture of this number, the value of which, as compared with other irons, stand as under:—

Mean of 72 results upon the Ystalyfera Anthracite Iron, No. 1 444 lb.

Mean ditto of 10 different sorts of No. 1, in Messrs. Fairbairn and Hodgkinson's list . . . . 430 lb.

being a superior strength in favour of the Anthracite Iron of about 3½ per cent. I regret that most of the other authorities give the breaking of 1-inch bars on a very limited scale, in few instances distinguishing the different *Nos.* they were made from, and broken between distances of every variety, which is an additional objection to my offering them in the above comparison; but in a summary of a few that I found more easy to reduce, they form rather an inferior value to Messrs. Fairbairn and Hodgkinson's irons.

The following table comprises a summary of the whole of the experiments made by Mr. Evans, together with the same from Messrs. Fairbairn and Hodgkinson's list:—

---

bars.—l = distance in inches between supports.—w = 112 lb.—c = breadth of bar.—d = depth of bar.—a = deflection caused by 112 lb.

Formula. $\frac{w\, l^3}{4\, c\, d^3\, a} = m$. or modulus of elasticity in lb. to work which logarithms had better be employed.

For the above formula, see Messrs. Fairbairn and Hodgkinson's report, Tredgold, &c.

§ "The precise determination of the maximum and minimum specific gravity of cast-iron is of importance to the Founder and Engineer as giving the data upon which the weight of castings are estimated, and which, as stated by authors, are an unsafe guide, inasmuch as the specific gravity of cast-iron varies with its composition,—the way in which it is cast, the rate of its cooling, and the depth of the mould, to an extent not generally considered; hence the different specific gravities of bars cast *vertical*, and those cast *horizontally*."—*Mallet on Iron*. See 7th Report of British Association.

Summary and Comparison of the Total Mean Results from each of the Tables, together with the same from Messrs. Fairbairn and Hodgkinson's List.

Number of experiments 4 ft. 6 in. between supports, and 2 ft. 3 in. bars, reduced to 4 ft. 6 in.	Specific gravity.	Modulus of elasticity in lb. per square inch, or stiffness.	Breaking weight in lbs. of bars, 4 ft. 6 in. between supports.	Breaking weight in lbs. of bars, 2 ft. 3 in. reduced to 4 ft. 6 in.	Mean breaking weight in lbs. (S.)	Ultimate deflection of 4 ft. 6 in. bars, in parts of an inch.	Power of the 4 ft. 6 in. bars to resist impact.
Mean of 72 on No. 1	7·093	13970644	444	445	444·5	1·843	821
Ditto of 65 on No. 2	7·120	14544293	494	499	496	1·632	811
Ditto of 61 on No. 3	7·130	16622197	531	537	533	1·640	916
Ditto of 41 on equal mixtures of Nos. 1, 2, & 3	7·110	15200982	465	479	471	1·553	749·7
Ditto of the same from the crucible, No. 16..	7·190	14894800	551	597	574	1·625	901·2
Ditto of 24 of equal mixtures as the 41, but planed	7·110	14676771	533	539	536	2·447	1313·1
Forty-seven Specimens from Messrs. Fairbairn and Hodgkinson's Tables of Nos. 1, 2, and 3, as under:—							
No. 1. 10..............................	7·032	14132994	433	428	430	1·597	694
No. 2. 25..............................	7·029	14570118	435	443	439	1·626	711
No. 3. 12..............................	7·122	17683712	478	487	483	1·374	685
Summary of the Mean of the 198 Results of the 3 Qualities of Anthracite, and the 47 from Messrs. Fairbairn and Hodgkinsan's List.							
198	7·114	15045711	489	493	491	1·705	849
47	7·060	15462274	448	542	450	1·532	696

In making a comparison of the same numbers of the Anthracite Iron, and those which are comprised in the latter 47 results, the three first of the six only, contained in the preceding table, must be taken, the other specimens being on iron, under other conditions, containing the mixed, planed, and crucible results, &c., a final mean of which may be taken as above:—

Which taken singly, or collectively, show a superior value in every column in favour of Anthracite Iron as compared with the most numerous list of other makes; and it would appear that the No. 1 is the most uniform in texture, strength, &c., having the greatest fluidity, softest, and lowest specific gravity, and for its strength, which is the weakest, is most to be relied upon, as far as it extends.

The No. 2, less uniform a little in texture, and strength, fluidity, &c., but of higher specific gravity, and stronger than No. 1.

The No. 3 still less to be depended upon in the above qualities, but of increased specific gravity and strength to the No. 2.

The equal mixtures show a deterioration of the several Nos., compared to their values separately, and the same as regards specific gravity. The same, but cast from a crucible, exhibit an improved list of values, including a greater specific gravity.

The planed bars show an increased strength above the same metal in the black bar: this is the only specimen whose strength is increased, without the specific gravity being greater also, which must be due to the planing, and not any alteration of metal, &c.

It may be inferred from the whole of the tables, except the last, and the higher specific gravity exhibited by the Iron, the greater the strength.

IMPROVEMENT OF LOUGH ERNE, IRELAND.

Report of the improvement of Lough Erne, for the purpose of rendering Navigable for Steam Vessels, and other Craft, and for keeping the Lake at a more uniform level.

The Upper Lake extends from Belturbet to Enniskillen, and can be navigated through the channels or sources; that along the eastern side is 18 miles in length, and that on the western is about 16 miles, which are described by red dotted lines on the map or chart No. 1.

The Lower Lake extends from Enniskillen to Belleek, its north western extremity, and measures about 24 miles.

The fall from the Upper Lake at Lisgoole Abbey to the Lake at Portora is only 2¼ inches. This is occasioned by the Danes Eel Weirs, the bridges at Enniskillen, and the shoal at Portora.

The Upper and Lower Lakes, considered together, present a most magnificent sheet of water, interspersed with numerous islands, which are in general highly cultivated; and for beauty and luxuriance of scenery cannot well be surpassed, and forms one of the finest lines of inland steam boat communication in the United Kingdom, creating as it does one direct line from east to west of upwards of 42 miles in extent, besides the numerous inlets to every village and farm along its coasts, which may be safely calculated at three times the above length—the whole of which may, when improved, be navigated without the interruption of a single lock or other obstruction, so that, with good steamers, the journey from Belleek to Enniskillen, Belturbet and Wattle Bridge, may be accomplished in a few hours, which at present, I am told, takes the boats, containing only a few tons of goods, upwards of a week, besides their having to be lightened at every shoal to enable them to pass.

The Upper Lough may be termed a series or chain of lakes, branching and ramifying its course along the vallies of the country, forming numerous inlets, which are sufficiently deep at the lowest water to navigate vessels of considerable burthen, and which afford a ready means of transit for merchandize, and the produce of the country, in every direction, particularly to Belturbet, Enniskillen, and Belleek, which latter place is situated on the Lower Lake, and is only three miles distant from the seaport town of Ballyshannon.

Near Wattle Bridge, on the eastern side of the Lough, the Ulster Canal enters, which I expect will be opened in the course of a few months. This canal will form one of the grand outlets for the produce of this finely cultivated country to Belfast, Newry, &c., it being at present shut out completely from competition in these markets, on account of the want of a ready and cheap conveyance by water; and when such great facilities for intercourse and trade present themselves, and requiring comparatively so small a sum for accomplishing such a desirable object, it appears somewhat extraordinary that the improvement of the navigation of this fine sheet of water should have been so long deferred.

The several shoals, eel weirs, and other impediments to the navigation, besides causing the before-mentioned disadvantages, also act as dams across the channel, and retard the natural and regular flow of the water, which is backed up to an incalculable extent, and thrown over the low lands along the different vallies bordering on the lakes, submerging and inundating for several months of the year, from 20,000 to 30,000 acres of the finest land in the country, which, if the water could be taken off, might be brought under the most perfect state of cultivation.

I found, from observations and levels taken on the spot, that the difference of level between the winter floods in January last, and the summer water in May, at the undermentioned points, wa as follows, viz.

Belturbet and Wattle Bridge	9 ft.	0 inches.
Enniskillen	7	10
Belleek	4	0

and the surface of the water, between these points, forms nearly an inclined plane. The least or smallest rise is at Belleek, which is owing to the Lower Lake being of so much greater extent than the Upper one, and acting as a compensation reservoir, and allowing the water to escape more uniformly.

Having given a general description of the lake, I will now enter more into detail, and describe the impediments which exist in the narrow parts of the river, their effects, and what alterations are necessary to improve the navigation and drainage of the country from Belleek to Belturbet, and having been supplied, as I before mentioned, with the very accurate charts published by order of the Admiralty, which point out distinctly the deep and shallow parts of the lake; it became, therefore, unnecessary for me to take the soundings of the whole extent of the lakes, my principal duty was to investigate the shoals and impediments existing at the following places and points, viz.

1st. From Belleek to Roscor.

2nd. Portora.

3rd. The two channels and bridges at Enniskillen.

4th. Dane's Eel Weirs.

5th. Carry Bridge.

6th. Black Rock, and some small ridges of gravel, on the south west passage near Crom Castle.

7th. Blockson Shoal, which is within two miles of Belturbet, and composed of solid limestone rock.

Accurate soundings were taken at the above places, and plans, longitudinal and transverse sections have been prepared which I now forward, showing the depth of water, with the line of proposed deepening for improving the navigation and drainage.

The soundings and other observations were taken at a very favourable time, viz., the latter end of last April and the beginning of May, when the season was remarkably fine and dry; so much so that the water was within six inches of the lowest point ever remembered by the oldest inhabitant residing on the Lake—the floods during the previous winter season being the highest ever recollected.

The above being the case, I was afforded a good opportunity of judging of the effects likely to be produced by "reducing the waters to a uniform level."

The datum or surface of water shown on the sections, is supposed to be nine feet eight inches under the lower edge of the string-course at the springing of the abutment arch, S. W. angle of the West bridge at Enniskillen.

At this level, the water being very tranquil, and with scarcely any perceptible current, I found, by taking accurate levels of the shoals at Portora, Enniskillen, and Dane's Eel Weirs, that the difference of surface between the Upper and Lower Lakes, at their extreme points, only amounted to 2¼ ins.—I was gratified upon determining this fact to find there was no necessity for erecting a lock, as I had been led to suppose there was a fall of from two feet to three feet between the two lakes. This not being the case, it will simplify the works required to be done, both in the execution and the expenditure.

The bridge of Belleek is of old construction, and appears in a very dilapidated state. It is built with rubble masonry, and composed of four arches of the following dimensions, viz.—35 feet, 19 feet 4 inches, 20 feet, and 7 feet 6 inches span. It rests on a solid rock of limestone; the water in the river flows through the large arch, under which there is a deep chasm cut out of the rock 30 feet in depth, caused by the incessant rushing of the water from the falls above, which descend with great violence and rapidity, falling, from the surface of the water at the Eel Weir to the level below, 15 feet in the distance of 100 feet in length.

The arches are evidently too small in capacity for so great a body of water rushing down during the floods, at which times it shakes the bridge very much, making it appear in danger of being carried away.

I would recommend a new bridge being built at this place, in a more direct line with the entrance of the town, with stone piers and abutments, and a cast-iron arch of 100 feet span, with two side arches of stone, 30 feet span each.

The Eel Weirs at the top of the fall are a great obstruction to the free passage of the water, being built of stone, and forming solid walls about 4 feet 6 inches high, and 4 feet broad at the base, by which means two-thirds of the distance across the river is blocked up. These walls or weirs should be cleared entirely away, and a wall erected about five or six inches below the summer level, and 1,100 feet in length, according to the form described on the drawings. The proposed site is a very favourable one for the purpose, being of solid limestone rock—the surface will require very little levelling or preparing, and upon an average one course of stone will be sufficient to build the Dam from one end to another; for this purpose and also for building the proposed bridge there is abundance of flat bedded stone on the spot.

The falls of water at this place are remarkably fine and well worth attention, as they present several such sites for mill power as are rarely to be met with.

The old corn mill at the end of the bridge, which is now working to great disadvantage, will require to be removed (to make way for the proposed weir) to a far better site to be selected.

The three channels of the river course leading to the dam will require to be deepened from one foot six inches to two feet, which can easily be effected, to allow the water to flow freely to the dam; also the point of rock below the line of the proposed dam should be taken off to allow the water to escape to the chasm below. Above the dam there are several good sites for landing places and quays for Steam Packets and Trade Boats.

The channel of the river from Belleek to Roscor, entering the lake is fine, and strait, and of sufficient width. There are several shoals which are composed of gravel and clay, besides the Carry Eel Weir, which is similar to the one at Belleek, (formed of stone) and dams up the water in a much greater degree, causing a head of from one foot six inches to two feet during the floods.

The above shoals and Eel Weirs require to be removed to the breadth and depth shown on the plans and sections, viz., 200 feet wide, and seven feet deep.

The shoal at Portora is formed of gravel and clay, and will require to be deepened as shown on the plan and section.

The West bridge at Enniskillen is of recent construction, and built of rubble masonry, ashlar quoins and arch stones, string courses and parapet for fixing the railing; it has three arches of 45 feet 6 inches span each; segments of circles rise 15 feet 6 inches, and 19 feet 6 inches in height from the surface of water to soffit of arches; piers are 11 feet thick. I was informed by Mr. Maguire, the builder, that the west abutment is sunk 6 feet under the bed of the river, and the other abutment and the two piers 3 feet. The water-way under the arches is very shallow, and the piers and east abutment would require under-pinning, as shown in the elevation; and the channel both above and below the bridge, as well as under it, requires deepening from opposite the Castle to the deep water near the Distilleries below the bridge.

There are several encroachments on the river at this place, in the shape of walls and quays, which should be taken down, so as to give the river its original sectional area.

The East bridge is an old structure and built of rubble masonry, it is composed of five arches of the following dimensions, viz., 22 feet 3 inches; 24 feet; 23 feet; 26 feet; and 21 feet span, and from the surface of the water to the soffit of the arches is 17 feet in height. At this time nearly all the arches were dry, with the exception of one of them, through which small boats might pass. I would recommend the bed of the river under the arches to be deepened and the piers under-pinned.

There are several shoals in the river in the East Channel, which require deepening, particularly at Boston's Ford.

The Eel Weirs at Dane's Weirs appear very formidable erections which almost choke up the channel of the river, merely leaving a small space of about 20 feet in width for the boats to pass through. In other respects, also, it forms a very difficult channel for the Navigation at any time; but particularly so in the winter season; and when the head of water is great, and is necessarily attended with much danger to the boats navigating up and down stream. In summer the boats are required to be lightened, in order that they may be enabled to pass over the shoal. The Eel Weirs are constructed according to the form represented on the plan, and composed of piles, stakes, &c., and made to close with wattles, &c., that few fish can pass through the eyes or gaps. The bed of the river where the Weirs are erected is very shallow, and is composed of clay and gravel.

The banks of the river at this place are high and slope towards the river's edge.

This shoal and Eel Weir, and the shoal and contraction of the Bridges at Enniskillen, are the principal obstructions in this quarter, and which cause the lands and property on the Upper Lake to be inundated to a great extent—these Eel Weirs to be cleared away, and the shoal deepened.

In case the Weirs cannot be purchased for a reasonable sum, I would propose making a cut across the bed of the river near Lisgoole Abbey. The line I have selected is very favourable for this purpose; it would lessen the distance considerably, and might be done for a comparatively small sum. At the same time I would prefer keeping by the river channel, although the distance is greater; still it would be easier accomplished and would keep the channel wider, so as to give every facility to the Drainage and Navigation.

The channel of the river from Dane's Weirs to Carry Bridge is fine and open, with the exception of a few small ridges or shoals of gravel, which can be cleared away in the course of a week, with a good Dredging Machine.

Carry Bridge forms a great obstruction to the navigation and drainage; in fact it can scarcely be called a bridge, as the opening is but 12 feet wide, and 10 feet high, the remaining part being a long wall forming the roadway to the island of Inishmore. In flood time this obstruction creates two feet head of water, and nearly stops the passage of the water; so that although this channel is the finest no boats are able to pass. This erection requires to be entirely cleared away, and the channel deepened according to the section: and instead of the present bridge, I propose that a new bridge be erected of three arches, each 40 feet span, the two side ones to be fixed stone arches, and the centre one of cast iron, in two parts, so as to allow steamers and masted vessels to pass at all times without lowering their chimneys or masts.

Proceeding along the western channel, the Black Rock is the next obstruction to be met with, upon entering the narrow channel, which is from 70 to 80 feet in width. There are a considerable number of large detached pieces of rocks in the sides and bottom of the river, which in summer have only about two feet water upon them, which can easily be cleared away either by blasting or lifting them out of the river with proper tackle.

There are two or three smaller ridges or shoals above this in the western channel, which are composed of clay and gravel, and which ought to be removed to the depth of 7 feet from summer water, and to the width of 100 feet, which can be easily done by the Dredging Machine.

At the ferry at Inishmore there is a fine site for a suspension bridge, which might be elevated sufficiently so as to allow masted vessels to pass. It would also be of great convenience to the county.

Above Crom Castle there are two shoals or ridges, also near Wattle Bridge, which are composed of gravel and clay, and easily removed at a small expense.

Blockson's Ford is of solid limestone rock; this shoal is a great obstruction to the free discharge of the water, and ought to be removed. This part is the most difficult to be remedied, and will require a Coffre Dam, so as to clear one-half of the river, first by blasting and removing the rock, and when this is accomplished, to remove the Coffre Dam to the other parts of the river, and clear it in like manner.

I have carefully prepared Estimates of the before-mentioned works, and find that the whole may be executed in a workman-like manner, for the sum of £29,797.

In conclusion, I beg to remark that I am not aware of any work or project whatever, where so much benefit might be derived at so small a cost, both on account of the Drainage and Navigation, and when it is considered that the Ulster Canal is now on the eve of completion, which connects the port of Belfast with Lough Erne: and the possibility of the projected Junction Canal, which will join Lough Erne with the river Shannon, being carried into execution, it will form a communication from the Atlantic Ocean to St. George's Channel, and as it is a work similar to the Shannon, and next to it in importance, it well deserves the consideration of the Legislature, so as to put it in every respect upon the same footing with that great national undertaking.

Trusting the foregoing Report may meet with your approbation, and the Gentlemen connected therewith, I have the honour to be, Sir,

Your most obedient and humble servant,

Thomas Rhodes.

Estimate of the cost of the proposed works for the improvement of the navigation and drainage of Lough Erne, to accompany Mr. Rhodes's report, dated 13th July, 1840.

	£	s.	d.
New Bridge at Belleek	£8,000	0	0
Dredging the bed of the river from Belleek to Roscor, including the clearing away of the Eel Weirs and the masonry of the proposed Weir	9,147	4	6
Dredging the bed of the river at Portora	784	14	6
Dredging both channels of the river at Enniskillen, and underpinning the piers of the bridges	1,860	19	6
Clearing away Dane's Eel Weirs, and dredging the bed of the river	2,250	0	0
Dredging the bed of the river at Black Rock	150	0	0
Excavating the channel of the river at Carry Bridge, and building a new bridge there, as shown on the plan	6,000	0	0
Excavating and blasting the rock at Blockson's Ford, and other small fords and shoals	1,604	2	6
Total amount	£29,797	1	0
N.B.—If the river course be abandoned at Dane's Weirs, and a cut made across the low lands near Lisgoole Abbey, a further sum must be added of the amount of	3,516	13	0
	£33,313	14	0

Thomas Rhodes.

In the above calculation no allowance has been made for the purchase of Eel Weirs.

FALL OF A SUSPENSION BRIDGE IN INDIA.

It is with feelings of much regret that we announce a lamentable accident which has just occurred at Madras, attended with great personal injury to many unfortunate individuals, though, as yet, so far as we have heard, with but one loss of life. On Monday afternoon the 33rd Regiment of Native Infantry (or certain companies of that corps) were crossing the Suspension-bridge at Chintan Iripett, on their way to escort His Highness the Nabob, and take part in the customary procession to his father's tomb, when one of the great suspension chains at the eastern end of the bridge gave way, precipitating the roadway and the concourse of persons then upon it (about a company and a half of sepoys) into the stream below. The crash must have been tremendous, and great personal injury sustained by many. We hear that 1 Subadar, 4 Havildars, and 26 men were severely hurt and bruised, and several more slightly injured; indeed, had not the elevation of the bridge above the water been so small, and the water itself so shallow, the accident would have been attended with great loss of life. The part of the bridge which gave way was the links of the eastern suspension chain, where they pass over the friction roller of the north-eastern pier. Two of the three links have snapped across, and on examining the fracture it is evident that both, but one more especially, has for a long time been in a defective state, having a crack extending almost through it. Indeed, it seems to us that the bridge has, at some former period, experienced a powerful strain, which had partially cracked these links, weakening them so far, that the pressure of the crowd at once tore away the remaining fibres, and occasioned the whole fabric to give way. It is a fact of some importance, and one perhaps not very generally known, that a concourse of people is one of the greatest loads which can be imposed upon any structure, since it brings a vast weight within a narrow compass, and that the strain is especially severe in the case of a body of military marching in regular order. We may here observe that one of the few occasions on which we have known an English suspension-bridge to fail was about ten years ago at Morpeth, in Northumberland, when exposed to a somewhat similar strain to the one in question, being crowded by persons returning from a fair. On two other occasions, where suspension-bridges at home have given way, it has been during the passage of troops in a regular march over them,—we allude to the bridges at Broughton and Montrose. The severe strain or vibration occasioned by the measured tread of a body of military is indeed so trying to these structures, that it is considered by engineers that they will in this case bear but one-eighth part of the weight they might be otherwise safely loaded with.—*Madras paper.*

ERECTION OF A SAFETY BEACON ON GOODWIN SANDS.

The task undertaken by Captain Bullock, of Her Majesty's steamer Boxer, of erecting a safety beacon on the Goodwin Sands, about seven miles from the town of Deal, has been successfully accomplished, by which it is hoped to avert the dreadful loss of life by shipwreck which has so frequently occurred in that part of the British Channel. To the high credit of Captain Bullock this desirable object was accomplished on Thursday, 10th ult., under his superintendence and that of Captain Boys, superintendent of the naval store deparment of Deal. Captain Bullock has been long engaged in carrying out the above object, and in the arduous duty of correcting the charts in various parts of the globe, and is now doing so under the authority of Government in the waters of England. He commenced at Westminster Bridge, and proceeded towards the Land's End, which is at present undergoing his survey. The beacon he has succeeded in erecting consists of a column about 40 feet above the level of the sea, having cleets and ropes attached to four of its sides, with holds for hands and feet. At the summit of the column is attached a gallery of hexagon form, made of trellis work, and capable of holding 20 persons at one time. Above the gallery, and in continuation of the column, is a flagstaff 10 feet long, thus making the entire beacon 50 feet in height. The sides of the gallery are so constructed as to enable the persons in it to be covered in with sailcloth, which is reefed in and round it, and can be used at pleasure; as also an awning to pass over it, which is fixed to the flagstaff; thus entirely protecting any unfortunate mariner who may seek shelter on the column from foul and tempestuous weather. A barrel of fresh water, together with a painted bag enclosing a flag of distress, is stationed on the gallery, and the words "hoist the flag" painted in the languages of all nations on boards stationed round the inner part of the gallery, so that the foreigner as well as native seaman may be enabled to show a signal of distress, and obtain help from shore, which is about seven miles distant from the beacon. The means by which the beacon has been erected in so extraordinary a place as the Goodwin Sands are as follow:—the foundation of the column is several feet below the surface of the sand, and is secured in the centre of a stout oak platform, extending from it on either side several yards. This is secured by upwards of two tons of pig-iron ballast being lashed to it. In addition to this, eight stout iron bars, each six feet long, are driven obliquely on each quarter of the column, and two also put at a distance of 12 feet on each quarter, and chains attached to them, communicating with the upper part of the column and the gallery. The sands for three or four hours during the tides are high and dry, and present a fine tract of level extending for several miles. Great numbers of visitors from Ramsgate and Deal attended the erection of this tribute to humanity. The first person to mount it was Lieutenant G. C. Boyes, a young and intrepid officer, who, on reaching the summit, hoisted his handkerchief, a fac simile to a union jack. The indefatigable exertions of Captain Bullock, Captain Boyes, Lieutenants Gull and Bowes, and the other officers and men engaged in the undertaking are deserving of the highest praise, they being compelled to work for several hours up to their knees in water. Several visitors afterwards ascended the column, and testified, in the strongest terms, their approbation of this stupendous work for the benefit of humanity.—*Times.*

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

March 31.—The PRESIDENT in the Chair.

The following were balloted for and elected:—John Brannis Birch, Charles Denroche, John William Power, Henry Rawnsley, and George Dobson, as Graduates.

"*On reclaiming Land from the Sea, with Plans illustrative of Works in Loughs Swilly and Foyle.*" By J. W. Bazalgette, Grad. Inst. C.E.

The art of reclaiming land from the sea has been practised from a very remote period. Among the instances best known to us are Romney Marsh, in Kent; the Foss Dyke, in Lincolnshire; and the coasts of Holland and Flanders. The extreme fertility consequent on such reclamations has caused many attempts to be made, and nearly all have been successful; but none presents a greater prospect of success than that about to be undertaken under the direction of Mr. Macneil on the borders of Loughs Swilly and Foyle, in the counties of Donegal and Derry.

Lough Foyle communicates with the Irish Channel by a narrow inlet, above which it spreads over a wide tract of land, and then, suddenly contracting, joins the river Foyle about four and a half miles below Londonderry, up to which city it is navigable for vessels of 500 or 600 tons burden. The rush of the tide through such a small inlet has carried with it great quantities of alluvial soil, which it has gradually deposited on the side of the lough, and thus formed a bank which extends four or five miles in length, and is only covered by the tide at high water. In order to reclaim this tract of valuable land, of about 25,000 acres, it is proposed to construct, somewhat below low water, an embankment or sea wall, of about 14 miles in length. The tide never rises here above 12 feet, nor is there ever any swell in the lough to endanger the structure.

Lough Swilly is wider at the mouth which opens into the Western Ocean, and is consequently more subject to the effect of wind than Lough Foyle. The highest tides rise about 18 feet. Several embankments are proposed, which will reclaim altogether about 2000 acres of land; a tract already reclaimed, which is considered to be of the best quality in the country, lets at 5*l.* per acre. The measurements and soundings to ascertain the best position and requisite depths of the embankments were thus taken. A tide gauge was permanently fixed on which the range of high and low water was marked; a constant register was kept of the soundings, and the time at which they were made; these were afterwards reduced to the high and low water of any one tide. The distances were determined at the same time, by means of a pocket sextant from the boat, angles being taken between certain fixed objects on the shore, so that the exact soundings could be ascertained and laid down with great accuracy. The slopes of the faces of the embankments vary on the sea face from three or four to one, and two to one on the land side. Each has a culvert 4 feet diameter, with sluices and flood-gates, founded upon piling with tie beams, and the spaces filled with concrete, the whole being covered with planking. The gates are at the lowest level of spring tides, so as to allow of the greatest degree of drainage. The wing walls of squared rubble stone stretching on either side of the gates are founded also on a bed of concrete, 4 feet wide by 2 feet deep. These gates are to be used either to keep back the fresh water for the purposes of irrigation, or for scouring away the silt which would accumulate externally in front of them. A bed of puddle, 4 feet 6 inches wide at the bottom and 3 feet wide on the top, extends longitudinally throughout the embankments. The land water is carried away by a series of catchwater drains, which extend around the reclaimed lands at the level of high water, having sufficient fall to secure its drainage through the sluices. These drains are puddled, and have their internal faces covered with sods, at an inclination of two to one.

As there are many situations where stone is very scarce, and where timber abounds, the author has turned his attention to devising a plan of embanking applicable to such localities. It may be thus briefly described; the body of the embankment should be of clay, earth, gravel, and stones, dug from the surface and thrown up in a bank, with a slope suited to the force likely to act upon it. On the water side is placed a strong facing of fascines, 6 feet thick at the bottom and 4 feet thick at the top, embedded in the soil in an oblique direction, the dip being towards the land; they are securely fastened down by iron screws running at right angles through the whole height. The land face is covered with sods. In a country where wood abounds, this kind of embankment would be formed at a very cheap rate. In other situations, where the embankments would be subjected to greater strain, the thickness of the mass of fascines should be increased to 13 feet at the bottom and 4 feet at the top. In this case, at four feet from the front of the bottom of the slope should be placed a row of fender fascines, 3 feet wide by 2 feet high, bolted down, for the purpose not only of defending the face of the bank from the action of the sea, but for retaining all deposits left behind by it; by which means the embankment would in time acquire a natural face of soil, as is the case with some of the embankments in Holland. The average cost of this kind of embankment, including the sluices and the necessary bed of puddle in the centre, would be about 12*l.* per running yard.

This paper is accompanied by seven plans of the proposed embankments and charts of the loughs.

"*On the use of Mica, as a substitute for Glass, in the Windows of Workshops.*" By Joseph Glynn, F.R.S., M. Inst. C. E., &c.

In the windows of the workshops at the Butterly Iron Works so much glass was broken by the chippings of iron, that a substitute was sought which should resist a moderate blow, and yet be translucent. A quantity of sheets of mica were procured from Calcutta, which, when fixed into the cast-iron window frames, were found to resist the blow of a chipping of iron driven off by the chisel with such force as would have shivered a pane of glass. Mica possesses both toughness and elasticity, and when a piece of iron does penetrate it, merely a hole is made large enough to allow the piece to pass, while the other parts remain uninjured. It is not quite so transparent as glass, but it is not so much less so as to be objectionable; but this circumstance is not important at Butterly, as, in consequence of the quantity of fluoric acid gas evolved from the fluate of lime used as a flux in the blast furnaces, the glass in the windows is speedily acted upon, and assumes the appearance of being ground. Mica is a little more expensive than common glass; but, as its duration promises to be much longer, it must be more economical; and if an extensive use of it could be induced, a more ready supply would be obtained—probably from Pennsylvania or from Russia, where it is commonly used for windows in farm-houses, and also on board ships of war, as it is less liable to be fractured by the concussion of the air during the discharge of heavy artillery. It can be procured of almost any dimensions necessary for ordinary purposes, as it has been found in Russia in masses of nearly 3 feet diameter. It is susceptible of very minute subdivision, as, according to Haüy, it may be divided into plates no thicker than $\frac{1}{300000}$ of an inch.

"*On a specimen of White Cedar from Bathurst, New Brunswick, sent by Mr. Churchill.*"

The specimen exhibited to the meeting was of the dimensions calculated for a railway sleeper, for which use it was proposed to introduce this timber, as it is stated to possess, in a very superior degree, the quality of durability in situations calculated to try its properties. It can be imported at about 3*s.* 9*d.* to 4*s.* per sleeper.

Mr. Hawkins observed, that he knew that species of timber well, having seen it extensively employed in the United States. It is an evergreen tree, and grows only in wet or boggy grounds, and is found most plentifully in New Jersey, Maryland, and Virginia. It attains the height of 70 to 80 feet, but is rarely more than 3 feet in diameter. The concentric circles in it are always perfectly distinct, and prove that the tree only arrives at its full growth after a long term of years—as many as 277 annular rings have been counted in a trunk 21 inches diameter, at 5 feet from the ground. The wood is light, soft, fine grained, and easily wrought. It has an aromatic odour, which it preserves as long as it is guarded from humidity. It resists alternations of dryness and moisture better than any other wood, and on this account is extensively used for shingles for roofing. They sell at Baltimore for 4 or 5 dollars per 1000. These shingles will last from 30 to 40 years. It is in great demand for household utensils, so much so that a distinct class of coopers are called cedar coopers. It is used for boat building on account of its great buoyancy. Cedar boards are sold at Philadelphia at 20 dollars per 1000 feet. White cedar rails, with red cedar posts, form the most durable kind of fence, being known to have lasted from 50 to 60 years. The rails are sold at 6 to 8 dollars per 100, and the posts at 12 or 15 cents each.

Mr. Brunel did not think it was a cheap or a strong wood. He had used it chiefly for covering locomotive boilers, as it resisted heat better than any other wood. When he purchased some there was but little in the market, and it was consequently dear.

Mr. Joseph Horne objected to its use for sleepers on account of its tendency to split so easily; but he had found it resist wet perfectly.

April 7.—The President in the Chair.

The following were balloted for and elected:—Thomas Hawksley, as a Member; William Pole and John Dickenson, as Associates.

"*Account of a series of Experiments on Locomotive Engines, more particularly on the 'England,' the 'Columbia,' and the 'Atlantic,' manufactured by Mr. Norris, of Philadelphia.*" By Captain Moorsom, R.E., Assoc. I.C.E.

The engines of which the author more especially treats were constructed by Mr. Norris, of Philadelphia, and sent by him to England, under an agreement to supply "locomotive engines of a higher power, greater durability, and less weight," than could be obtained in this country. They were to be subjected to fifteen trials within thirty days, and prove their capability of drawing "up a gradient of 1 in 330, a load of 100 tons gross weight at the speed of 20 miles per hour; and up a gradient of 1 in 180, a load of 100 tons gross weight at the speed of 14 miles per hour." The pressure of the steam in the boiler was stipulated by the Grand Junction Company (on whose railway the trials were made) not to exceed 60 lb. per square inch.

The construction of these engines is very simple, and the work plain. The boiler is horizontal, and contains 78 copper tubes, 2 inches diameter and 8 feet long each, with an iron fire-box. The cylinders, $10\frac{1}{2}$ inches diameter, are slightly inclined downwards, and so placed that the piston rods work outside the wheels, thus avoiding the necessity of cranked axles. The frame is supported by 6 wheels; the two driving wheels, of 4 feet diameter, are placed close before the fire-box; the other 4 wheels, of 30 inches diameter, are attached to a truck, which carries the front end of the boiler, and is connected with the frame by a centre-pin, on which it turns freely, allowing the truck to accommodate itself to the exterior rail of the curve, and with the assistance of the cone of the wheels to pass round with very little stress upon the rails.

	Tons.	Cwt.
The weight of the engine, with the boiler and fire-box full was	9	$11\frac{1}{4}$
That of the tender, with 21 cwt. of coke and 520 gallons of water, was	6	$4\frac{1}{4}$
Total weight . . .	15	$15\frac{1}{2}$
The engine, when empty, weighed	8 tons.	

The trials were made on the Grand Junction Railway in April and May, 1839, and were continued over the whole distance from Birmingham to Liverpool, except when stopping short at Warrington to take loads; and occasionally making double trips, so as to travel the total distance of 156 miles per day. Attention was more particularly paid to the speed when ascending the gradients, which rise at the rate of 1 in 330 (16 feet in a mile), or 1 in 177 (29 ft. 4 in. per mile), and as the engines approached these gradients frequently either at an accelerated or a diminished speed, the observations were made at the points most remote from the cause of variation from uniform velocity. Some of the trials were made with such a number of empty waggons to make up the weight, that the train attained a length of nearly an eighth of a mile: this required some allowance, which was estimated at from one-eighth to one-ninth in addition to the actual weight of the empty waggons.

The extreme limit of working pressure of the steam in the boiler was 62 lb. per square inch, except for a few minutes on one occasion, when it rose to 64 lb. The usual pressure for the locomotive engine boilers on railways now generally at work, is from 50 to 75 lb. per square inch.

An analysis of the tabulated results of the several trips give these general results:—that on a plane of 1 in 330, with a load varying from 100 to 120 tons, the speed varied from $13\frac{8}{10}$ miles to $22\frac{1}{2}$ miles per hour; that on a plane of 1 in 177, with a load of 100 tons, the speed varied from $9\frac{8}{10}$ miles to $13\frac{8}{10}$ miles per hour.

From the analysis it appears, that allowing in five of the trials the stipulated amount of performance to have been made, and that in five other trials a doubt may exist, still in the remaining eleven trials the exact amount of duty demanded was *not* performed.

A comparison of the journeys *up* from Liverpool to Birmingham, with those *down* from Birmingham to Liverpool, gives rather a singular result. The aggregate rise of the gradients from Liverpool to Birmingham is about 620 feet, that from Birmingham to Liverpool is about 380 feet (exclusive in both cases of the Liverpool and Manchester Railway); the difference, therefore, up to Birmingham is about 240 feet. In 7 journeys of 596 miles up to Birmingham, the engine conveyed 682 tons gross, evaporated 12,705 gallons of water, and consumed 177 sacks of coke ($1\frac{1}{2}$ cwt. each). In 7 journeys of 596 miles down from Birmingham, the same engine conveyed 629 tons gross, evaporated 12,379 gallons of water, and consumed 177 sacks of coke. It would thus appear that the consumption of fuel was the same in both cases, and the only difference was the evaporation of 326 gallons of water more in the journey up than in the journey down, conveying nearly the same load both ways.

The author remarks, that in the early stage of his observations on the engine, he would have inferred that, from the mode of construction, it was not calculated for high speeds, such as are required for the mail trains; yet that he has often seen it travel with apparent ease at the speed of 30 miles per hour; and he thinks that, with some slight modification of the working parts, engines of this construction may be made to do any duty now required from locomotive engines; and, from the small quantity of repair required during the trials (only renewing the fire-bars, which were originally intended for burning wood, and putting nine stronger ferules in the tubes), he is of opinion, that the present construction is exceedingly well calculated for heavy loads—that it may be modified for attaining high speeds—and will prove a durable and economical machine.

Captain Moorsom, in reply to some questions from several members, stated, that although the American locomotive engines had not strictly complied with the stipulated conditions, yet he considered them good, serviceable engines, and it was the intention of the directors of the Birmingham and Gloucester Railway Company to have ten of them on their line. The price of the engine complete, including the import duty of 20 per cent., is from £1500 to £1600. One of the greatest advantages of the engines is the facility afforded by the truck for going round curves—the same engineers managing indiscriminately the ordinary six-wheel engines, and the American ones are observed to go faster round the curves with the latter than with the former. Round a curve of 10 chains radius, they had gone at a speed of 20 miles per hour. They run also quite as well on a straight road. He had travelled on them between Whitmore and Crewe at the speed of from 30 to 40 miles per hour. They appeared less likely to be thrown off the rails than other engines, as in some instances they had run over the short pointers of the Grand Junction Railway—the engineer had merely felt a slight jar, but no accident had occurred. He attributed this to the truck adapting itself so readily to the rails. The coke used in the trials was the same as that in daily use on the Grand Junction Railway, and was of average quality. The mode of attaching the tender to the engine was peculiar, and he conceived it to be advantageous, as it threw a portion of the weight upon the engine and was an assistance in starting. The engines, as they are now constructed, will do well for all ordinary speeds; but if higher speeds are required, a greater expense must be incurred, and certain alterations must be made in them.

Mr. Bury conceived the chief peculiarity of the engine to consist in the end of the boiler being placed on the moveable truck, which certainly enabled it to adapt itself easily to any curve in the railway. The cylinders are in the same position as those in the first of Stephenson's engines, and the other parts are as nearly as possible identical with plain engines constructed in England. The pointers on the Grand Junction Railway are constructed and placed in such a manner as not to throw off a carriage which might run over them, and a four-wheeled engine would not have been thrown off by meeting a closed pointer. To enable him to form a correct comparative estimate of the work done by these engines, it should be shown what power was exerted at the wheels. This was a clear mode of arriving at a result and comparison with other engines.

Mr. Donkin remarked, that the flanches on the wheels appeared to be all that retained them on the rails, and that the truck turning on a centre-pin would allow considerable lateral friction, unless there was some mode of keeping the truck in a proper position when on a straight line of railway. If this kind of engine is superior to those generally in use in this country, it must be in some part of the construction which is not shown in the model or by the description. He inquired whether, in any of the four or six-wheeled English engines, any provision is made for changing the position of the axles, so as to allow of a divergence from parallelism when rounding curves.

Mr. Bury replied, that in the engines on the Leeds and Manchester Railway, although the axles were placed parallel to each other, a considerable allowance was made in the journals of one pair of the wheels, so as to facilitate the passage round curves.

The President observed, that the wheels being turned conically was of much assistance in passing curves, even although the axles were confined by the journals in a parallel position. He was aware that this threw an extra strain upon the curve rails, but that would only require more attention in securing them than on the straight line of railway.

"*Model of the Coal Field of the Forest of Dean.*"

Mr. Sopwith exhibited a model of a tract of 36 square miles of Gloucestershire, comprising the mining districts in the Forest of Dean. This model showed all the undulations of the surface, the towns, villages, and detached buildings, railways, coal and iron mines; and separating vertically through the centre from north to south, and from east and west, exhibited the geological formation down through the coal measures to the old red sand-stone: the construction is such that, by lifting off horizontal layers, the extent and position of each bed of coal is shown, with the extent of the workings in the different collieries, and on each bed is marked the portion that can be worked by level and freed from water by natural drainage. This coal tract forms an elliptical basin; the longest diameter of which, from N. N. E. to S. S. W. is about 10 miles, and the shorter about 6 miles, ranging round Coleford as a centre. There are about 20 beds of coal of various thickness, containing together nearly 37 feet of clear coal. The carboniferous strata crop out regularly all round against the mountain lime-stone and old red sand-stone, and dip uniformly towards the centre of the basin. This could scarcely be shown clearly, even by an almost indefinite number of plans, which induced Mr. Sopwith to project the model, the method of constructing which he described to be by framing together in squares a given number of thin strips of wood, joining them by half lapping at the intersections; on these strips, the profiles of the sections were drawn, from measurements and borings. The compartments of these skeleton frames were then filled in with lime-tree wood, as being lightest and easiest to work, and carved out to the depth of the lines drawn on the strips; by these means a series of horizontal sections fitting into each other were obtained, and when painted of the proper colours, both on the surfaces and on the edges, produced the complete model which he exhibited. The cost of it was about £30 complete. It was constructed under Mr. Sopwith's direction, and from surveys made by him for the Government.

April 14.—The President in the Chair.

The following were balloted for and elected:—James C. Sherrard, and George H. Phipps, as Members; and John Harris, as a Graduate.

"*Description of the Steam Ship 'India,' with a table of the proportions of large Steam Ships.*" By Lieutenant E. N. Kendall, R.N., Assoc. Inst. C. E.

This vessel was built at Greenock by Messrs. John Scott and Sons, and the engines were constructed by Messrs. Scott, Sinclair, and Co. To render her eligible as a packet ship between London and Calcutta, *via* the Cape of Good Hope, the timbers were lengthened so as to admit of the quarter deck and forecastle being raised 2 feet more than is usual; by which means a flush deck was formed along the whole length of the vessel, 200 feet by 29 feet, materially adding to the comfort and convenience of the passengers.

The long flat floor, with straight sides and fine ends, adopted in all the best of the Clyde-built ships, for the purpose of attaining a considerable speed with comparatively small power, and uniting with a light draft of water a good capacity for cargo or passengers, has been adhered to, although the established usage on the Clyde of making the length six times the beam has been somewhat exceeded, without impairing the speed, as the voyage from Greenock to London was made in 86 hours, against a strong head wind during a considerable portion of the time.

The rigging is fitted so as to combine lightness with strength, and the facility of making every thing "snug" when steaming against the wind; the spars being so proportioned as to carry a large spread of canvass when running down the trade winds. There are several improvements in the rigging. Two of them are particularly mentioned. 1st. The employment of iron sockets, into which the shrouds, having been tapered, parcelled, and served, are inserted and firmly rivetted. Instead of passing over the mast-head, they are attached by shackles to a series of holes along the edge of a strong wrought-iron plate or cap which surrounds the mast. This is more secure than the ordinary fastening, as it prevents all chafing or injury from the wet, besides being more compact, and allows any repairs to be more easily effected. 2nd. The mode of fitting the foreyard for coming down readily in bad weather. The truss bow is made sufficiently large to admit of the heel of the fore-top mast passing readily through it, and has on its fore-end an eye through which passes an iron bolt, 5 feet long, which is held in its position by a chain passing round the mast-head; to the lower end of the bolt is attached a chain, which passes through a swivel eye on the yard, and is drawn tight by a screw traversing one of the deck-beams. When the yard is hoisted up, it slides along the chain jackstay, which prevents it from swaying about until it reaches the bolt which enters the swivel eye, and when it is close up, the yard is slung by two short chains shackled on to the mast-head chains. The operations of striking the yard and top-mast may be thus accomplished simultaneously in a few minutes in the worst weather, or they may be replaced in the same short period.

The engines have most of the acknowledged improvements, and are fitted with "Hall's Condensers" in such a manner that they can work with them or with the ordinary condensers. The cylinders are 62 inches in diameter, with 5 feet 9 inches stroke. The diameter of the paddle-wheels is 26 feet; the length of the floats is 8 feet, divided into two parts in the depth, and fixed one before and the other behind the arms. There is an apparatus for cutting off the steam at any portion of the stroke. The boilers are of a peculiar construction, combining vertical flues with a series of horizontal fire tubes, exposing a very considerable surface so as to be worked by slow combustion of the fuel from two sets of fire-places over each other; by throwing on the coals alternately, the gas evolved from the fresh fuel is ignited in its passage over the other fire-places. A considerable economy has been effected by these means.

The paper is accompanied by a drawing of the improvements in the rigging, with plans of the vessel and engines, and a tabular statement of the proportions and scantling of a number of other large steam ships.

ON IRON AND TIMBER BUILT SHIPS.

On the Nemesis private-armed Steamer, and on the comparative efficiency of Iron-built and Timber-built Ships. By Augustin F. B. Creuze, of H. M. Dockyard, Portsmouth.

(From the United Service Journal.)

Most persons who take any interest in naval affairs will have observed, for some years past, occasional notices in the newspapers, of boats and vessels built of iron. It appears to be very probable that this material may eventually almost wholly supersede timber in the construction of boats, barges, steam, and the smaller classes of sailing vessels; and therefore any information as to the manner of building such craft, or on their qualities, and the comparative increase either of safety or danger, by the substitution of iron for timber, must be worthy of notice. The Nemesis, a steam-vessel of nearly 700 tons burthen, and built wholly of iron has been lately docked at her Majesty's Yard, at Portsmouth, for the purpose of having damages repaired, which she had sustained by striking on a rock off Scilly, in thick weather, when on her passage from Liverpool to Odessa. This afforded a most favourable opportunity of obtaining considerable insight into the details of her construction; while the courteous anxiety displayed by the gentleman who built her, Mr. Laird, of the Birkenhead Iron Works, at Liverpool, and by the officer, Mr. Hall, a Master in the Royal Navy, who commands her, to give every information that was in their power, removed all the difficulties which generally attend such a task. The following particulars, as far as facts are concerned, may therefore be relied upon as correct: the opinions which may be intermingled with those facts must, of course, be received only as such. The dimensions of the Nemesis are as follows:—

Length between the perpendiculars	165
Length over all	184
Length from stem to taffrail	173
Breadth	29
Depth	11
Burthen (old measurement) tons	660

The keel-plate was laid in August of the last year; the vessel was launched in November; her engines put on board, and she herself tried in December; and, finally, she was ready for sea by the middle of January.

The vessel is built almost entirely of iron; the exceptions being the plank-sheer or gunwale, which is of oak 4 inches thick and 10 inches broad, brought upon and secured to a planksheer or gunwale of angle iron; the flat of the deck, which is of 3-inch fir; four beams under the deck, 9 inches square. These are forward, and support the carrick-bitts, paul-bitts, and the foremost gun. The remainder of the beams, with the exception of the paddle-beams, which are of oak, 12-inch sided and 14-inch moulded, are of iron. The knee of the head, the rudder, the paddle-boxes, and a light berthing above the gunwale, about 2 feet 8 inches high, are of wood. The coamings and fittings upon deck are generally of wood, although for these purposes more iron is used in the Nemesis than in timber-built vessels. The cabins and fittings for the officers, passengers and crew, are of wood, and are very neat and handsome.

The mean launching draught of water—with masts, yards, rigging, anchor, and cable, with the cabin fittings in a forward state—was, according to the information afforded by Mr. Laird, 2 feet 4½ inches. The mean load draught, with 12 days' full supply of coals, water and provisions, for a crew of 40 men for 4 months, and 3 years' ship stores of all sorts, with duplicate and extra machinery, is also stated to have been 6 feet.

The engines were made at Liverpool, by Messrs. Forrester and Co. The diameter of the cylinders is 44 inches, and the length of the stroke 4 feet. The estimate in horse-power for the two engines is 120. The framings or supports for the engines are of wrought iron. It is usual to have them of cast iron. The greater strength of wrought iron enables them to be made of much less size and weight, and their appearance is also necessarily lighter. The boilers may be worked either separately or together. The paddle-wheels are 17 feet 6 inches diameter to the inner edge of the rim. The floats, which are 16 in number, are 6 feet 9 inches long, and 14½ inches broad. The paddle-shaft is 78 feet abaft the fore-end of the water-line. The vessel carries two 32-pounder medium guns, one forward and the other aft, on pivot-carriages, to fire over all; and it is this which constitutes one of the chief points of interest in the Nemesis. The guns are reported to have been fired several times with an extra charge of powder, and double-shotted. The concussion has left no visible traces on the vessel; and, the experiment, as far as it has as yet been carried, certainly does not militate against the adoption of iron in the construction of ships for war.

The fore-mast rakes 2 feet in 20, and is 32 feet abaft the fore-end of the water-line. The main-mast rakes 1 foot in 20, and is 111 feet 6 inches abaft the fore-end of the water-line. The bowsprit steaves 5 feet 6 inches in 20 feet. The following are the dimensions of the spars:—

	Length, ft.	Diameter, in.
Fore-mast, from deck to hounds	12	15
Fore-mast, from head	8	—
Main-mast, from deck to hounds	42½	15
Main-mast, from head	8	—
Fore top-mast	24	10
Fore head	4	—
Sliding gunter-mast	28	6
Sliding pole	8	—
Main top-mast	33	10
Main pole	13	—
Fore gaff	23	7½
Main gaff	23	7½
Fore-yard cleated	52	10½
Fore-yard arms	3	
Fore topsail-yard, cleated	36	8½
Fore topsail-yard arms	2	
Fore topgallant-yard, cleated	25	6
Fore topgallant-yard, arms	1½	6
Bowsprit, out-board	21	15
Jib-boom, out-board	13	8
Jib-boom, in-board	13½	—

The form of the midship section may be best described by saying that it is an oblong, 11 feet in depth and 29 in breadth, with its base curved downwards 6 inches in 15 feet, to the middle line of the keel, its sides slightly curved outwards, and the lower corners rounded off in the arc of a circle to a radius of about three feet. The midship portion of the body, in which the engines, boilers and coal lie, preserves much the same section throughout its length. Forward and aft, the form becomes finer, and gradually approximates to the usual bow and stern of sailing vessels. The stern-post is plumb. The stem rakes forward of the perpendicular at an angle of 16°. It may here be remarked, that the body is throughout remarkably fair; and that an observer, standing either before the stem looking aft, or abaft the post looking forward, can detect no more difference, if any there be, between the two sides, than would be observed in a vessel built wholly of wood.

With respect to the method of connecting the various parts, strictly speaking there is no keel, although the lower plate of iron, which connects the two sides of the ship, and which is about a foot in breadth, is called the keel-plate. This plate is slightly curved, with its convex side downwards, so as to form a channel for water in the direction of the length of the vessel, under the floors. The floors are straight bars of angle iron, with one flange, four inches wide, lying horizontally; the other 9 inches deep, hanging vertically. The vertical flange is connected to the bottom-plates of the ship by 3-inch angle iron—that is, angle iron of 3 inches width of flange. Upon the upper surfaces of the floors, five ranges of sleepers, of timber 12 inches square, and extending the whole length of the hold of the ship, are laid, and securely bolted to the horizontal flanges of the floors, by 1-inch bolts, their points secured under the flange of the floor by nuts on to screws at these points. The frames, which are of angle iron 3 inches wide, are 18 inches apart along the midship body of the vessel; but forward and aft this space is gradually increased, until they become about three feet apart. The in and out flange of the frames is riveted to the vertical flange of the floors by $\frac{3}{4}$ iron rivets, about 6 inches apart. The iron plates forming the planking, or rather skin, of the vessel, are secured to these frames by being riveted to the other flange of the frames with rivets of $\frac{3}{4}$ iron, which are distant apart about 3 inches from centre to centre.

The connection of the sleepers or keelsons, which are of red-pine timber, with the iron floors, and of the floors with the frames, and of the iron plates with these frames, may be more easily understood by reference to Fig. 1. The rivets by which the plates are secured to the frames, are put in from the inside of the vessel, and are clenched flush on the plate; the outer part of the hole through the plate being counter-sunk to receive the rivet, so that the bottom of the vessel is a perfectly even and smooth surface. The whole of the riveting is performed with rivets heated nearly to a welding heat; therefore, the contact between the surfaces of the iron is exceedingly perfect, as it is insured not only by the care applied to the riveting, but by the contracting of the rivets in cooling. The frames run up to and end upon the iron gunwale, which has been before mentioned. This is of 3-inch angle iron, with one flange horizontal, to which the 4-inch wooden gunwale is secured by screw-bolts; the other flange is vertical, and to that the upper ends of the frames are riveted. Between the wood and the iron forming this compound gunwale, felt is laid, which is so firmly compressed by the screw bolts, that the joint is perfectly water-tight. The beams are of iron, and formed by two bars of angle iron, having their vertical flanges back to back, with a bar of iron 9 inches deep and $\frac{1}{2}$ of an inch thick riveted between these two vertical flanges. The deck is of fir, 3 inches thick, lying upon and being secured down to the horizontal flanges of the beams by screw bolts, the heads of which are sunk about $\frac{1}{2}$ an inch below the surface of the plank, and are hidden by plugs driven down upon them with white lead. Thus the fastenings of the deck are scarcely perceptible. The points of these bolts are secured beneath the horizontal flanges of the beams by nuts on a screw. The connection of the angle-iron gunwale with the wooden gunwale and with the planking; also, the connection of the deck with the beams, and the method of forming the beams, will be more easily understood by the following sketches: (Figs. 2 and 3.)

Fig. 3.—Section of beam.

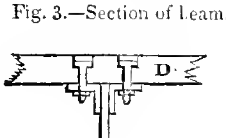

Fig. 1.

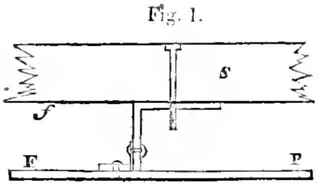

Fig. 4.

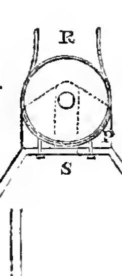

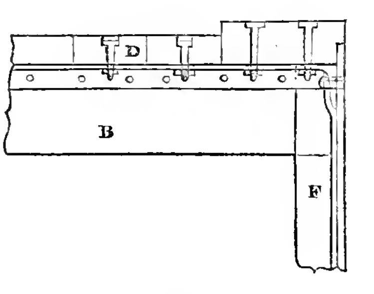

Fig. 2.

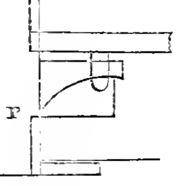

Fig. 5.

Reference—Fig. 1.—S, sleeper. P, iron plate. *f* F, frame between.
Figs. 2 & 3.—D. deck. B. beam. F, frame.
Figs. 4 & 5.—R. rudder. P, port. S, stern.

The ends of the beams are secured to the sides by angle-iron knees. The paddle-beams, which, it has been before said, are of timber, pass the sides of the vessel through what may be called sockets, formed by bars of angle iron placed above, below, and on each side of them. One flange of each bar is firmly riveted to the planking o the vessel; and the other flange is secured to the beam by screw bolts. Felt is also inserted here in the joints between the wood and iron. This appears to be a general precaution in similar connections.

The stem is formed of sheet-iron, in the same manner as has been already described for the keel. At the lower part of the stem there is a sort of a socket of iron, which forms the gripe, and in which the lower end of the wooden knee of the head is inserted. It has been already mentioned that the rudder of the Nemesis is of timber: but this appears to be an exception to the general practice in these iron vessels. The main piece inclusive of the head, is usually of iron: and when of iron, is thus formed and connected with the stern-post. (Figs. 4 and 5.)

The stern is strengthened by a fashion-piece of angle iron: and the tie across the stern is by a transom, also of angle iron. The berthing all round the vessel, already mentioned as being of fir, is secured to short top-timbers of wood, which are let through the gunwale and run down about two feet below it. They are secured by two riveted bolts through the planking of the vessel; and at their intersection with the iron gunwale, by angle iron on each side.

The sheets of iron which form the planking of the vessel are about 8 feet long and 2 feet 6 inches broad. Of course, these dimensions vary according to the place of the sheet in the body of the vessel. The lower 5 strakes which form the bottom, and extend from the keel-plate to the turn of the bilge, are clinker-built. The strake at the turn of the bilge, and the 5 strakes which form the side of the vessel from this turn upwards, are carvel-built. The lands of the clinker seams are riveted with $\frac{3}{4}$ iron rivets similarly to the lands of a clinker-built boat, without any strengthening bands. The carvel seams, and the butts of both clinker and carvel strakes, are secured by bringing the edges of the plates in contact, and riveting each edge to a strip of plate-iron, lying on and lining the inside of the joint. The seams are caulked by closing the edges of the two plates together with blows of a cold chisel. The whole of the rivets are flush on the outside of the vessel. The keel-plates are 7-16ths of an inch in thickness. The clinker-worked plates covering the bottom of the vessel are $\frac{3}{8}$ths of an inch in thickness; and the carvel-worked plates, covering the top-sides, are from 5-16ths to $\frac{1}{4}$ of an inch in thickness. The iron work is first painted with several coats of red lead, and then varnished with a patent varnish. This covering to the iron did not appear to be at all disturbed on any part of the bottom excepting where it had been rubbed off by the rocks on which she had grounded.

There are several peculiarities in the internal arrangements of the vessel. The whole internal space is separated into seven water-tight compartments, by six iron athwar ships bulkheads.* Four of these—those in the wider part of the vessel—are of 5-16ths of an inch iron. The bulkhead nearest to each extremity, being of small surface, and liable to less immersion, is only 3-16ths in thickness. The wooden sleepers necessarily pass through each of these bulkheads, and they are secured where they pass through by strong flanges bolted down to them over felt, and riveted to the bulkheads, so that no water can possibly pass from any one compartment to the other. Therefore, a leak which may be sprung in any part of the bottom of the vessel, can only affect that compartment between the bulkheads of which it happens. Thus the damage caused by the rock on which she struck, admitted 4 feet of water into the compartment in which it occurred, before the leak could be stopped, but there was none in any other part of the vessel. There is a small hand-pump fitted to each compartment, the pipe from which leads into the hollow of the keel-plate. Large pumps are not necessary, as the compartment can only fill to the level of the external water, and may then be emptied at leisure; or, if the leak be greater than the discharge of the pump, may remain filled until a port is reached.

In the space between the engines and the boilers, usually called the stoke-hole, there is a very ingenious means adopted to strengthen the body, without interfering with the accommodations of the engine-room. This is the introduction of a partial bulkhead with an aperture bounded above by an erect, and below by an inverted arch of bar-iron; thus supplying by mechanical contrivance the support which otherwise could not be obtained for this part of the body, without great inconvenience. To obviate the disadvantages attendant on the small draught of water which this vessel draws, there are two sliding keels, similar in principle to those which were originally proposed by Capt. Shank, of the Royal Navy, when in command of the British force on the American Lakes, during the War of Independence. These keels are each 7 feet long, and capable of being protruded 5 feet below the keel of the vessel. They are of wood, $4\frac{1}{2}$ inches thick, and each works up and down by means of a small windlass and an endless chain, in a water-tight case or trunk 12 inches wide, formed like the rest of the bulkheads, of sheet iron, and running from the bottom of the vessel up to the deck. The plates of these trunks are 7-16ths of an inch thick, and they are strongly secured by angle iron to the athwartship bulkheads, which they also serve to support.

The report of the officers on the advantage which they derived from these keels, when under sail, in enabling them to keep the vessel up to windward, and in keeping her steady, is very favourable. In fact, they are an ingenious modification of the lee-board. One of them is situated just before the engine-room, and the other just abaft it. There is also a contrivance by which the depth of the rudder in the water may be increased whenever these sliding keels are used.

Having now described the vessel, we will proceed to describe the damage she sustained by striking. When she struck, her speed is reported to have been nearly 9 knots: her average speed was $8\frac{1}{2}$. The first blow was evidently received exactly in the centre of the front of the fore-foot or gripe, which was dented in about 3 inches, and split about 8 inches in its length. This blow must have been inflicted by a rock at least as sharp as the pea of a moderate sized anchor. The blow appears to have been repeated under the keel-

* We have been told that this method of dividing the whole length of a vessel into separate water-tight compartments is adopted in all sea-going Chinese junks. We trust our naval men engaged in those seas will keep their eyes open to these and many other interesting particulars respecting the Chinese vessels—for a description of which our pages shall always be open.—Editor.

plate, about 7 feet abaft the fore-foot, but there it only occasioned a slight, though long indentation. The principal damage was on the starboard side under the bilge, and at the station of the foremost bulkhead. The outside plate or planking was cut through by the blow having forced it on to the edges of the bulkhead plates; and the lower plate of the bulkhead was broken by the pressure. The wooden sleeper, which lay on the iron floor almost directly above the blow, was started up $1\frac{3}{4}$ inches from off the floor, and the iron bolt which secured it to the floor was broken.

The blow, to have produced such damage as has been described, must evidently have been very severe. It apparently clearly establishes that the injury affects the part struck only, for the rivets seem to have held as tight, and the contiguity of the plates of iron to have remained as perfect after the blow as before it had occurred, excepting only the plates cut by the bulkhead. There might have been a very rational doubt, before the experience this accident has afforded, whether, under such an injury, sheets of iron would not have rent almost as sheets of paper would tear; and whether the rivets would not have started by the dozen at a time, as the stitches in the seams of a sail. Several of the plates abaft the cut plates were indented in a long wavy indentation. The greatest depth of the indentation occurred at the cut, where it was $3\frac{1}{2}$ inches.

The injuries were repaired by placing a shoe over the fore-foot, somewhat similar in shape to the shoe used to drag the wheel of a carriage when going down hill. This shoe was riveted strongly, by rivets passing through it and the gripe, from side to side. The two plates of the bottom which were cut, and the plate of the bulkhead which was broken, were taken out by punching out the rivets, and new plates were substituted for them. Those plates which were only indented were taken out, straightened in the fire, and replaced. A small quantity of the angle iron framing, connecting the bulkhead to the bottom, was also removed, and substituted by new. According to information afforded by Mr. Laird, the weight of new materials used in the repairs was under 3 cwt, and the expense for the materials, and wages of the smiths and riveters, about £30; which, he says, would have been diminished to £20, if he could have had the facilities that are afforded by his own factory.

It is not easy to institute any comparison between the expense of this repair and that of a similar accident to a timber-built ship, because we cannot ascertain what would have been the extent of the damage. If any timbers had been broken, which would in all probability have been the case, the expense would have been much greater. But unless timbers had been broken, the mere upsetting of the gripe of a ship, the rubbing off of a few sheets of copper, and the shifting of a plank or two, would not have involved expense much exceeding that of the repair of the Nemesis.

Before the vessel was grounded upon the blocks, sights were placed towards each extremity, 140 feet apart, with a third sight between them. By means of these sights, observations were taken before and after grounding, and the deviation from the straight line, in the length of 140 feet, was only a quarter of an inch.

Two questions now naturally arise:—1. What are the advantages or disadvantages of the substitution of iron for timber in the construction of ships? —2. To what limit may this substitution be advantageously carried? Among the advantages are the employment of a less material, of which the supply is inexhaustible, and for which supply we are totally independent of other nations. Also, the greater durability of the material, not only arising from its relative durability with that of timber, but from its requiring no metallic sheathing to protect it from the ravages of worms. Also, the greater durability of the structure as a whole, in consequence of the greater permanency in the perfect combination of its several parts, arising from the fastenings being of the same hardness of texture as the portions of materials brought into connection. The metallic fastenings to a timber-built vessel act, it must be remembered, not only chemically but also mechanically, to accelerate her destruction, immediately the close connection of the several parts is at all diminished.

These appear to be the principal advantages of iron in connection with the question, as far as first expense of material and durability are concerned. But these considerations are independent of the expense in relation to the comparative total quantities of materials required to build a ship of each sort. For it must be remembered that the iron-built vessel is of iron alone; the timber-built vessel is of timber, iron, and copper.

Were it possible to compare an iron-built ship with one entirely built of timber, setting aside the question of durability, undoubtedly the advantage would be wholly on the side of the timber-built ship. For the strength of oak is one-fifth that of wrought iron, and its weight is only one-eighth that of wrought iron. But this comparison is untenable, because of the great quantity of metal which necessarily enters in the construction of the timber-built ship, by which its relative weight is very much increased, and its relative strength diminished. By the term "timber," in speaking of a timber-built ship, a compound of timber, copper and iron is meant, having less strength in proportion to weight than the timber alone, but greater weight in proportion to strength. It is impossible within the limits of this paper to investigate the actual weights of wood, iron, and copper, which enter into the composition of a timber-built ship, in order to ascertain the exact answer to the question as to which is the heavier material in proportion to its strength, the "timber" of the timber-built ship, or the iron of the iron vessel. We shall, however, assume as correct that which we believe would be found to be so, viz. that the material of the timber-built ship would be the heavier in proportion to its strength, and shall proceed to the further investigation of the original questions on that assumption. Therefore, by the substitution of iron we obtain equal strength with less weight of material. From which advantage it follows, that if the "timber" and the iron vessel be each built for the same loaded displacement, the iron vessel, with equal strength will be capable of carrying a heavier cargo, and with greater strength an equal cargo. Also, that if a "timber" and an iron vessel be built of the same strength, and to carry the same weight of cargo, the iron vessel may be of less displacement, and consequently smaller in dimensions, or if of less displacement with the same dimensions, may be more advantageously formed for velocity and for weatherly qualities. The small dimensions involve the advantage of light draught of water, diminished expense, and less numerous crew. The diminished displacement with the small dimensions involves quicker return of capital and greater safety in navigation.

The answer to the second question, as to the limit in the size of the vessel to which the substitution of iron for "timber" may be carried, appears also to be involved in the foregoing considerations. For, if greater strength may be obtained with equal weight of material, or equal strength with less weight of material, there can be no limit short of that limitation which may equally apply to "timber." And, by an application of the foregoing reasoning to the question at issue, it appears that a first-rate may be more strongly built of iron than of timber, with the same light displacement, and equally strong built, but capable of carrying a greater quantity of water, provisions, and stores, with the same load displacement; or, equally strongly built, and capable of carrying an equal quantity of water, provisions and stores, with a less load displacement. This may appear to be a bold and startling result of our investigation; but if our original assumption be correct, it is nevertheless, within the bounds of truth. Nay, it is even an under estimate of the limit to the substitution of iron for wood in the construction of ships. For the limit to the possibility of constructing a fabric of any conceivable dimensions is necessarily dependent upon the ratio of the strength of the material used to its weight. And as this is greater in iron than in the "timber" of the timber-built ship, the limit of dimensions for the iron-built ship is more extended than the limit of the dimensions of the timber-built ship.

It may, perhaps, be necessary to repeat that the word "timber" in this investigation means the copper, iron and wood of the timber-built ship.

If we take into consideration the very few years that have passed since the first application of iron as a total substitute for timber in building ships, it is astonishing to what perfection this branch of art has arrived; and, consequently, very great credit attaches to Mr. Laird, for the intelligence and talent which he has displayed in thus adding to the manufacturing resources of this country. As the art proceeds, and becomes more general, there can be no doubt that great improvements will be made. This is said without the slightest intention of withholding from Mr. Laird the high meed of praise which is so justly his due. In speaking of the progress of improvement, we are too prone virtually to set bounds to its advance; forgetful of the fact that perfection being unattainable by mortals, it is a mere abstract term, meaning one thing yesterday, another to day, and another tomorrow. One improvement, and that probably not an unimportant one, would be the diagonal arrangement of the plates or planking of the vessel, and also of the angle iron frames. Iron offers greater resistance to compression than to extension. And bar-iron offers greater proportionate resistance to extension than plate-iron. These facts, which have been ascertained by experiment, enable us to determine upon the positions in which to place the plates, so that the peculiarities of strength of the angle and bar-iron shall be most advantageously developed. The angle iron should be placed so as to act as trusses in supporting the weight of the extremities of the vessel; the weight or downward pressure of which is necessarily greater than the upward pressure of the water. The frames should, therefore, be placed with their heels toward the midship part of the ship, and their heads inclining forward in the fore body, and aft in the after body to an angle of 45 degrees with the horizon. The plates have already been described as connected together at their edges by being riveted to strips of bar-iron. These may form the ties, and the direction of these continuous bands should be at right angles to the direction of the angle iron frames. Thus the whole body would be divided by these two series of lines into compartments; which, in the vertical part of the body, would be squares, each with one diameter vertical and the other horizontal, as in the following sketch. The double lines are the angle iron frames, the single lines the continuous bars to which the edges of the sheets are riveted. Of course, the angle iron frames will receive the rivets of one series of seams, and therefore by this adjustment some small weight of iron will be saved.

The floors and all the lower part of the vessel may remain as in the Nemesis. The introduction of water-tight bulkheads is very good. This has been before attempted in timber-built ships, but has failed, from the ignorance of the projectors of the nature of the pressure of water. They assumed that a caulked bulkhead of three or four inches in thickness, that would be quite adequate to resist the pressure of a small depth of water, would also be of sufficient strength to resist the pressure to which it would be subjected by deeper immersion. Bulkheads, to resist the pressure of water, must increase in strength in proportion to their depth below the surface of the water. This fact must not be lost sight of in the construction of these water-tight iron bulkheads. It is not of consequence with small draughts of water; but when larger and deeper vessels are built of iron, it will become a question of importance; and if not duly attended to, the idea of safety from water-tight bulkheads may be most delusive.

The question of the durability of these vessels, of their little liability to accident, and of the ease with which damage done to them may be repaired, appears to be very clearly proved from the experience which has already been obtained on these points; and this is not little, for there are boats built by Mr. Laird in both North and South America; in all parts of India, and on the Euphrates and the Indus; in Egypt, on the Nile and in the Mediterranean; on the Vistula, on the Shannon, and on the Thames. One of these boats on the Savannah has been constantly at work for these last six years without any repair; which is a great test, if we consider the frequent, constant caulkings required to preserve a timber-built ship. There is also a steam-yacht built of iron, the Glow-worm, the property of Asheton Smith, Esq. This vessel has made the passage from Bristol to Carnarvon, a distance of 210 miles, in 18 hours. In the report to the House of Commons on steam-vessel accidents, we find the following stated of the Garryowen, one of these vessels:—"We went ashore about two cables' length to the eastward of the pier (Kilrush) and struck very heavy for the first hour. The ground under our weather-bilge was rather soft clay, covered with shingle and loose stones, some of them pretty large. Under our inside, or lee-bilge, the ground was very hard, being a footpath at low water. I was greatly afaid she would be very much injured by it in her bottom, but am happy to say she has not received any injury: in fact, her bottom is as perfect and as good as on the day she left Liverpool—not a single rivet started nor a rivet-head flown off. If an oak vessel, with the cargo I had on deck, was to go on shore where the Garryowen did, and get such a hammering, they would have a different story to tell. . . . Out of twenty-seven vessels that got ashore that night, the Garryowen is the only one that is not damaged more or less."

Colonel Chesney, the commander of the Euphrates expedition, writes thus of the iron vessels which were employed on that service:—"It is but right to tell you that the iron vessels constructed by you far exceeded my expectations, as well as those of the naval officers employed in the late expedition, who would one and all bear testimony anywhere to their extraordinary solidity; indeed, it was often repeated by Lieut. Cleaveland and the others, that any wooden vessel must have been destroyed before the service was one half completed; whereas the Euphrates was as perfect when they laid her up at Bagdad as the first day she was floated. As I am now occupied in preparing a work on the expedition, I shall have a better opportunity than the present of doing justice to the subject of iron vessels, for it is my belief that they will entirely supersede wood, on account of their comparative strength, cheapness, and durability, whenever people are satisfied that their only disadvantage—the free working of the compass—has been overcome.

REVIEWS.

Seville and its Vicinity. By Frank Hall Standish, Esq., Author of the "Shores of the Mediterranean," &c., 8vo. London, 1840. Black and Armstrong.

"The work now presented to the public," we are told in the preface, "contains an enumeration of almost all the Convents and Public Buildings, which existed in Seville during the last century, with their most remarkable contents in the present;" it is accordingly one, far more calculated to interest architectural and antiquarian readers, and those who study the history of art, than the public generally: for the description of the Alcazar and Cathedral alone, the one a splendid monument of Moorish, the other of Gothic architecture, extends to somewhat more than sixty pages. In fact, a considerable mass of information relative to architecture and the other arts, and to many Spanish artists, is here presented to the English reader, which has hitherto been hardly accessible to those who are unacquainted with Spanish. Instead of being as its title alone would, perhaps, lead us to suppose, a traveller's sketch of the city and its inhabitants, this volume is altogether topographical in form,—and so far rather a phenomenon in these days of 'light reading.' It is in fact rather one for study and reference, than for off hand perusal; and therefore we conceive, ought to have been furnished with that now almost obsolete appendage, an Index. Neither is that all we here desiderate, for we conceive that the Alcazar and the Cathedral might very properly have been made to furnish something like disquisition as to the Moorish and the Gothic architecture of the Spanish peninsula generally; and so also would the Lonja (here printed throughout Louja), or Exchange, have afforded an opportunity for discussing the peculiar character of the style transplanted from Italy in the 16th century. Something of this kind would have relieved the dryness of the work which is written too much in the usual technical Guide-book style. As it is, the volume is too much of a mere catalogue raisonné of buildings and pictures, and therefore likely to be considered dull by the many, and tantalizing by the few for whom it seems to have been more particularly intended; for as there are no illustrations of any kind—not even so much as a general plan of the city to enable us to form some distinct idea of its topography, little positive information, except as to historical facts, and names and dates, can be collected from it. Nor do we, we must confess, understand why so many minor—not to call them trivial, circumstances should have been brought forward in regard to a place so very unlikely to be visited by English travellers, and which requires to be described to the English public quite as much by the pencil as by the pen.

At present only one or two of its buildings are known to us, and those very imperfectly—the Giralda or Tower of Gever, some portions of the interior of the Cathedral, the Patio de Naranjos, the Sala de los Embazadores in the Alcazar, the Golden Tower, &c., which we meet with in Roberts' Spanish Sketches, and the Landscape Annual, and which are certainly calculated to excite a vehement desire for a complete acquaintance with those edifices, and with similar information as to others. Though not to be compared with the Alhambra, the Alcazar alone would supply materials for an architectural volume, if we may judge from the Sala above mentioned, and from some other views of the edifice, which we lately met with in a recent French publication, whose exact title we do not now remember. As to the Cathedral, we are here told the architecture is of all classes—Arabic, Gothic, the 'Plateresco,' and the Greek-Roman; yet, although all these are jumbled together, and an abominably unsightly "grand entrance" has been recently attempted—fortunately, not finished, by a Sevillian architect, Cano, and a good deal of the outside walls are left rough, "nevertheless, of all the cathedrals I have seen, this is the one which, upon the whole, has most pleased me in Europe," says the author. After this we naturally look for some vindication of such opinion—for some remarks that would explain to us, in what its particular charm and merit consists, more especially as we are told that, "the interior of this temple is of the plainest Gothic."—However, provided too much be not expected from it, we can recommend this volume to those—their number, we fear, is but small—who have not the means of consulting Ponz and Cean Bermudez, yet are desirous of obtaining more minute information relative to Seville, and Spanish art and artists than English publications will supply. For our own part, we greatly regret that Roberts did not return to the Spanish Peninsula, and devote his pencil to illustrating and recording the, at the present almost unknown, treasures it contains, in the class of architectural and picturesque objects, instead of proceeding to the Holy Land which is not exactly the land best fitted for the display of his talent. At all events, we hope that in these days of travelling, some other artist will visit the Spanish territory, and return with a portfolio well stocked with architectural subjects there to be met with in profusion, and of which we have, as yet, had no more than a mere whet—a slight foretaste, a provocative that is in itself quite provoking.

Egerton's Views in Mexico; being a Series of Twelve Coloured Plates, executed by himself from his Original Drawings. Large Folio. London, 1840. D. T. Egerton.

If it was not every one who could afford to visit Corinth, so neither have all of us, even in this age of steam navigation, the means or opportunity of taking a trip to Mexico; although in the course of another generation such a trip may become a very ordinary feat, and that too, in a still more expeditious mode than that by a sea voyage across the Atlantic,—to wit, in a balloon, should the experiments which are now actually making, to prove the practicability of such mode of travelling, be found to realize the sanguine expectations of its projector. In the meanwhile we are well content to take our ideas of Mexican scenery and vegetation,—of the costume of the people, of their habitations and cities, from Mr. Egerton, an artist who has not merely visited, but been long resident in the country, and whose drawings are no less attractive as landscapes, than they appear to be faithful and characteristic as local portraitures of the sites they represent. We say seem, because of course we cannot pledge ourselves, as eye-witnesses, to their veracity; but they certainly do bear very strong internal proofs of it, not only the general physiognomy of the landscapes and buildings, bearing testimony to it, but more especially the plants and shrubs in the foregrounds, whose particular characters are clearly discriminated.

Looking at these views as imitations of the original drawings, we may place them among the most successful attempts we have ever met with, to give the effect not of mere tinted ones, but the depth of tone, the vigour, the surface, and the peculiar execution of the modern school of water-colour drawing. Therefore, though the work is much higher in price than any of the masterly productions in lithography that have of late been published, it cannot be called dear, considering the great dimensions of the plates, and the time, labour and care bestowed upon the colouring, which has been executed under the artist's immediate inspection. Nay, as compared with what is frequently asked for a single drawing, not at all of more value as a work of art, than one of subjects forming this set, it may be termed cheap. One great advantage, too, attending the form in which they are done up, namely, their being a series of separate drawings mounted upon card-board, and put into a portfolio,—is that any one or more of them may be selected and framed, and would then scarcely be at all distinguishable from an original or autograph production of the kind. A separate sheet of letterpress descriptions forms a very suitable accompaniment to the engravings, for the information it affords gives additional interest to the subjects it explains. Perhaps we cannot do better than quote by way of specimen the description of the first plate, the city of Puebla, as it commences with an observation that meets an objection very likely to be made by those who do not take into account the peculiarity of the climate where the scenery lies.

THE CITY OF PUEBLA.

In representing scenery within the tropics, where the atmosphere is so highly rarified, more particularly in situations that are considerably elevated above the sea, it is quite impossible to convey, to the inexperienced eye, an adequate idea of distances, which always appear to be lessened: and the hardness of outline, with the distinctive form of objects, as exhibited in faithful pictures, frequently subject the artist to the imputation of a want of skill;—thus, in the two eminences shown in this subject, they appear to come forward upon the eye, whilst their bases are at a distance in a straight line from the foreground, of about thirty miles. The sides of these mountains are covered with deep forests, extending from the base to that point where vegetation ceases to exist; this may be observed in the picture, where the grey tone of the forest is succeeded by a warm sand colour, and the higher elevation is distinctly marked by the snow, which perpetually covers the summit. The loftiest of these mountains, called Popocatepetl, stands at an elevation of 17,884 feet above the level of the sea (nearly three miles and a half), and at about 10,684 feet above the city of Puebla, from whence the crater of this volcano is plainly visible, the edge of which falls considerably towards the south side; it still burns feebly, and the surrounding country bears the devastating marks of violent eruptions; though no records have been kept of these. The neighbouring mountain, called Iztaccihuati, is supposed to be an extinguished volcano—and these two form the barrier to a direct communication between Puebla and the Capital, which places are distant from each other about 70 miles, the former being 162 miles from the port of Vera Cruz. The city, a small portion of which only is seen in the picture, is the richest bishoprick in the country, and is celebrated for its fine cathedral, the altars of which are decorated with the most costly magnificence.

As likely to be interesting to several of our readers, we shall also copy what is said of the Mine of Rayas.

INTERIOR OF THE MINE OF RAYAS.

This mine, situated at Guanaxuato, is esteemed the richest upon the *Veta Madre* (mother vein). One of the principal *levels* is shown in this plate, "the cañon of San Cayetano." This excavation has been formed by blasting the rocks, amongst which the silver is disseminated in minute particles; occasionally threads and lumps of silver are found in a pure state, but these form an insignificant proportion to the mass. The principal shaft of this mine is of large dimensions, being 31 feet in diameter, of an octagonal form, and 461 *varas* deep (1,276 feet). In the lower workings, the air is very confined, and the heat rather oppressive, the mean temperature being 85° of Fahrenheit; in the level represented here it is 80°. The *Tenateros* (carriers) who convey the ore from the different workings to the bottom of the shaft, from whence it is raised to the surface, are paid according to weight and distance; they are, from long practice, rendered capable of bearing great weights—the average allowance is 9 or 10 *arrobas* (225 lb. and 250 lb.): but there are instances of their far exceeding this; and in the *Despacho* (office) of Santa Rosa, belonging to this mine, there are two masses of ore which have been brought up entire by one man, in successive journeys, one weighing 18 *arrobas* (450 lb.), the other 22 *arrobas* (550 lb.), which are kept as trophies of human strength. When it is considered that 300 lb. is the average weight that a mule carries, and that those masses were brought from the level shown in the plate, to a distance of 260 *varas* (nearly as many yards), with an ascent of upwards of 100 *varas*, it will appear more extraordinary. The miners, who are voluntary workmen, are a very superstitious race: they are subject to many accidents, from blasting, rush of waters, descending and ascending the shaft, &c.; but the limits of a short description cannot convey an adequate idea of the life of these singular men, which is full of stirring incidents.

The Palace of Architecture: a Romance of Art and History. By George Wightwick, Architect. Imp. 8vo. 67 Plates and 143 Woodcuts. London: Fraser, 1840.

If the singularity of its title is well calculated to excite curiosity, and the splendid appearance of the volume itself is likely to secure for it admiration, the author's aim is by far more singular than the one—more admirable than the other; while some of his opinions and remarks are so striking as to be absolutely startling. It is not the least extraordinary circumstance of all that, although a professional man, Mr. Wightwick is so free from professional prejudices, so ultra-liberal, in fact, that he is in danger of being considered highly illiberal in many parts of his book by his brother architects. That he is not at all anxious to have the art kept, as heretofore, a sort of close borough, is evident from the very first: nor is there any mistaking his object, which is nothing less than to divest the study of architecture of that kind of freemasonry, mystery, and mystification, in which it has hitherto been kept shrouded from the million. Nay, he even goes so far as to express the hope "that quackery may no longer practise its meretricious frauds, to the delusion of ignorance;" a pretty broad hint that there has been a good deal of quackery in architecture ere now, and that such quackery has succeeded mainly in consequence of the inability of the public to detect it, and to discern plodding feebleness and sterility of mind just *plated over* with the specious, yet superficial surface of art. In time, perhaps, the plating wears off, and people begin to be ashamed of the sorry stuff which they had been taught to look upon as sterling metal; but in the meanwhile the mischief has been committed, and the public have no other means of consoling themselves for the despicable specimens of taste foisted upon them, than by sneering at the want of discernment on the part of the generation which could allow itself to be so duped, notwithstanding that they themselves are probably gulled to the very same extent, although after a contrary fashion. Had the course here recommended by Mr. Wightwick been adopted a century ago, and had the study of architecture been considered one of the requisites towards a polite education, the art itself would, in all probability, have been in a very different condition among us from what it now actually is. If executed at all, many things that have in their day obtained praise, would have incurred derision at the very first. Hardly would such men as Taylor and Wyatt have obtained the celebrity they did—more to the astonishment of the present time than to the credit of their own—for their talent, more especially that of James Wyatt, is now beginning to be better understood, and rated at its actual worth, which is exceedingly low indeed, for he was at the best a complete mannerist, while his manner was at the best completely insipid. Nash's reputation is now scarcely worth a bawbee; nor would we give much for the reversion of that of Sir R. Smirke, whose frigid soulless *classicality* has impoverished our modern architectural style most deplorably.

Should Mr. Wightwick's counsel be followed, the next generation will not, we conceive, be put to its shifts, so much as the present one, to find competent judges in matters of architectural taste; whereas now it is universally complained that hardly two or three non-professional persons can be found at all qualified to be entrusted with the selection of designs at competitions. So far, therefore, Mr. W.'s book is eminently calculated to be of service, by inducing people to discard the fatally absurd prejudice that the study of architecture concerns architects alone. Either it is, or it is not, a fine art: in the latter case, of course it deserves to be applied to only by those who practise it; but in the other, it claims the attention of all who make pretensions to taste, and the more extensively it is cultivated the better, else how can the public sympathize with it?—how can they appreciate or enjoy it?—how should they encourage it properly, or wherefore should they encourage it at all? because a public without taste for architecture does not need architects, but merely builders. All this we take to be pretty self-evident, whether it be exactly palateable or not.

To ourselves it is most satisfactory to find that there is at least one individual in the profession, who, with no ordinary degree of eloquence and persuasion, strives to induce non-professional persons to apply themselves to architecture as one of those pursuits which of themselves reward the student. We do not say that others have actually dissuaded from such attempt, or that they have not occasionally acknowledged the ability and services of amateurs; but it has been as if they looked upon the latter as a class necessarily limited to a very few individuals, and those chiefly wealthy ones. Never do they seem to have contemplated the possibility of that class—if it now deserves the name of one—becoming a numerous one; for never have they uttered any exhortations to that effect; never have they recommended that architecture should be taught at schools and colleges; never have they pointed out what course of study in it would be most suitable for such purpose. Without doubt every one has always been at liberty to make architecture his hobby if he pleased, but then, whenever it has been taken up at all, it has been entirely through accident or fortuitous circumstances, and not in consequence of any provision made for the study in the usual course of previous education. The question, then, is, why has no provision of the kind been made? how happens it that architecture has been completely overlooked as a branch of education? And to this question no one, we will venture to say, is prepared with an answer, for the reason that no one has ever thought of its being ever asked. Shall we say it is because architecture has nothing whatever to recommend it as an elegant and liberal pursuit to those who do not intend to follow it as a profession? and because, although nominally accounted one of the fine arts, it has nothing in common with the rest, being, in fact, no better than a dry, plodding, mechanical calling, fit to be left entirely to those whose trade it is? It may be so; at any rate such is the light in which it is generally considered, though architects would fain have the world believe quite the contrary.

Let us disguise it as we may, the truth is, there is very little relish for art in this country; for instead of any pains being taken to instil a taste for it into young persons, they and all others are left either to pick up their notions of it as well as they can, or else to remain all their lives in a "gentlemanly ignorance" of it, while they find more congenial food for their taste in dandyism or politics, or on the turf and at the gaming-table—perhaps in amusements *à la Waterford*.*

* It would not be amiss were we to look at some of the portraits drawn of us by foreigners. It was not very long ago that we met with a very long

article in a German review which animadverted most severely upon our present extraordinary predilection for "mob literature," upon our Jack Sheppard and Oliver Twist mania, and upon productions of that Newgate school of literature which is calculated only to beget a low and scoundrelly sympathy with crime and vice:—an odd taste for a people who give themselves the airs of being the most moral nation on the face of the earth. Hardly more complimentary are some of the remarks we have met with in foreign publications, in regard to our feeling for art, and the mode in which we profess to encourage it. As far, too, as architecture is concerned, English buildings do not always make that favourable impression upon foreigners which it were to be wished they should do.

Whether this state of things is at all to be regretted or not, certain it is that we have no reason to be surprised at it; whereas it would be almost miraculous were we to find a strong love of art diffused throughout the public without any pains being taken to implant it, or there being anything in the present constitution of society to cherish a passion for art, as was formerly the case in this country, as well as others, when art was munificently patronized by the church. There is now scarcely any inducement for those who have leisure, to devote any of it to architecture as a recreative study, for they, no doubt, know that they would have very few to sympathize with them, and also that they may be wholly ignorant of it with perfect impunity.

Possibly the time—should it arrive at all—is not very far distant, when an acquaintance with the principles and elements of architecture will be considered nearly as indispensable as several other things that are now taught as accomplishments. At any rate it will be no fault of Mr. Wightwick's should such not prove to be the case, the primary object of his work being to gain proselytes to the study from among the educated of both sexes, although hitherto there seems to have been a kind of Salic law, excluding females from it altogether. Yet wherefore an art which depends so much upon the beauty of forms and their combinations, and the study of which tends so greatly to correct and refine taste generally, should have been considered unsuited for the female sex, or else far above their mental faculties, is one of those questions that when considered without prejudice, startle us by there being any occasion for putting them at all. There can be little doubt but that indirectly at least, female taste—or rather the want of it—has been more influential than is suspected, upon architecture; for almost one entire branch of the art has in consequence been exterminated—or rather checked and prevented from developing itself; that which should properly belong to the architect and the artist, being allowed to devolve upon the upholsterer. We cannot, however, allow ourselves to enter here upon a topic that would lead us on to a very great length, and shall therefore merely observe that architecture had been previously recommended as a very suitable study for females, both in the Foreign Quarterly and Loudon's Architectural Magazine; therefore supposing there is any absurdity in such view of the matter, it is not here broached for the first time by Mr. W., although his advice in that respect, will, no doubt, appear entirely novel to most of his readers. Whether so considered or not, we trust that it will not be altogether thrown away; and coming directly from a professional man, it may probably, have greater weight than it else would. So far from objecting to it ourselves, we could wish that the author had expatiated more fully upon this particular point, and had gone so far as to advise that those who have any inclination for the study at all should go through such a course of elementary lessons with an *Architecture-master*, as would familiarize them with all the technicalties of architectural drawing and detail, and thereby enable them to carry on their studies afterwards by themselves. Until an acquaintance with geometrical representation be formed, and a relish acquired for that as well as perspective delineation, little progress can be made in the pursuit; and although such mode of study may at first sight appear formidably tedious, it in fact opens a source of interest unknown to those who for want of such instruction see only general masses and forms, without taking any note of minor traits which confer individual character and expression.

Why then not call in the Architectural Master?—Because, people will say, it would be so very odd, and after all the acquirement itself would be a useless one, especially to ladies. This last ought of course to be admitted as a most reasonable reason; yet when we consider by how many exceedingly useless pursuits women now suffer themselves to be engrossed, that of architecture would be such a trifling peccadillo, that it need not weigh heavily upon their utilitarian consciences. It would seem, however, that there is at least one lady, and she too of high rank, who does not consider architecture—that is, the æsthetic or artistical part of it, either an unfeminine or a vulgar study; for as Mr. Wightwick has dedicated his volume to the Countess of Morley, we may presume that in her he has met with that example which has encouraged him to recommend the study to others of the sex. If it be true—but as we have only newspaper report for it, it is just as likely to be false,—if it be true, we say, that her Majesty is now taking lessons in etching, we hope she will, by and by, condescend to take some also in architecture, because there her taste might prove of singular benefit, and might encourage works that would redound to the credit of the age and of the nation, whereas her Majesty's etchings are likely to have just as much effect upon art as those of any other young lady—and no more. Had George IV. possessed a tithe of the taste for which he was so liberally credited by flattery, Buckingham Palace would have been a worthy architectural monument of his reign, instead of being, as at present, an ignominious one, and even Windsor might have, perhaps, been better by several degrees, than it now actually is. If there be any one of the fine arts which it is more especially desirable that a sovereign should be able to appreciate, it is surely architecture, because its more important productions are durable, and ought therefore to be noble, memorials of the period when they were erected.

If we have thus far said very little in regard to the volume before us, it is Mr. Wightwick himself who has diverted our attention from its contents generally, by adapting it to those who are without the pale of the profession, and by his endeavouring to enlist as many as he can into the volunteer corps of amateurs. And if we have confined our attention to this single point, it is because we consider it to be one of paramount importance, and perhaps go further in regard to it than even Mr. Wightwick himself, being of opinion that unless the public be educated to understand and relish architecture as a fine art, it is almost hopeless to expect that it should flourish among us. We may probably bestow some further notice on this work, but lest we should not do so, we will here express our hearty approbation of the writer's intention; nor do we entertain any doubt as to his book effecting considerable good.

A Treatise on Engineering Field Work. By PETER BRUFF, C. E. Second edition, corrected and enlarged. London: Simpkin and Marshall. 1840.

In our last number we took a cursory glance at the contents of this work, we shall now proceed to point out what is additional in the new edition: in the first place we must state that the whole of the work has been carefully revised, and that there are several passages distributed throughout, which did not appear in the former edition; we shall now confine ourselves to the leading subjects which have been introduced in the present volume.

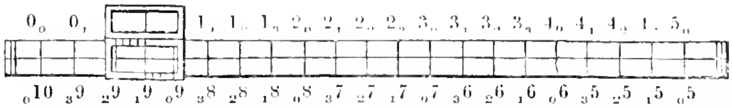
Chapter 3 is entirely new, and contains directions for conducting a survey, laying out a base line, a most important object in land surveying, and more particularly in railway surveying; for the latter we think it should be, if possible, marked out the whole length of the line by the engineer or his principal assistant, and that the connection of the work of the different surveyors should also be done by him. This chapter likewise contains some useful directions for the student in detecting and avoiding errors.

In chapter 4 we have some judicious observations on parish surveying, and remarks on Captain Dawson's directions for the surveys made under the Tithe Commissioners.

Chapter 5 contains instructions for surveying with angular instruments—town surveys and subterranean surveying.

In chapter 6 there are several hints for facilitating calculations, and various methods and instruments explained for that purpose; for our own part, we are generally averse to most ready reckoners, for in nine cases out of ten, if a person has any nonce, he will beat, by mental calculation, one who has recourse to tables and instruments, both in accuracy and time;—we, however, shall give the description of an instrument which, Mr. Bruff tells us, has lately been adopted in the Tithe Commissioners Office, and which appears to be an instrument not easily put out of order.

"The last, and most simple method, which we shall describe, and which is now in the course of adoption by all surveyors, and at present exclusively employed at the Tithe Commission Office, presents the greatest facility in performing computations, without in the least damaging the plans, by equalizing boundaries, &c., as by all the previous contrivances. The principle of the plan has long been in use by some few surveyors, but they prudently kept it to themselves, in order that the price of such work might not be reduced; but at last the method has become publicly known, and a vast reduction has taken place in the remuneration of such operations. In the first place, tracing paper of a superior quality is procured, and parallel lines, at exactly one chain apart, drawn in one direction only along the whole width of the paper. This paper is then carefully laid over the enclosure which is to be computed; the scale to which the map has been plotted is then laid on the first division of one chain—the inequalities at either end being equalized by the eye—and the distance noted. This first distance is brought forward at the second division, and the sum of the first and second at the third, and so on; thus, if the length of the first division is five chains, the scale, when applied to the second, is set on the left hand at five chains; and if the second division is seven chains in length, the right hand extremity is set to twelve chains, which quantity is again brought forward at the third division, and so on until the whole distance of a field, in strips of one chain, is ascertained, when the acreage is at once deduced, by cutting off three figures from the right hand—those on the left are acres—which are multiplied for roods and perches. An ingenious application of the above system is now in operation at the Tithe Office, by which means all calculation is avoided, and the area has merely to be read off on a scale. The following diagram and explanation will enable any surveyor instantly to practice it:



"The instrument consists of a box rule, with divisions at $2\frac{1}{2}$ chains apart, and numbered 0_0, 0_1, &c.: at four of these divisions, or ten chains, it is numbered 1_0, or an acre—the reader bearing in mind that the divisions, on the tracing paper laid over the field to be computed, are one chain apart—therefore each single division, as 0_1, is a rood. There is a brass slider attached to the rule with a horsehair strained perdendicular to its length, for the purpose of equalizing the fences at the end of each strip. On this slider—which embraces rather more than two roods in its aperture—are laid off 40 divisions, on alternate sides, each way from the centre, and which are exactly the length of one rood, consequently each division is a perch The figures on the upper side denote the acres and roods, as far as the rule extends, and are continued backwards on the lower part: the large figures are acres, and the small figures roods. Now, to apply this instrument to practice, lay the ruled tracing paper over the enclosure, and move the slider until its centre is on 0_0; place the scale in such a position that the horse-hair forms a mean line of such part of the left hand bounding fence as is included in the first strip of one chain wide, and press it gently on the paper; with the right hand move the slider along the rule, until the horsehair forms a mean line on the required part of the right hand bounding fence. Then move the instrument *altogether* on to the next division—the slider still remaining as last set—the horsehair forming a mean line, as before, with the left hand hedge; press the rule gently, and move the slider on the scale, until the horsehair forms a mean line with the right hand hedge, as before; which process is repeated until the entire length of the rule is passed over, when it is reversed, and the slider moved towards the left hand, the equalization in this case commencing first on the right hand side. When the slider is brought back to its original starting point, if there remains any further quantity, it is again moved forward to the right, as at first, the continuous measurement being easily kept up by the decimal arrangement of the contents. For example, in the position the slider occupies in the diagram—supposing it had been moved over the scale and back—the contents would be ten acres and 3 roods; and if, instead of the centre exactly coinciding with the division representing 3 roods, it was 20 of the small divisions on the slider beyond it, the contents would be 10 acres, 3 roods, and 20 perches. As a proof of the great saving effected by this instrument, we need only observe, that the price of scaling* has been reduced from 50 to 75 per cent. since its introduction."

In our last number we stated that in this work, there would be found several useful hints, we shall therefore conclude by giving another extract, although it may not be new to the experienced practitioner, we have no doubt it will be found serviceable to the student.

"On the subject of reducing and copying plans we cannot be expected to say much. For ordinary purposes the pentagraph presents the readiest method, both for copying on the original scale, and also for reducing or enlarging the copy to any proportional size of the original. There are, however, several improved instruments for copying with greater accuracy than the common pentagraph admits of. The reducing of a plan by hand, is commonly performed by drawing squares of a size commensurate with its minutiæ all over its extent. Similar squares of any required proportion to the first are then drawn on the paper on which the plan is to be copied, and in every square of the copy is constructed that which is contained in the corresponding square of the original; to enlarge a plan the operation is reversed.

"A much more accurate method than the above for reducing or enlarging plans for railways or other similar purposes, is, to lay down lines of construction thereon, in precisely the same manner as would be done in surveying it; then take off the lengths, offsets, &c., with the proper scale, and replot the survey to that scale on which it is required. The usual method of copying plans by hand is to prick all the angular points and principal features through the original on to a plain sheet of paper fixed beneath it, on which the copy is to be drawn; these points being then connected—first with pencil lines—are inked in, and a tolerably accurate copy obtained: but the method is not to be recommended, from the injury it does to the original, and the incidental errors from oblique punctures of the pricker, &c. The best method of copying plans, which we are aware of, is either by a copying glass, or by tracing and transferring. That by the copying-glass is performed thus:—in a frame, which can be fixed at any inclination, is placed a sheet of plate glass; to the frame is fixed the original plan, and above it the paper on to which it is to be copied; the frame is then placed behind a strong light—or lighted candles placed below it—which enables the draughtsman to see all the lines of the original, and to trace them in ink on the plain paper without difficulty.* The second method is to make a tracing of the original on proper tracing paper; rub the back of it with powdered black lead, and fix it down carefully on to the paper on which the copy is to be made; then lightly trace all the lines with the end of a porcupine's quill, or other pointer which will trace fine lines, and a perfect copy similar to pencil will be obtained, which has then to be inked in."

We again with much pleasure recommend this work to the student, we think it the best practicable work that has been published on land surveying.

ON THE ORIGIN OF THE ARCH.

All must admit that any attempt to fix the date of antiquities is a dangerous task: that all who steer amidst the shadows of the past are subjects of suspicion and mistrust, is also true, Yet though I do seek the region of doubt, and, like the antiquary, revel for a little amidst problems and enigmas, I trust the importance of the subject may guarantee me in some measure from the fate predicted. In throwing out a few hints then, upon the "origin of the arch," wrapped as it is in mystery, it is not from an idea that to fix the period of its birth is vital to art, but rather that to assign to the relics and fragments of antiquity their proper age, seems virtually to guide us into the spirit of past times. Thus we shall be prevented from identifying much that is curious and singular in design, or grand in invention, with a barbaric æra; when a more civilized race might more consistently claim it.

Rome, we say, deserves credit for this invention, because Livy, in allusion to the "Cloaca maxima," remarks, that Tarquinius Priscus drained the low grounds of the city about the Forum, and the valleys lying between the Palatine and Capitoline Hills, by carrying sewers from a higher level into the Tiber. (Lib. i, c. 38.) But the drain was unfinished, and Tarquinius Superbus completed it, for he adds, "Tarquin the Proud made the great subterranean cloaca to carry off the filth of the city, &c. &c. (Lib. i, c. 56.)

Let us presume Livy to be correct, and that Tarquin really constructed that magnificent work; still we cannot conceal the statement of Herodotus and Strabo in their description of Assyrian monuments, &c. We may admit, perhaps, the cloaca maxima as a work of the Romans, but if Strabo be an authority, the arch was instrumental in the construction of the hanging gardens of Babylon, which must have been raised somewhere about 1200 years before Christ. Authorities may and do disagree as to the real author of those works, but that the pile of terraces was sustained by vast arches, raised upon other arches, seems indisputable. (Strabo, l. xvi, p. 738.) Then, again, as to the date assigned to them, whether we take Ktesias or Herodotus, still their date was very long before the building of Rome. Thus it fol-

* We have frequently practised this method in copying railway plans and sections in the country—using common window glass for the purpose, and found a great saving of time in comparison with the common method of pricking through.

lows that, if Babylon displayed the arch in her magnificent works, long before Romulus flourished, then Rome must (if she is to share in the discovery of its properties), at least yield in the *antiquity* of her claim to that of the Assyrian capital.

Then another question arises out of this. Can the statement of Livy be correct? May not the cloaca maxima be as Ferguson hints in his Roman Republic, the relics of some great city, on the ruins of which Romulus pitched and settled. That the arch existed in Assyria is, as far as nice authorities are concerned, certain. That two countries might discover a grand principle in construction at distinct times, is *possible*—but that the arch is exclusively of eastern origin, is *more* than *probable*. To say nothing of the magnificence of such a work as the cloaca maxima, in the ruder times of a republic, unequalled as it was in the time of Augustus, there are those who countenance the idea of a city on the site of Rome long before the time of Romulus. Virgil alludes to this; for Evander, in speaking to Æneas, is made to say:

"Hæc duo præterea disjectis oppida muris
Reliquias veterumque vides monumenta virorum:
Hanc Janus pater, hanc Saturnus condidit urbem,
Janiculum huic, illi fuerat Saturnia nomen."—Æn. viii, 355.

In another passage Virgil again alludes to this, and presumes it of Lydian extraction:

"Ubi Lydius arva,
Inter opima virûm leni fluit agmina Tybris."

In looking into the history of Lydia, we discover that Ninus, who married Semiramis (the probable author of the hanging gardens,) subdued the Lydians about 1232 years B.C., and it is probable that, when his second son Ezron became the king, the arts of Babylon might have crept after him, and thus the arch might have travelled with he Lydian colonists. Then, again, there are those who contend the arch was unknown in Greece till within a hundred years of the Christian æra. So that if Rome were its original source, it would seem much more reasonable to expect its application at an earlier period, since we discover the arch, even in China, in familiar and extensive use at a very early period.

Such are the doubts, I humbly offer to the curious antiquary, and without prejudice to the pretensions of Rome, would add, that there seems a disposition in us to fancy that great city to be the cradle of this important principle in construction, since in Rome we find its boldest application. Existing evidences, too, carry us back into times so remote, that we yield insensibly to this *material* impression, and hush all whispers of record and history in behalf of claims, when no remains of the past confirm them. Perhaps an abler hand than mine may yet clearly *prove* these suggestions, and discover Tarquin the elder, in his attempts to drain the city, as the finder of a hidden wonder, and not as the introducer of a novel discovery; whilst Tarquin the proud may appear only applying to the magnificence of Rome the skill of an earlier day—worthy, however, of praise for the ingenuity which detected, and the bold promptitude which applied it to the improvements of Rome.

FREDERICK EAST.

Sept. 10*th*, 1819.

THE NELSON MONUMENT.

THERE seems to be a pretty strong feeling entertained against Railton's Corinthian Column; and it is to be hoped that such a hackneyed and tasteless object will never be erected as a monument to Nelson, for in reality, it will prove a disgrace to Brittish art. Even at this eleventh hour it will be better for the parties more immediately concerned, to make the best of a bad bargain, and to put up with the loss of the money already thrown away, than obstinately to persist in completing an absurdity, because it happens to have beeu begun. The Nelson Committee ought rather to think themselves fortunate in having a very good excuse for even yet re-tracing their steps, and thus sparing themselves the obloquy, and art the discredit, that must else redound to them from such a puerile monstrosity.

Are we never to profit by experience, however dearly bought?—Must we continue to doom ourselves, time after time, to the sneers and reproaches directed against our blunders in nearly all matters of taste, by other nations?

Some may perhaps, be of opinion that quite enough has been said upon the subject already, and that any further remonstrance would be useless. We however, think very differently, being persuaded in our own mind, that it is mainly owing to want of determined perseverance in remonstrance, that so many abortions in architecture are inflicted upon this country. Or are we to be told that there is no public opinion whatever worth attending to in such matters?—that there does not as yet exist among us even one class of persons that can justly be considered as forming an architectural public? If such be really the case, the next question is, are we ever likely to have one?

As to the Nelson *bore*,—for such it now turns out to be,—there was, if we mistake not, a good deal said beforehand in the newspapers relative to the talent that would be elicited by the Competition. Talent, forsooth! Well, if there was talent, the Nelson Committee had certainly not *nous* enough among all of them, to find it out; else never would they have pitched upon such a miserable *pis aller* as they have done.—Should the Column—as we devoutly hope it will not—ever be erected, at all events a statue personifying the Collective Taste of the Committee ought to be clapped on the summit of it. Verily it deserves to be *extolled* and in no other way.

THE NELSON MONUMENT.

SIR—I am desirous of addressing you upon the subject of the proposed Nelson Monument; feeling that an unaccountable effort being now apparent to render our metropolis a laughing-stock to foreigners, it is a duty of every lover of art to raise his voice, however feeble. for the warding off of the impending calamity. I will for the most part confine myself to the examination of the question, whether an isolated column can with propriety be employed. Columns at first rude in execution, were erected by the ancients as actual supports to horizontal entablatures, and indeed according to one theory, that of Lebrun, we may say that their proportions, chosen as producing the most beautiful effect, were also those best calculated to ensure stability. The epistylia being of great length, the supports or columns were corbelled out at the top, with a view to shorten the part unsupported, and thus was invented the capital. It is erroneous, according to Sir William Chambers, and all other great artists. to employ ornaments which have not the semblance, at least, of utility, and if this excellent maxim be observed, we shall not admire a statue whose features cannot be distinguished, a capital without an architrave, and a column with nothing to support, and in fact, as I have heard it said, we might with as much propriety erect a colossal representation of the leg of our great hero. But, I am aware, there is yet a powerful argument in favour of isolated columns, viz. that they were employed by the ancients. But those who favour this opinion surely forget, that though in the columns of Trajan and Antoninus, the impropriety still exists, it is almost obscured by the ornaments and the spiral basso-relievos which, twining round the shafts, destroy in a considerable measure the idea of support. The object of the Roman structures could not be mistaken, they are evidently *monuments;* but the proposed erection will never have other than the appearance of a huge fac-simile of a small column. Surely some who argue that Roman precedent is sufficient to prove the proposed structure beautiful, pass over the numerous instances in which Roman artists have tortured and debased their plundered architecture. They it was, who totally ruined the proportions of the Doric and Ionic orders, who introduced broken entablatures and overloaded cornices, who placed order above order, and who set the order upon a lofty pedestal, and crushed it with a ponderous attic.

The truth of the saying of Aristotle, let us all hope will be manifested, and that "the people" will prove that they are the best judges of whatever is "graceful, harmonious or sublime," and I am confident that the best results would have followed, if *they* had been allowed, in the first instance, to give judgment between the competing designs. Amidst the general apathy, whilst the column is actually being commenced, an important Journal, Sir, like your's, should raise its voice, and you will therefore pardon, I hope, my trespass on so much of your space.

I am, Sir, very obediently, your servant,

A LOVER OF THE BEAUTIFUL.

47, *Lower Stamford-street.*

COMPARISON OF STONE AND BRONZE STATUES.

SIR—I observe with regret, that the statue for the summit of the Nelson column is to be of stone, from the very nature of that material it is impossible to make a statue which can look well in such a position, and this for reasons which I think have been overlooked, not only where statues of bronze have been placed on columns, but also in the majority of bronze statues erected in our public places. An error in judgment and in taste is observable in these, which becomes particularly offensive when a statue is placed on the summit of a column, and it arises from not considering the nature of the material employed. Bronze statues are, in our times, executed on the same principles of composition adopted in marble statues, from the necessities of the latter material. A glance at the arrangement of bronze statues amongst the ancients may assist us in determining what principles of composition should be followed; in these we find that trunks of trees, masses of drapery, and the various contrivances necessary to strengthen marble statues, and *only tolerated* because *ne essary*, are entirely dispensed with, and where drapery is essential to the subject, it descends in peculiarly light folds, and is generally tighened round the ancles, every advantage of the material being taken to imitate the thinness of real drapery. There cannot be a doubt of the propriety, and consequently of the taste of this arrangement, and an examination of the heavy dark masses in our streets and squares cannot fail to impress us with the conviction that the ancient practice is the proper one. The consequences where such masses are placed on the summit of columns, are peculiarly disastrous; it cannot, however, be doubted that bronze is the material which should, at all times, be adopted in such situations. We find, by the examination of ancient coins, that the statues of Trajan and Antoninus, placed upon the summits of their respective columns at Rome, were of a lightness in the arrangement wholly unattainable in marble or stone; these were clad in the military costume of their times.

The able artists who executed the statues of St. Peter and St. Paul now occupying (very incongruously, it is true,) the summits of these columns, had this difficulty to contend with, that their statues were, of necessity, enveloped in drapery; the talent with which the difficulty has been met is evident, and viewed at any reasonable distance, the statues look well. The drapery is arranged so as to be narrowest at the ancles, and the small perforation which it has been possible to take advantage of between the feet, has not been neglected, whilst the narrowing of the upper portion of the pedestals has greatly aided the grace of the general contour. It seems to me apparent that bronze is the only material which can enable the sculptor to make a statue fit in every respect for such a position; besides, to raise a monumental statue of so mean a material as that proposed, is altogether indefensible, placed on a magnificent column it becomes absurd; reason and good taste require, and the universal practice of the best periods of art point out, that statues in the position of that contemplated, should be of a more costly material than the pillar, which can only be considered its pedestal. The same reasoning by no means applies to the lions or sculptured portions of the column, as witness such ancient monuments as we are acquainted with, where the sculpture is merely intended as appropriate architectural decoration. In the Parthenon, the exterior sculptures were of marble; they only served to mark distinctly the character of the temple, the statue of the Deity within. The object, so to express myself, of the erection, was of far more costly material. The columns at Rome were decorated with appropriate and historic sculptures marking their character; the statues of the Emperors, the objects of the monuments, were of bronze.

I have some doubts whether the bronze columns which the French have erected are in good taste; they are imitations, or are designed on the principles of structures erected in marble. On the contrary, it has ever appeared to me that Bernini has displayed more philosophy and taste in his famous Baldachino in St. Peters, in having erected, as he has done, a light and peculiar structure, in which he has taken every advantage of the capabilities of his material.

When we look around us and see, I had almost said in every important city in Europe, monuments of the most magnificent description erected, it is with a feeling of mortification that we contemplate a proposed departure from propriety and good taste in our great and wealthy metropolis. I hope that an effort may yet be made to amend the resolution as to the statue. Should you think these few general observations worthy of a place in your excellent journal, you will gratify,

Sir,
Your very obedient servant,
C. H. W.

Edinburgh,
Sept., 1840.

CONSUMPTION OF SMOKE.

Sir—The possibility of ridding a large manufacturing town of the smoke which rises in such dense volumes from the long chimnies has always been a desideratum; but the methods employed to effect this have been so expensive or complicated, involving loss of power or extra labour, that they have been but little used, and the nuisance with all its disagreeable effects continues unabated.

Mr. Hall of this town has just patented an invention, simple, cheap, and effectual. I have this day witnessed its effects, and was much pleased with its simplicity, and astonished by the effective consumption of the smoke.

The principle of the invention, that smoke passed over a bright fire is consumed, has long been known; Mr. Hall only claims the adaptation of the principle which is thus effected:—

The fire place is divided lengthwise, by a thin wall of fire bricks, so that there is as it were two fire places under the boiler, each of which communicates with the main flue or chimney by a separate flue, therefore the two fire places would have no connexion were it not than an aperture is left at the top of the partition wall, near the front of the fire-places, by which means the two fires can communicate with each other, so that were the flue at the end of one fire closed, and the other open, the only passage for the hot air and smoke of the fire, whose direct communication with the chimney is cut off, would be through the aperture at the top of the partition wall, and over the other fire whose direct communication with the chimney is still open. It will be seen that by means of this arrangement the principle is easily applied. The fire, whose direct communication with the chimney is closed, being charged with fresh fuel, its smoke, in its route to the chimney, must pass through the aperture of the partition and over the other fire, which, being bright, effectually consumes it. By the time the fire last charged has burnt bright, the other will require replenishing, its communication with the chimney is therefore closed and the other opened, the low fire is charged, its smoke passes over and is consumed by the other bright fire. Thus by alternately charging one fire and then the other, all the smoke is consumed. The machinery for alternately closing the dampers is exceedingly simple. The smoke being all consumed a saving of fuel is obtained.

Whether the manufacturers will avail themselves of this invention, and thus materially improve the town, is uncertain; it is to be hoped they will: they ought at least to investigate the matter. One of Mr Hall's furnaces is generally at work in Messrs. Brigg and Sons' mill in Carlton-street, where its operation and effects may be seen. The inhabitants of Leeds should not let this opportunity pass without making an effort to abate this nuisance.

Your's respectfully,
C. L. Dresser.

Commercial-buildings, Leeds, Sept. 16th, 1840.

COMMENTS ON PORTICOES.

Sir—When in his 'Remarks on Porticoes,' page 295, speaking of those which project across the pavement for foot passengers, A. W. H. says: "the beautiful portico of Hanover Chapel, in Regent-street, and those of the Haymarket Theatre, and Melbourne House, Whitehall, favourably illustrate this position," are we to imagine that he at all regards with a favourable eye, or intends to express himself in favour of, Nash's portico to the theatre abovementioned? If he does not, he has expressed himself most incautiously; and if he does, I for one certainly do not envy his taste, nor covet his compliments, since in my opinion that portico, in whatever direction it may be viewed, is a most vile and trashy piece of design. Its poor miserable and starved looking cornice—as meagre and shrivelled as that of the United Clubhouse,—would alone suffice to damn both the design and the designer.

If your readers are not so ultra-genteel as to shudder at those horrible vulgar things called proverbs, I would remind them of that which says "Fine words butter no parsnips," as being quite à propos to the occasion, for though that miserable affair in the Haymarket, is called Corinthian, its more proper title would be the Cockneyfied Order. With regard to the inner or back elevation, it would disgrace a modern Ginshop. I know not what A. W. H.'s ideas may be of a portico "gracefully breaking," the line of houses by projecting into the street; but I do know that seen in profile the Haymarket portico, presents a most ungraceful gap, looking as if a column had been there knocked out *pro bono publico*, so as to leave room enough for a half-a-dozen fat old ladies to walk through arm in arm.

As A. W. H. has condescended to mention St. George's, Hanover Square,—which is so little spoken of as a piece of architecture that we might fancy it to be some most obscure and insignificant church, not included within the 'bills of gentility,'—it is strange he should not have quoted that one as the very best instance of all where the footway is carried through the portico. A portico projecting over the foot pavement is it seems just about to be erected in front of the Adelphi Theatre; but it may with tolerable safety be predicted beforehand, that it will not be particularly ornamental to the street, since unless extended in front of the adjoining house on each side, it cannot be much bigger than an apple stall, and will perhaps look not much unlike an unglazed shop front, dragged forward before its neighbours.

C. C.

THE ARCHITECTURE OF LIVERPOOL.

By a Stranger.

In the following remarks, let it not be supposed that the writer is governed by prejudice or partiality, or "set down aught in extenuation or malice." He scarcely knows an individual in the town, and his visit has been but to add a little more to his stock of architectural knowledge, which, with a student's patience and perseverance, he has spent days in travelling and many nights in study, during nearly half his life, to obtain.

And first to the Custom-house. This edifice, uniting within itself the Post-office, and one or two other departments beside, is considerably larger, more imposing and magnificent, than its namesake in the metropolis, and yet there are many things deteriorating from its otherwise grandeur of appearance, and most painful to the practised eye of taste or travel. The principal front facing Castle Street consists of a quadrangle, the centre composed of a massive prostylar* octostylar† portico, the columns being copied from those of the little Ionic Temple of Ilissus, situated upon the banks of the river of that name in Greece. This portico is simple, grand, and expressive, and its large and chaste proportions beautifully adapted to its purposes. The proportions of the rest of the building are upon the same scale of plainness, simplicity, and largeness, I had almost said ponderosity of proportion, suitable to the extent and commercial nature of the building, where not elegance, but the substantiality and solidity commensurate to its objects are required. The plain portions of the buildings are adorned by pilasters, but the highly ornamental base, both of columns and pilasters, should never have been permitted to continue their corrugated torri‡ round the edifice, thus disproportionately mixing richness and plainness upon the same face. The wings are simple and unexceptionable, and the bold, handsome stylobate§ gives both

* Projecting. † Eight columned. ‡ Circular portions of the base.
§ Plinth or base, on which the building seems to rest.

dignity and elevation. But, upon carrying the eye upwards, it is most painfully offended by the unsightly dome and tambour upon which it rests. This excrescence is most truly unfortunate; firstly, the Greek character of the architecture did not require a dome, a thing utterly unknown to the Greeks themselves; and, secondly, the contour of the thing itself is both ugly and inharmonious. Had the architect, when he had resolved upon a dome at all, consulted the graceful simplicity, swelling circumference, and tapering outline of that of St. Paul's, London, his conceptions might have been more chaste, and his work less open to criticism. The circular heads to the windows are equally architectural anachronisms. The sides facing the Dock and Hanover Street, are adorned by a similar portico to that last described, and placed upon a bold flight of steps. Here the critic can only praise the pilasters, intercolumniations, entablature, cornice, windows, and doors; the latter, especially, are bold, handsome specimens. The rear elevation is most infamously miserable. The eye is pained and disappointed at the wretched poverty of ornament and detail; entablatures discontinued; two tiers of windows in one part, and three tiers in another, the upper one being beggarly loopholes in the place where the entablature should have been. The interior has also faults of no mean order; besides want of taste, the mixtures of styles, the commonplace, unimaginative nature of the details, it wants light. Still, upon the whole, in spite of many serious defects, this edifice, from its size, grandeur, chastened simplicity, isolation of position, and importance as to utility, is well worthy of admiration from the stranger, and respect from the citizens of the good town of Liverpool.

Let me now turn to the Royal Bank, Dale Street, *i. e.* from the extreme of simplicity to that of richness and luxuriance. This edifice is just completed, and is composed of a basement of enormous height, upon which is placed a Corinthian order containing two tiers of windows. The centre is composed of seven-eighths columns. There is much richness and originality in this edifice, and although its gorgeousness and profusion of complicated carvings, mouldings, and details may please vulgar taste, it is too sadly overdone to please the more practised eyes of the architect or amateur. The basement is ridiculously high; the Venetian windows too redundant of carving and various ornaments; the cornices would not be too rich upon a plainer face, but now, cut dentil, carved ovolo, and running beads weary the eye, which, like the dove of old, finds no resting-place to fix upon, but, wearied and fatigued, it turns away, but is reluctantly compelled to own the extravagant richness and luxuriance of ornament. And yet, whilst some parts are more adorned than any building in the country, the central windows are mere loopholes, not having even an architrave round them, whilst the rest of the windows have not merely rich architraves, but revel amid a profusion of carved foliations. The top is surmounted by a balustrade, which, with the plinth, is ridiculously high. I would also call attention to the wretched life-size sculpturing of the arms in the centre of the building, which bears a distant resemblance to an amatory lion making love to some sportive unicorn, who, rejecting his addresses, and tossing up his head with its tremendous horn, seems to repeat to himself the scriptural piece of self-satisfaction, "My horn hall be exalted." Upon entering the interior, the eye is dazzled by the rich profusion of architraves, friezes, cornices, ceilings, panels, and ornaments; the eye is wearied and confused, and attention exhausted; no repose, no chasteness, all is the most lavish profusion. The grand error seems to have been to have crammed as much ornament and expense as possible within a given surface.

I will now turn to the Town-hall and Exchange. It is much to be regretted that the former does not face directly down Castle Street, instead of the portico approaching one side of the street considerably more than the other. This edifice is highly creditable for the day in which it was executed; and, although there are no great beauties, there is little actually to condemn beyond the meagre, wretched carvings between the capitals of the columns. The assembly-rooms are admirably proportioned, more especially the great room, which is in sesquilateral proportion, but the ornaments are somewhat few in number, and poor in detail. To the staircase, a later work, by Sir Jeffry Wyatville, must be afforded the most unqualified approbation. Its proportions, decorations, colour, and all other adjuncts, are beyond all praise. Its effect is that of the most chaste repose; and, of its size, there are few finer in the kingdom. Returning to the "place" forming the quadrangle of the Exchange, the stranger is much struck with the similarity of this, upon a small scale, with certain edifices upon the Continent. The effect of this square from one corner, with the Nelson monument in the centre, is particularly fine; for, although there is nothing worthy of note in the architecture itself, still there is an importance highly pleasing and effective. The monument is worthy of attention; the lost arm of this great hero is here ingeniously hidden by a flag. The base, which is circular, is ornamented by basso relievos and statues, full size, chained to the base, and resting upon a step, which gives a pleasing breadth to the lower portions. This adds much to the effect of the base; but whether it is worthy of the better feelings of humanity to commemorate our triumphs by figures in chains and painful postures, thus perpetuating the fierce passions of war, now that peaceful times are emptying their cornucopias around us, I leave to more philosophic critics.

EDER.

An enormous organ is now in the course of erection in the Abbey of St. Denis. It contains about 6,000 pipes, amongst which are some measuring 52 feet, and weighing 12,000 lb. This magnificent instrument is nearly completed.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

TENTH MEETING.—*September*, 1840.

(*From the Athenæum.*)

SECTION G.—MECHANICAL SCIENCE.

President.—SIR JOHN ROBISON.

Vice-Presidents.—His Grace the DUKE OF ARGYLE: Rev. Dr. ROBINSON (Armagh); Messrs. J. TAYLOR; J. WALKER.

Secretaries.—Messrs. J. S. RUSSELL; C. VIGNOLES; J. THOMSON; J. TOD.

Committee.—Messrs. J. Dun, T. Edington, W. Fairbairn, J. Glynn, Professor Gordon, Messrs. R. Griffiths, I. Hawkins, E. Hodgkinson, W. Jessop, A. Liddell, J. Macneil, R. Napier, Sir J. Rennie, Messrs. J. Roberts, J. Smith, C. W. Williams.

THE first paper read was "*On Safety-valves for Steam Boilers,*" By Mr. Galliae.

The merit of the proposed alteration rested on the general principle, that the safety valves at present in use are not large enough; and Mr. Galline's object was to allow a large surface, like the lid of a chest, to rise when the pressure becomes sufficient to force it up; so that, on an accumulation of steam, it might escape, before any accident could take place. His proposal was, in brief, that a large valve shall open instead of a small one.

"*On extinguishing Fire in Steam Vessels.*" By Mr. Wallace.

Mr. Wallace proposes to effect this by steam itself. The plan has been some time before the public, and many successful experiments made in the presence of scientific persons. Among the most important was the following, made on board the *Leven* steam-boat:—On the cabin floor, a space of 10 feet by 14 was covered with wet sand, on which was laid iron plates and on these a fire was kindled with about $4\frac{1}{2}$ cwt. of very combustible materials, such as tar barrels, &c. A hose 34 feet long, $2\frac{1}{2}$ inches in diameter, extended from the boiler of the engine to the cabin, and when the fire had been sufficiently kindled, so that the panes of glass in the windows of the cabin began to crack by the heat, the steam was let in, and the door of the cabin shut. The fire was extinguished in about four minutes. Several trials were made, and all with like success. On another trial, a metal pipe of a greater diameter than the hose was connected with the steam-boiler, and extended into the cabin. A small square hatch was cut in the deck immediately above the cabin, and through this opening were lowered down into the cabin two moveable grates, each containing a blazing fire, well kindled, of about 1 cwt. of coals. The hatch on the deck and cabin doors were then shut, and the steam let in, and in 15 minutes the small hatch was opened, and one of the grates hoisted up, when the whole mass of coal and cinders, which had before formed a powerful fire, were found to be completely extinguished. This experiment was repeated twice with equal success.

In reply to a question from the President, Mr. Wallace said, that the hose might be made either or silk or canvas painted. It was stated that in Philadelphia, and now in London, the firemen always direct the water to the lowest part of the fire, that it might be converted into steam. Dr. Hamel, of St. Petersburgh, mentioned, that in Russia they have used woven hemp hose for fire-engines more than forty years. Mr. Roberts, of Manchester, said, that in that town there had been a fire in a factory some time since, when the men went in, broke the steam-pipes, which were charged, shut the doors, and the fire was out immediately.

"*On Wheels of Locomotive Engines.*" By Mr. Grime.

The rim or felloe of the wheel is turned, welded, and blocked in the usual way to the size required, say three feet diameter; the side, or front rim of the wheel, is formed out of boiler plate-iron, say $\frac{3}{8}$ of an inch thick, clipped round to size required. I then, said the writer, take the plates and punch out the centre, which forms the eye of the wheel. After this the shapes are punched out, leaving the boss and arms standing together, with a sufficient breadth of iron at the extremity of the arms that will be equal to thickness of felloe, say $1\frac{1}{2}$ inch to 2 inches, for wear, and, when welded, forms part of the felloe. The boss of the wheel is punched out of plate-iron, say $\frac{3}{4}$ of an inch thick, into what I denominate washers; I then pile them one upon another, to the breadth of the wheel, taking notice to cross the grain of iron every washer when piling them. By so doing, the boss, or nave, will be considerably stronger and tougher than if the grain of iron went all one way. When this is done, it bears the name of "faggotted iron." The washers being piled to the required thickness, I pin them to one of the punched plates, the diameter of wheel required; then put the rim or felloe on, and pin it to the plate. This being done, I put in the midfeather, say $\frac{1}{2}$ inch thick, and the depth of felloe and piled plates or boss, there being in every washer a half circle punched out to receive the midfeather; the other plate is then put on, and pinned to the other parts. The wheel being now formed, it is taken to the furnace, which is constructed with a revolving table at the bottom, so arranged that it can be dropped or raised. This table is formed of fire-brick, and on the top are placed five loose bricks, to keep the wheel from touching the table, and to enable the workmen to get the wheel into the furnace and out again by means of a fork. The furnace having been got up to an intense heat, the table is set to a particular mark, the door of the furnace is raised, and the wheel slided on to the table; the door is then closed, and the table, which is worked from underneath by a tooth and pinion, is turned round, presenting every part of the wheel regularly to the flame, as the flame rushes through the furnace. The wheel, having been in about three-quarters of an hour, and having arrived at a perfect welding heat, the table is turned to the mark before mentioned, and the wheel is slided out on to an anvil. This anvil is planed perfectly true on the face, and is larger in diameter than the wheel. Above the anvil is the hammer, of about 15 cwt., suspended at a height of about 12 feet, the face of this hammer being planed perfectly true, to correspond with the face of the anvil. As soon as the wheel is placed on the anvil, the hammer is released, falls on the wheel, and perfectly welds it into one entire solid at a single blow. Before pinning the wheel together, I put the various parts into a solution of vitriol and water, and, should there be any part corroded, it immediately removes it, so that there is nothing but pure iron, and a good welding is easily obtained. The wheel, when cold, is turned up in the usual way.

"*On Warming and Ventilating Buildings.*" By Mr. Ritchie.

The principal object of this paper was to call the attention of architects to the construction of houses, with a view to a better provision for heating and ventilation. The author described the method adopted by Sir J. Robison, whose house is warmed by a large supply of air heated to 70°, which is allowed to issue directly into the lobby and staircase, which it heats to 60° even in the coldest weather. This heated air is allowed to enter the sitting rooms freely by concealed apertures over the doors, and the vitiated air is carried off through openings in the ceilings by separate flues in each room.

Mr. Hawkins always found that, in the sitting rooms, open fires were required to warm the feet, though not necessary in bed-rooms.—Mr. Hartop agreed, and considered Sylvester's Radiating Stove the best for the purpose, in addition to the general heating apparatus.—Mr. Vignoles concurred, and stated that nothing prevented Sylvester's stoves being universally introduced, but their high price.—Mr. Hawkins stated, that, from experience, a large fire with a small supply of air, was the most economical mode of using fuel.—Sir John Robison stated that, with the apparatus in his house, he can keep his staircase at a temperature of from 58° to 62°, when the current of heated air was only 64° as it issued from the apparatus, and that the additional expense caused by his provision for ventilation did not exceed 20*l*.

"*On the Temperature of most effective condensation in Steam Vessels.*" By Mr. J. Scott Russell.

Much (said Mr. Russell) has been said regarding the perfection of the vacuum formed in the condenser of a steam-engine, especially a marine engine. It does not appear to be known, that a vacuum may be TOO GOOD. We hear it boasted every day, by rival engineers, that their engines have the best vacuum. Some boast their vacuum at 27 inches, others at 28, others at 29, some at 30, and at last an engineer appears who boasts a vacuum of $30\frac{1}{2}$ inches! It is to be regretted that time and talent should be thus wasted. It is a fact of great importance, and it is the result of theory, established on incontrovertible truth, and confirmed by experiment and by practice, that a vacuum may be too good, and become a loss instead of a gain. The truth is simply this, and should be known to every engineer: *If the barometer stand at $29\frac{1}{2}$ inches, the standard of this country, the vacuum in the condenser is* TOO GOOD *if it raise in the barometer more than 28 inches of mercury.* This important truth is incontrovertible—it is practically exhibited every day. The following is a simple proof of this doctrine, divested, as far as possible, of a technical form, and put in the shape of an inquiry into the best state of a condenser:—

Let l = the caloric of water of 1°.
c = the constituent caloric of water in the state of steam.
e = the total force of steam in the boiler, in inches of mercury; and
x = the elastic force of steam at the temperature of best condensation, which we seek to discover.

Then from the law which connects the elastic force of steam with temperature, it follows, that in case of maximum effect, or the temperature of best condensation,—

$$\frac{l}{c} = \frac{x}{e}, \text{ that is, } x = \frac{e\,l}{c}$$

Now c is 1000; and if the steam in the boiler be at 5 lb. above the atmosphere, or if $e = 40$ inches of mercury, and $l = 1$,

$$x = \frac{40}{1000} = 0{\cdot}04$$

Again, if the steam be at $7\frac{1}{2}$ lb. = 45 inches,

$$x = \frac{45}{1000} = 0{\cdot}045$$

Again, if the steam be at 10 lb. = 50 inches,

$$x = \frac{50}{1000} = 0{\cdot}05$$

Hence we find, that the best elasticity or temperature in the condenser depends on the elastic force of the steam in the boiler.

With steam of 5 lb. in the boiler, the elasticity of maximum effect in the condenser is 93° Fah., and the best vacuum on the barometer is 28.

With steam of $7\frac{1}{2}$ lb. in the boiler, the elasticity of maximum effect in the condenser is 95°, and the best vacuum on the barometer is 27·8.

With steam of 10 lb. in the boiler, the elasticity maximum effect in the condenser is 97°, and the best vacuum on the barometer is 27·6.

In like manner it would be found, that with steam of 50 lb. in the boiler, worked expansively, as in Cornwall, the best vacuum in the condenser would be about 26, on the barometer.

It is hoped, therefore, that engineers will not in future distress themselves at finding the vacuum of their condenser much less perfect than the vacuum of others who have obtained 30 and $30\frac{1}{2}$ inches at so great loss of fuel and power. To obtain a vacuum of $29\frac{1}{2}$, with the weather glass at 29·75, and steam at $7\frac{1}{2}$ lb., would be to sacrifice four horses' power out of every hundred. In a day when the barometer is as low as $28\frac{1}{2}$ inches, the vacuum in the condenser would indicate 26·8. In speaking of the vacuum in the condenser, it would save much ambiguity to indicate the elasticity merely of the steam in the condenser; thus, if the barometer stand without at $29\frac{1}{2}$, and the barometer of the condenser at 28, it might be stated that the steam in the condenser stands at $1\frac{1}{2}$, being the point of maximum effort. The indication would convey at all times more precise information.

Mr. Russel stated that the President had just put into his hands a communication in French on this subject from Mr. Barnes. Instead of a jet playing inside the condenser, M. Barnes allows it to rush in suddenly, and then stops it by a slide valve.—Mr. Fairbairn wished to know whether the facts stated by Mr. Russell had been practically established.—Mr. Russell stated how the experiment might be made.—Mr. Fairbairn considered this a very important subject, as bearing on the economy of fuel, and regretted that Mr. Russell had not given an account of his experiments.—Mr. Russell suggested that Mr. Fairbairn should himself undertake the experiments.—Mr. Hodgkinson considered it very important that experiments should be carried on; and Mr. Fairbairn, that experiments should be made on steam at all pressures. It was suggested that this was a proper subject to be inquired into by the British Association, and it was agreed that the Committee of the Section should discuss the propriety of applying for a grant to pursue the experiments.—Mr. Taylor stated that they use plungers in the air-pumps in North Wales; and Mr. Hartop, that in America air-pump buckets have been made without packing, and found to answer well.—Mr. Roberts stated that he had made engines with solid pistons without packing, both cylinder and air-pump.—Mr. Vignoles mentioned that such solid pistons had been used on some of the first locomotive engines on the Dublin and Kingstown Railway.

"*On Timber Bridges of a large size, in special reference to Railways.*" By Mr. Vignoles.

Mr. Vignoles commenced his remarks by stating, that he had, by permission of the committee, selected this subject for illustration and discussion before the Mechanical Section, from the notes of a work he was preparing for publication, 'On the General Principles and Economy of Railways,' his object in so doing being to elicit the opinions of his brother engineers, and to invite discussion and obtain information, but especially to direct the attention of all parties interested in the extension of the railway system to a principle of construction which, in many cases, would be found of great advantage in the economy and facility presented for overcoming obstacles, otherwise insurmountable, within reasonable limits of expense. Mr. Vignoles took a rapid view of the history of timber bridges, tracing their first erection in Germany, then through the United States of America, and back to Great Britain. He also described the difference between the principles of large bridges constructed with baulks and half-baulks, and of timber arches, formed of layers of plank laid over each other, and fastened securely together, and, with felt or other means, to make the joints and beds wholly impervious to water. Mr. Vignoles stated, that the first bridge on this principle in Great Britain had been erected at some place in Scotland, by an ingenious mechanic of that country, whose name he regretted not to be able to state. This was many years since. The principle had been also made known, particularly of late years, by the timber viaducts erected under the direction of Messrs. Green and Son, of Newcastle-on-Tyne, who had been built several, and had designed more; and Mr. Vignoles further explained, that Mr. Nicholas Wood, of Killingworth, who at this time erecting, for the Duke of Buccleugh, a timber viaduct, of great height, and with large openings. Mr Vignoles disclaimed any intention of discussing the question as to whom the merit of orginality belonged, and observed, that he, at present, purposely refrained from any details, as these had been entered into by Mr. Green both at Newcastle and at Birmingham, reserving any remarks on such details for a future occasion, should it present itself. Mr. Vignoles then explained the peculiar applicability of timber bridges or viaducts to the passage of deep ravines, so often met with in hilly and mountainous districts, illustrating his remarks by diagrams. The communications, for example, to be made between the north of England and Scotland would probably have to be sought along some of the valleys leading to the passes through the Cumberland Hills, and here, as in many similar districts, engineers in the habit of considering such lines well knew, that many miles of favourable country for roads or railways were often to be obtained along the sides of such principal valleys, until some unavoidable appalling obstacle appeared in the passage across some of the lateral openings or ravines. Instances had and might occur where the whole of such a line, otherwise highly desirable, would have to be abandoned, unless some economical construction were devised to surmount the difficulty: and here the timber viaduct would most advantageously be introduced, since many feet additional height in the level of the railway would add but little to the expense. He then instanced several places of formidable height, and of various breadths, where he had already designed, or knew of the applicability of such constructions. In reference to the expense, he stated, that it was chiefly when extraordinary height and either one arch of great span were required, or where a series of arches, of large openings, were wanted or could be introduced, that the timber viaducts were the most economical. In ordinary heights of 50 or 60 feet, and with arches of less span than 100 feet, and particularly in countries presenting facilities for construction of stone, these latter would be undoubtedly preferable; but when the height of the construction became great, the great expense for the centering for arches of masonry, and the multiplication of the number of piers, in order to keep the span of the arches to a moderate size, greatly increased the expense, and threw the balance vastly in favour of the timber. Mr. Vignoles instanced the Ribble Viaduct on the North Union Railway (a model and description of which is in the Model Room of the Association), which was about 50 feet high, with five large arches, of 120 feet span, and had cost 60*l.* per lineal foot; whereas, in another place, a timber viaduct, of 140 feet high in the centre, and averaging 100 feet high, with arches of 130 feet span, and extending for a length of nearly 2000 feet, was proposed, which would not exceed in price 20*l.* per lineal foot, the breadth of roadway being, in both cases, 28 feet for a double line of rails. Mr. Vignoles stated, that in extending lines of railways through the west of England to the packet stations, through the mountains of Wales for a communication between London and Dublin, and through many parts of Ireland, along the lines laid out by him for the Government Railway Commissioners, the timber viaducts would, from their cheapness, enable the works to be entered upon, which the great cost of stone would quite forbid; and he concluded by calling on his fellow engineers to turn their attention to this while laying out new lines, and to take bolder steps across the valleys, relying on the timber viaducts to accomplish their objects.

Mr. Blyth thought that Mr. Vignoles had over-estimated the expense of stone, which Mr. Blyth knew had been executed at about 25*l.* per foot.—Mr. Vignoles replied, that it was seldom that stone could be had at so small an expense; when the span is large, and the height great, it is much more costly. —Mr. Smith, of Deanston, agreed with Mr. Vignoles, but did not think that planking was the best method, as it would not stand so long. A wooden bridge should be so constructed, that any decayed part could be taken out and replaced.

THE THAMES EMBANKMENT.

The Select Committee appointed to consider the Petition of the Corporation of London relative to the Embankment of the River Thames, and to report their observations and opinions thereupon to the House, together with the best means of carrying the same into effect; and to whom several Petitions relative to the measure, and Reports of former Committees, were severally referred;—have considered the matters to them referred, and have agreed to the following Report:

The Committee have met and proceeded to examine a Plan and Estimates of the proposed Embankment, submitted by Mr. Walker and Mr. Higgins, and other witnesses: that several petitions for and against the measure having been referred to the Committee by the House, and many other witnesses both for and against the intended plan being proposed to be examined, the Committee are obliged, by the near approach of the prorogation of Parliament, to conclude the inquiry without the examination of many plans for the embankment of the river, or the consideration of any plan for the improvement of the navigation, without any alteration of the present line of embankment. Upon the general subject, therefore, of the improvement of the navigation, with or without any embankment, they give no opinion in the present state of the inquiry.

29 *July* 1840.

Abridgement of the Evidence.

James Walker, Esq., was examined and stated that he has been professionally acquainted with the river Thames, in reference to the subjects of inquiry, for the last 30 years he has been employed, either as assistant or principal engineer, at the greater part of the docks that have been constructed in the port of London. In 1816 he constructed Vauxhall Bridge, and in 1821 his attention was called directly to the effects that the then proposed removal of London Bridge would have on the river Thames. He has been almost constantly employed on works of a similar nature on the Thames from that time to the present day. He was called in by the committee for letting the Bridge-house estates in 1821, along with his friend Mr. Leach, to report on the effect that the removal of London Bridge would have on the water of the river Thames. He did not think that ballasting has done much good: it is done for the purpose of obtaining ballast, and it is only where the ballast is good that the dredging engines have got to work; that has not much regard to the interests of the navigation. It does nothing to take away the shoals. At present the water ebbs so low in the river, above bridge, that in some parts of it, where the width is very great, the shoals are perfectly dry for the greater part of the width across the river; mostly in that part of the river above Waterloo Bridge and the neighbourhood; between Westminster and Waterloo Bridges and below. The dredging vessel above bridge is used chiefly for obtaining gravel for roads, not for ballasting ships and similar purposes. The effect of the removal of London Bridge operating in the way he has stated, increased the velocity of the current through Blackfriars Bridge, and had nearly undermined the piers: so that by going down, which he did in a diving helmet, he could put his leg under the caisson bottoms, under the platform on which the bridge stands; the consequence was that the city, partly through that cause, and partly through the decayed condition of the stone, ordered a survey to be made, and an estimate; and since that time, five of the piers have had coffer-dams put round them, and the foundations extended down to about 14 feet below the old bottom. as regards Westminster Bridge, although a great deal of trouble had been taken for a great many years in supporting it, the Commissioners of Westminster Bridge, also for the same reason, have commenced strengthening the piers in the same way as has been done at Blackfriars Bridge, by coffer-dams; he considers that both of them are the effect of the removal of London Bridge. He did not think that any increase of ballasting would prevent the accumulation and increase of shoals, because while the river is so unequal in width as it is now, you may keep ballasting, but the velocity being slow at the wide parts, you will have a settlement always taking place there again, and then you must go on constantly with the ballasting. The first thing to be done is to regulate the width of the river. The plan of the river which is before you will show you, that in places now between London Bridge and Vauxhall Bridge the river is double the width that it is at other places. The effects by London Bridge being removed since 1821, are what he has before described, to deepen narrow places very much, and to cause large shoals in the places where the river is so very wide. To give the Committee an idea what the present width is, he stated, that the width now opposite the Penitentiary is 600 feet at high water: opposite Millbank, to the Bishop's-walk, it is 1,050; opposite the Board of Control it is 1,200; and opposite Buckingham-terrace it is 1,480. Then it keeps narrowing by degrees, until below Southwark Bridge it is 720, and at London Bridge the waterway is 690. While the river is so unequal as that no dredging would do much good. If you dredged so as to get proper depths for navigation in the wide parts, you have a settlement of mud, and a constant removal of that again, or an accumulation of shingle to fill up those cavities. The idea here was, first to endeavour to get something like a regular section, not strictly increasing in width by degrees, but approaching to it as far as could be done consistently with the value of the property on the sides of the river. The waterway of Vauxhall Bridge itself is 702 feet: the width of the river 200 or 300 yards above is 680 feet at high water, between the wharfs. He does not consider the whole of that waterway useful for the purposes of navigation as a thoroughfare, but it is for the general purposes of trade, that is to say, that the barges can go up to the wharf-side, and can go away again at high water at all times. There was an apprehension that the present embankments that have been carried out, such as that one at the House of Commons and others, would have left in the parts of the river near it a considerable quantity of mud, and the proprietors of property above bridge had a clause introduced into the Act for building the Houses of Parliament, keeping open their claim for compensation in case of damage being done. He has, from time to time, as employed by the Commissioners of Crown Lands, sections taken of the states of the ground at different times, and the fears of those parties have proved to be very much over rated: the increase is not so great as he expected. The increase is very variable; perhaps in some places it is lower, and in other places higher, but as a general position he does not think there is much increase. There are now deposits in consequence of the embankments. The coffer-dam around two of the piers of Westminster Bridge tended to send the water over to the opposite side, and to cause a settlement of mud on the Middlesex side: that coffer-dam is now removed, and the opening which was closed by the coffer-dam is deeper and better than ever it was. The deposits have been between high and low-water mark. The effect, opposite the projection itself, is to decrease the deposits by narrowing them; but the effect also is to cause the settlement of mud above and below. The effect that would otherwise be produced is much lessened by the constant passage of steam-packets up and down the river. The mud is kept in a state of suspension instead of being deposited. What the embankment would have tended to have done has been prevented or removed by the wash of the steam-packets. The removal of the coffer-dam from the western arch of Westminster Bridge will tend to remove the deposit that has taken place in the course of last year, and when the coffer-dam in front of the new Houses is removed (which it will be when the Houses of Parliament are finished), with the large quantity of ground which he had put out for the purpose of securing the coffer-dam, that will tend to bring the current over to the Middlesex side. He hopes the effect of continuing the embankment will be, if properly done, to remove the shoals. The idea would be, whether by embankment or otherwise, to deepen the river by the removal of the shoals, and to apply those shoals to filling up behind the embankment. He contemplates two operations, both deepening the river artificially and building the embankment; the embankment could not be made without the material which will be taken from the bed of it to fill in behind the embankment, which will have the effect of deepening the river. Deepening the river, the supply of water remaining the same, will tend to throw a greater quantity of water within a certain part of the channel, but it will not be at the expense of that side of the river where there is no embankment; the embankment being to be formed close up to low-water mark on the north side. There will be more water on the south side than there was before.

Mr. Walker explained that it is not only the land floods coming down, that chiefly forms the current of water in the river Thames opposite Lambeth; but it is also owing very much, except in extreme floods, to the tides. Now, whether it be from tidal water, or from land floods, the effect of narrowing the river on the north side would be, as there is a given quantity of water to come down during the land floods, to press that water more over to the south side, and to increase the velocity. With land floods the quantity is given; that is to say, it is fixed, whether the opening be large or small. With regard to tidal water, it depends on the space to receive the tidal water; but the effect in any way would be to give greater velocity, and tend to the removal of mud from the shoals on the south side. Where the river is very wide and straight, there is a very considerable quantity of mud, three, four, or five feet and more: at other places, at Waterloo Bridge, for instance, although the width is very great, there is not so great a quantity of mud, because the flood-tide rather takes that off. Mr. Walker stated that his evidence given referred to one side of the Thames only. The ultimate scheme is to embank both. It may be done with one side only, but not so complete as with both sides. Although he uses the word embanking, the Committee must not understand that there is an intention, or that it is practicable to embank both sides of the river by [illegible] from side to side, but that every respect must be paid to the way in which the present premises are occupied, still improving the navigation and the value of the property. There is a large space occupied now by coal barges, some on the opposite side by barges with timber. There may be places where, by carrying out the embankment wall, the trade may be so much interfered with as to damage the property, unless provision be made in the proposed improvements for accommodating those barges. He proposes to place the barges alongside the wharfs, and extended a great way out, and to lie on their beds as they do now; but still the river, as regards the navigation, and as regards the health of the town, and he thinks as regards the property itself, improved. The area of the river would be diminished where it is too wide.

The effect of the removal of London Bridge on the severage has been to expose a larger surface of the bank of the river at low water, and to render, therefore, the injurious or unpleasant effect from a discharge of the sewers greater than before. The effect on the bottom of the river generally has been to deepen it in certain places, and to render it shoal in other places very much, as he ascertained, and as he read from the report of 1821. He thinks it is quite impossible to look at the river Thames, at low water now, without seeing, as regards the trade up the river, and the navigation opposite to London itself, that the river is in a state that wants improvement very much; and this is to be taken along with it, that as the effect of all those floods is constantly to deepen in one place, and to shoal in others, that that deepening will extend in time, so as to be injurious to the property on the banks of the river, as regard its foundations. He thinks the river will undergo further change. The effect of the dam at London Bridge was to keep the bottom, above London Bridge, very much higher than below London Bridge; the dam is now removed, and there is, as was predicted by Mr. Smeaton, a constant movement of the bottom of the river downwards, and an increase in the depth in certain places; and that will go on for many years to come, perhaps generations. The effect on the water-side property, if continued without some protection, may be, as he has already said, to endanger the foundations of some of the best buildings on the river Thames; I refer to the great current in one place, and to the forming pools in the middle of the river, which tends to draw the sand from under the buildings on the banks of the river. It would be desirable, in his opinion, that the bed of the river should be made uniform, or nearly so, in point of depth, and gradually increase in width from Vauxhall Bridge downwards.

The calculation which has been made for forming the embankment has been, in the front of the private houses, where the embankment is to be made, built of brick and filled behind with the excavations from the bed of the river: the Government property in the neighbourhood of Whitehall, and also Somerset House, has been estimated to be faced with stone. He has no hesitation in saying that this embankment would improve the navigation throughout: there is no way, he contemplates, in which any person could say otherwise, excepting this, that where the embankments are made there is a small decrease of tidal water, somewhat less of tidal water comes up the river than would before, referring to width only, and therefore a somewhat smaller velocity of the ebbing tide: but that would be partly compensated for by the deepening. He has seen this done under his own directions on the river Yare, and the effect has been good, both as regards the harbour from the removal of the bar, and the improvement of the navigation up to the town: that was done not by embankment wall, but by a dwarf piling, exactly as the section now before the chairman shows it. Extensions into the river Thames are sanctioned, and their extent defined and regulated, by the navigation committee of the city of London. The proposed width varies from 600 to 800 ft. If the conservators of the river think that barges can lie without prejudice to the navigation or highway, they may lie in the river afterwards just as they do now: but if the embankment be carried on, and these recesses left, both as regards the current of the tide, and as regards being injured by other barges, those docks would be snugger than the barges lying out in the river. Injury may be done to the individual by not allowing him to go far enough into the river, or injury may be done to the river by allowing him to go too far, unless a general plan is laid down and acted up to. When one embankment is carried out, or a wharf carried out beyond the other, great inconvenience arises to both of the parties; and it is a constant source of quarrel in the river Thames at this moment; one party opposing the embankment and another supporting it; and he takes it the members of the navigation committee itself are much annoyed by individual applications, they themselves having no certain rule to go by. He proposes that the allinement should be general; it should be either an embankment or a dwarf piling, to regulate the section of the river. He need hardly say that his answers must be very general; but in a great work, such as this, reference would be had to the interests and wishes of the individual parties who have property on the banks of the river, and their wishes complied with, so far as that can be done without prejudice to the great public measure; and if that were done, he thinks benefit would be done to all. These recesses would, in degree, be injurious to the general plan of regulating the velocity of the river, and the less of them the better; but as they would be recesses with their sides at right angles with the line of the river, their effect would be far less injurious than gradual widenings and narrowings. He presumes that the only way the thing could be done practically, is to consider these recesses, as well as the back ground, private property after the works should be complete; he thinks it impossible to introduce any occupier or proprietor between the present bank of the river and the proposed embankment. His idea is, that all the ground reclaimed should be considered as belonging, upon terms to be agreed, to the owner of the adjoining property. He considers that the property on the banks of the river will be improved in value by the alterations; he does not mean to say there may not be some exceptions, but he thinks very few; and it is impossible, in a great work like this, to have good done to all without some injury, perhaps, to individuals. He has estimated for a brick wall, generally; but, in some places, stone; he considers all the answers he has given now to have reference to the north side of the river.

The whole length of the embankment, between Vauxhall and London Bridge, is 11,055 feet, which is exclusive of the part that is not intended to be interfered with. The length he has given terminates at Dowgate Dock: that is the whole length he proposed embanking on this plan. There has since been, he has been informed, applications made by the owners of property below to extend it farther, nearer to London Bridge. Dowgate Dock is about 1,000 feet from London Bridge. The 11,055 feet includes not only the portion he proposes to embank, but also these recesses which he proposes to leave for the accommodation of the trade. The total distance from Vauxhall to London Bridge is 15,900 feet, according to the present line of river frontage; his whole estimate is £310,000; £105,000 of that, as far as he can ascertain, is crown property. He thinks *2d.* per foot per annum would cover all the expenses of the cost, with moderate additions for contingencies, expenses of management, rent, &c. He considers that the mud so carried away would not be deposited in a still more important part of the river, in the Pool, for instance. There would be a diminished quantity of tidal water, but that would be compensated partly by increased depth, by removing the shoals which now appear above low water, and would be more than compensated by making the bed of the river of a uniform character both in breadth and depth; at present there is a rise at low water from London Bridge up to Westminster Bridge of 2 ft. 5 in., the water being kept up by the shoals in the way described: if the river were regulated and deepened, the effect would be to lower the water at Westminster Bridge, and all the way up the river lower than it is now: therefore in depth there would be a greater quantity of tidal water to ebb and flow, which, he apprehends, in cubic quantity would exceed the contents of the embankments. The width of the river when the embankment is done, with what is its present width at those points, will be as follows:—at the Penitentiary no diminution is proposed to take place in the 600 feet. From Millbank to the east end of Bishop's-walk is intended to be reduced from 1,050 to 800 feet. Opposite the Board of Control it is proposed to reduce it from 1,200 to 810 feet. Opposite Buckingham terrace, from 1,480 to 850 feet. Opposite Somerset House, from 1,250 to 870 feet. Opposite Temple-stairs to Lett's timber-yard, from 1,240 to 870 feet. Opposite White-friars-dock to Bull-stairs, from 1,040 to 770 feet. From Trig wharf to the opposite side, from 920 to 730 feet. West side of Queenhithe dock to opposite side, from 700 to 680; after which the diminutions are small, and the river gets narrower.

(To be continued.)

STEAM NAVIGATION.

STEAM NAVIGATION IN FRANCE.

Extracts from the Report of Count Daru to the Chamber of Deputies, in the name of a Special Commission intrusted with the examination of a projected law relative to the establishment of Steam Packets between France and America.

THE form, dimensions, and power of steam-boats evidently depend on the service to which they are destined. They were not long merely employed in the ascent and descent of rivers, but soon the limits of steam navigation were enlarged, increasing the power of the engines from 20 to 80, 160, 200, and 250 horses, it became possible to extend the field of their employment to venture on the sea with them. Towing boats, which had been constructed in a few ports, soon threw a light on the superiority of the new system, by bringing out large vessels, weather bound and condemned to inactivity, and drawing them in their wake with a facility which seemed to defy the elements. From that day the bright days of sail-navigation, which, till then, was looked upon as the *chef d'œuvre* of human understanding, were eclipsed. Now vessels were started on every coast. Regular and rapid communications linked together every important town, such as Havre, London, Dover, Hamburgh, Rotterdam. This was the forerunner of more daring attempts.

In 1819 a vessel from the United States, "the Savannah," had crossed the ocean from Liverpool to New York, partly by wind and partly by steam. America, then, had the lead again in daring to apply Fulton's machine to long voyages, and this is the more remarkable, that it has always had but few steam-boats on sea service. This first essay was not repeated, until, in 1835, when the English undertook the passage from Falmouth to the Cape of Good Hope; the Atalante, provided with an engine nearly similar to that of the Savannah, accomplished in 37 days a distance of 2,400 nautical miles. The Berenice, the Medea, the Zenobia, performed passages of different lengths on the coast of Africa, and in the Indian seas. All these boats were English. In the Mediterranean, steamers of different nations, Neapolitan, Sardinian, Austrian, French, crossed from one port to another. Lastly, our service of steam-packets from Marseilles to Alexandria was established, and threw open to us a new access to the East. The passage to Constantinople, which was sometimes 45 days in duration, was thus reduced to 13½ days.

These numerous experiments gave rise to the idea that, by the aid of steam, it was possible to accomplish the distance between Europe and the United States. The difficulty of carrying the necessary quantity of coals for the consumption of an engine acting, without interruption, from one shore of the ocean to the other, during a space of from 15 to 20 days, was no longer an obstacle. It had been discovered that the consumption of combustible did not increase in the same ratio with the power of the motors,—that an engine of 250 horse power, for instance, was far from burning twice as much fuel as was necessary for an engine of 125 horse power; that, moreover, certain parts of the mechanism might be simplified in such a manner as to take up less room, and consequently, leave more space at disposal for the accommodation of passengers or merchandize. From this time operations were commenced, and on the 4th of April, 1838, the first experiment was tried. You are all acquainted, gentlemen, with the result. You all beheld the enthusiasm excited by the success of the voyage undertaken by the Sirius, 15 days had been sufficient for its passage. Scarcely had this vessel arrived in the port of New York, when it was joined by the Great Western, which started from Bristol on the 8th of the same month, after a passage of 14 days.*

Henceforth the problem was solved. America was nearer the European continent by half the distance which formerly separated them. There could be no more doubt concerning it; the events which have since occurred have ratified these first expectations.

The Great Western has crossed the Atlantic 28 times during the period of the 14 months just elapsed without accident, maintaining an almost uniform speed, of which the average time was 16 days going, and 13 to 14 days coming back: the last voyage was even accomplished in 11½ days.

During two years since they began their operations, with what strides have the English advanced?

A first line from Bristol to New York was established in 1838. The company to whom it belongs has four steamers of 450 horse-power—namely, the Sirius, the Great Western, the Royal William, and the Liverpool. The price of each of these boats is 1,300,000f. It is said that they now are building an iron steamer, which is to carry two engines, whose united powers will amount to 1,000 horses. These engines were constructed on the plan of Mr. Humphreys; the boat will only be 100 meters in length, and will have room for 300 passengers, and a considerable quantity of merchandise. The works are in active continuation, and will be terminated, according to appearances, in the course of the year 1841.

Another line was established for the service of London and New York. Two vessels were employed on it—the British Queen and the President; the engine of the British Queen was of 500 horse-power, that of the President 600; they can accommodate from 225 to 250 passengers, and receive a load of from 500 to 600 tons. A third line connects New York to Liverpool, so that there are already three establishments sending steam-vessels from different parts of Great Britain to the United States.

Moreover, a compact was sealed on the 4th of July, 1839, between the Admiralty and Mr. Samuel Cunard for the transit of letters from Liverpool to Halifax. Mr. Cunard has engaged that there should be two departures per month, and receives from the Government an annual remuneration of 1,500,000f. The Britannia, of 450 horse-power, was launched into the sea in the beginning of February, 1839.

Lastly, a more extensive service will soon connect Great Britain with the West India islands: there is a company in existence under the name of the Royal Steam Navigation Company, which is preparing vessels for New Orleans, Mexico, and part of the South American coast. This company the Government indemnifies by an annual payment of 6,000,000f.

You must all perceive, gentlemen, that we must not delay entering into the lists, for we are urged on by competition from every quarter, and the appearance of English steamers on every point of the New World to the exclusion of our own would soon banish us from those regions.

However serious the character of these motives, gentlemen, they are, however, secondary when compared to a consideration which we will not endeavour to conceal. The navy is a weapon, and one which to all appearances is destined to play an important part in the conflicts which a future day may bring to light. Attempting to foretell what consequences may be reserved for a future period by the introduction of steam in constructing ships of war would be presumptuous; it is a question of entirely recent origin; experiments with regard to it are in their infancy. It is, however, already discernible that the use of new motors will infallibly produce the following effects:—In the first place, it will render every vessel in similar conditions equally supple and tractable, by whatever men she may be manned. It will be sufficient to have able engineers in order to effect manœuvres with a facility and precision as entirely independent of the state of the sea as of the greater or less aptitude of the sailors.

Secondly, the number and proportion of the men required for the performance of the ship's duty would be entirely changed. The Great Western, whose form and dimensions are nearly those of an ordinary frigate, is conducted by 50 men, including engineers and stokers. Now, if it be true that the naval enrolment of France is incompetent to supply all its necessities, this inconvenience will vanish; and the more so, because the zone in which we shall be able to find men fit for the service will be extended.

Lastly, the draught of water occasioned by a steamer depends upon its power; but for all it is less than that of ships of war. Whence it follows, that instead of the five or six ports to which our vessels and frigates can resort, steam-boats will be able to cast anchor off any coast, and, so to speak, in any bay.

Thus the new vessels provided with a good engine will be swift, will offer less hold to the enemy, will have a greater number of safe harbours to resort to, will require a less numerous crew, and require less previous apprenticeship than in sailing vessels. This will evidently become a new weapon; and if these ships carry guns for the discharge of bombs of a recent invention, whose effect is such that at one discharge they are capable of disabling the largest craft, they will become a weapon at once easy of management, safe, and of the most destructive nature. Is there not wherewithal here to change the whole direction of naval tactics, all the proportions existing between the powers of nations? Here is an entire revolution. Slow or fast, partial or complete, this revolution will ensue. Now, with the example given us by a Government whose energetical endeavours are dedicated to the continued increase of its naval resources, when we see Great Britain during two years continually multiplying, at the cost of such enormous sacrifices, its steam navigation, and finding in the gigantic establishments of its industry those inexhaustible resources of which we are deprived, would it be wise, would it be prudent to continue our *materiel* in its present state, to abstain from making some progress in the new career which has been traced out to us? Undoubtedly we do not indulge in the chimera that our country can ever equal the English in their naval establishment. The strength of the British nation rests entirely on its foreign trade; they are an exclusively seafaring nation. All the springs of its prosperity are there; it drags after it that colossal superiority which constituted at once its greatness and its peril. The conditions of existence in which France is situated are different; but the extent of its coast, its position, the genius of a portion of its inhabitants, compel it to possess a navy, and in that case it is becoming that, wherever she may be pleased to hoist her flag, she may be enabled to assemble and display a sufficient force in order to insure respect. Without this she could never effectually protect her national interests beyond the seas.*

The construction of steam-boats for transatlantic voyages presents, then, a double object to our view. Applied, in time of peace, to the growth and preservation of our commerce, they may be transformed, during hostilities, into ships of war; they may assume, in turn, the double character of a defensive weapon and of a means of conveyance—of a commercial and of a military navy; to-day they may carry merchandise, and when requisite guns.

* The length of this boat is 236 feet, its depth 23 feet 3 inches, its width outside the paddle boxes 58 feet 4 inches, draught corresponding to the load, 16 feet, tonnage 1,340 tons. The engines are so constructed as to diminish the consumption of steam and fuel. It is said that they consume 33 tons of coal a day. The total cost of the vessel when it was launched was 55,000*l.*; since that time improvements have been effected in it which have amounted to 15,000*l.* It carries 700 tons of goods, 135 passengers. The rest represents the weight of the engine, the boilers, and the water.

* England had, in 1831, 840 commercial steam-boats, representing altogether 64,700 horse power. Besides which, the English Admiralty possesses 66 vessels, whose powers amount to nearly 9,400 horses, while in France we reckon only 640 commercial steamers, and 38 belonging to Government.

STEAM PACKETS TO CONVEY THE MAILS BETWEEN FRANCE AND AMERICA.

We, Louis Philippe, King of the French, have proposed, the Chambers have adopted, we have ordered and do order the following:—

Article 1. A line of steam-packets shall be established in order to convey the mails between the ports of Havre and New York.

The Minister of Finance is authorized to treat, within the space of three months, with a commercial company who will undertake the service, on condition that they receive in payment an annual fee not exceeding 880f. per horse power. The number of steam-packets to be employed in the service of this line shall be three at the least, or five at the most; each packet to be propelled by engines of 450 horse power.

A list of conditions, to be drawn out by the administration, will determine the times of departure, the number of passengers, and every detail relative to the service of this line.

2. Two principal lines of communication shall be established by the Government, in order to convey the mails between France and America, and served by steam-packets of 450 horse power, one starting from Bordeaux every 20 days, and from Marseilles every month, in order to arrive at Martinique, and continuing by Guadaloupe, St. Thomas's, Porto Rico, Cape Hayti, and St. Jago, to Havannah; the other starting from St. Nazaire every month to Rio Janeiro, passing by Lisbon, Goree, Pernambuco, and Bahia. Three secondary lines, served by steamers of 220 horse power, will be established in order to continue the principal lines, the first to Mexico, touching at Vera Crux, Tampico, Galveston, and New Orleans; the second to Central America, touching at Chagres, Carthagena, Santa Martha, and La Guayra; the third to Montevideo and Buenos Ayres.

To effect this a special credit has been opened to the Minister of the Navy, to the amount of 28,400,000f., to be devoted to the construction, arming, and fitting up of 14 steam-packets of 450 horse power, and 4 steam-packets of 220 horse power, and which is to be appropriated to the expenditures of 1840, 1841, 1842, and 1843.

From the total sum of 28,400,000f. a grant is made to the Minister of the Navy—

	Francs.
1. For the year 1840, of	5,000,000
2. For the year 1841, of	10,000,000
Total	15,000,000

3. The steam-boats belonging to the Government shall be constructed so as to enable them, in case of necessity, to carry guns, and when performing the duty of packets to carry merchandise.

In the latter case the Government may either intrust them to the command of officers of the Royal navy or to sea-captains, whichever, in the interest of the service, it considers preferable.

4. When the command is intrusted to officers of the Royal navy, an agent commissioned by the administration shall be placed on board, and specially

intrusted with the details of the service, respecting the carriage of passengers, merchandize, bullion, and the mails.

5. The articles of the title 1 of book 2 of the Code of Commerce, determining the responsibility of sea captains towards the consignors and their assigns, will apply exclusively to the commissioned agent.

6. Ordinances, published in the form of administrative regulations, will determine all the details of the service of steamers undertaken by the Government.

7. The steam-packets which are under the direction of the state will be considered as part of the Royal navy, and the time served by seamen on these packets will be considered as in the service of the state.

8. Royal ordinances, inserted in the *Bulletin des Lois*, and the official portion of the *Annales Maritimes*, will fix the postage of the letters, journals, gazettes, and printed documents of every kind transmitted by the French Transatlantic packets.

Modifications introduced into the courses indicated in art. 2 will be published in the same manner, but such changes cannot take place with regard to the starting points in the kingdom or the general direction of the different lines.

9. The expences authorized by art. 2 will be provided for from the sums granted for 1840 and 1841 by the financial laws.

10. After the year 1842 the projected law for expenditures will include the demand of the funds necessary for carrying on the above lines of packets.

Steamers on the Pacific.—Extract of a letter from Captain Peacock, dated on board the Pacific Steam Navigation Company's steam-vessel Peru, lat. 9 15 N., long. 25 50 W., out 14 days from Plymouth :—"The Peru has hitherto had a most prosperous voyage, answering in every respect my most sanguine expectations. On leaving Plymouth we experienced a head wind, with a heavy cross swell, until the evening of the following day, when I ordered the fires to be burnt down, blew out the boilers, and made sail. On this first trial of sailing, although deep, we got seven knots out of her. There was a good deal of swell on, and the vessel occasionally rolled deep, but after a minute investigation of the moveable parts of the funnel, I saw no risk in lowering it, and in eight minutes from the commencement I had the gratification to see it snug in the chock, without straining a rivet or a rope-yarn. When the wind died away, we had every thing in its place again, and the fires alight in four minutes from hauling taut the main gears. The operation elicited the admiration of every one on board, and the correct workmanship of the arrangement reflects the highest credit on Messrs. Miller, Ravenhill, and Co. The funnel, when down in the chock, lies within the level of the paddle-box boats, and at a distance would resemble a long midship gun. It is completely out of the way of working the square mainsail, and when down, the operation of sweeping it is much simplified. We had only one entire day's sailing before getting into the trades, and then we had only three more. The trade wind was very light, except for two days out of the three, when, with the wind dead aft, with lower, topmast, and topgallant studding sails set, we went 11 knots for four consecutive hours, and in 24 hours ran 225 miles. This was the greatest run under sail. The least was 140, and this was the fifth day of sailing, when near the edge of the variables. We only consume half a ton of coals per hour on the average, and find no difficulty in keeping steam, without the additional length of funnel. The Hull coals are excellent; and in my own, as well as the chief engineer's opinion, are superior to the Llanelly coals. The sails all fit admirably, and the engines work extremely well. The vacuum now exceeds 28 in both. I perceive the great advantage of Sir W. Burnet's patent solution on the studding sails and awnings; it will increase their value 50 per cent. I am happy to inform you that my passengers are well, very contented, happy, and comfortable, which is daily expressed. I hope to be at Rio on the 26th day, of which there is every prospect."

Father Thames.—On Tuesday the 8th ult., an experimental trip was made with this new vessel intended to run from London to Gravesend. She is an iron boat, built by Messrs. Ditchburn and Mair, of Blackwall, and fitted with a pair of 37 horse oscillating engines by Messrs. Penn and Son, of Greenwich. She started from the Brunswick Wharf, Blackwall, with several Directors of the Blackwall Railway, and a party of scientific and naval gentlemen, at 21 minutes after 3, and arrived at the Pier, Gravesend, at 33 minutes past 4, making the trip in 1 hour and 12 minutes. She ran the mile distance at Long Reach (with the tide) in 3 minutes 22 seconds, which is at the rate of 17·8 miles per hour. After staying at Gravesend for some time, she started off with the *Ruby*, the crack Gravesend boat; it was very soon perceived that Father Thames was making a head of the Ruby, and after running a short distance the Father went completely round her. The Father Thames then followed her, passed her again, and by the time she was off Blackwall, the Ruby was 2 miles astern. Messrs. Ditchburn and Mair have so constructed the bow of the vessel that she does not throw up the slightest wave in front, in fact we could scarcely perceive a ripple so clean did she cut through the water. This is an important improvement, and one that Mr. Ditchburn has been trying to obtain for many years, and who at length, we are happy to say, is successful.

ENGINEERING WORKS.

WOOLWICH DOCK-YARD.

The extensive improvements taking place in this great naval depôt are such as will, in a short time, render it superior to any in the kingdom. The dry dock opposite the blacksmith's shop at the east end of the yard, is without exception the finest and most commodious that has ever been built, and is constructed of the most durable materials, being first laid in the bottom with one foot of brickwork, and over it large granite stones, about 3 feet 6 inches in thickness, and each many tons in weight. The base of this dock is 230 feet in length and of a proportionate breadth; but it will contain vessels of upwards of 300 feet in length on the upper deck, owing to the manner in which it is constructed. At the west end of the dockyard excavations have been going on during the whole summer, for the purpose of making a dock of still greater dimensions, designed by Mr. Walker, engineer, and it is intended to lay the foundation stone in the course of a few days. The contractors for this dock, Messrs. Grissell and Peto, of York-road, Lambeth, have had great difficulties to contend with in making the excavations. At a few feet from the surface they came on a rich alluvial deposit, in which the hazel and other nuts and clumps of trees were found in a perfect state of preservation, and the leaves were in many instances in layers six feet thick. Under these was a considerable bed of concrete like blue clay, all of which had to be gone through before a safe gravelly bottom could be found. This has now been obtained, but not without great interruption from powerful springs rising in all directions, and it has required the constant and unceasing exertion of a 40-horse power steam-engine pumping night and day to enable the men to proceed with their labours. The dimensions of this dock will be 300 feet at the base, and, as it will be constructed on the improved principle, it will admit of vessels of 400 feet in length on the upper deck. This is considerably larger than any ever yet made, but it is anticipated that steam-vessels of this gigantic size will be laid down when docks capable of containing them for fitting and repairing are ready for their reception.

Fiskerton Drainage.—The new steam water engine, for the better drainage of the fen-lands on the north side of the river Witham, between Fiskerton and Short Ferry, is at length upon the point of completion. A meeting of the proprietors was held at the City Arms hotel, Lincoln, on Friday, the 4th ult., for the purpose of hearing the opinion of Mr. Tuxford, engineer, of Boston, relative to the working of the engine, he being deputed to inspect the works, and to advance part of the contract money to Mr. Smith, of Belper, who furnished the building with the necessary works for the engine, and to decide upon paying him the remaining sum when the alterations pointed out by Mr. Tuxford were completed.—*Nottingham Journal.*

Woolwich.—The foundation stone of the new dock at Woolwich, was laid on Tuesday, 22nd ult., by Mr. Walker, the engineer, attended by the authorities of the dock-yard. The construction of this dock is different from any that has ever been made before. The stones are so cut that when placed together they will act on the same principle as an inverted arch. By this plan the greater the weight and pressure of the vessel in the dock, the greater the security that the bottom will not be raised by springs of water or from any other internal cause.—*Times.*

Liverpool Dock Committee.—At the meeting of this committee on Thursday, Sept. 17, Mr. Ald. Evans gave notice of his intention to move for a sub-committee to frame a Bill to Parliament for the construction of a new dock or docks, and warehouse on the docks and quays in this town.—*Liverpool Chronicle.*

PUBLIC BUILDINGS, AND IMPROVEMENTS.

The City of London and Tower Hamlets Cemetery, situated in the Mile End Road, comprising 22½ acres of land, is now proceeding under the directions of Messrs. Wyatt and Brandon. The style of the buildings and enclosure will be Early English.

The Pedestal at Hyde Park Corner, placed in the centre of the crossing from St. Georges' Hospital to the entrance to Hyde-park, has been erected by the trustees of the Grosvenor-place District, and is about 100 feet westward of the district boundary. The pedestal which is circular, is executed in *Park Spring stone*, and is 2 ft. 8 in. diameter at the base, and 6 ft. 1 in. high. The column supporting three lamps is executed in cast iron, and is 7 ft. 9 in. high to the brackets, supporting the two side lights. The total height from the paving to the top of the centre light is 19 ft. 6 in. The whole pedestal is surrounded with Aberdeen granite kirb, enclosing a causeway 10 feet square, which is paved with Yorkshire stone, forming an octagon line round the base of the pedestal. An Aberdeen granite post 13½ inches diameter at the base, diminishing to the top, and 3 feet high is fixed at each angle of the causeway for the protection of foot passengers on their way from one side of the road to the other, being a distance of 87 feet. The top arrises of each of the plinths of the pedestal is chamfered off, and the cap (above a band upon which is inscribed "Grosvenor Place District, 1840"), molded for the purpose of preventing persons climbing up, and to obviate, if possible, the necessity of having the encumbrance of iron rails or spikes. The pedestal has been executed and fixed by Mr. Samuel Cundy, of Belgrave-wharf; the iron work by Messrs. Thompson, of Eccleston-street, East; the granite posts by Messrs. Thompson, of Millbank, Westminster, and the paving by the workmen belonging to the trustees, from designs and drawings, and under the superintendance of Mr. Turner, the surveyor to the trustees.

A Church in Bethnal Green, in the Early Lombardy style of architecture, is now being built under the directions of Messrs. Wyatt and Brandon.

Ramsgate Chapel.—This building is 110 feet in frontage, 60 feet in width, and 90 feet in height, to the top of the tower. The style of architecture is original, uniting the features of Saxon and Norman, with a slight indication of the Gothic, which are so designed and blended together that the whole building is kept in perfect symmetry of style throughout. The interior is fitted up in a kind of double theatre, having at each side rising seats, with a row of seats in the centre. The interior is plain, but would have been executed in a more elaborate style had not the limited funds prevented. There are galleries at each end of the chapel, one appropriated for the organ, and the other for children. The cost of the entire building is about £4,000, and is capable of containing 1400 persons. Mr. James Wilson, of London and Bath, is the architect.

A spacious building for the Southwark Literary and Scientific Institution, situated in the Borough Road, occupying a frontage of 50 feet by 70 feet deep, is now in course of erection: it will comprise a Library, Reading Room, Newspaper Room, Class Rooms, Lecturers' Room, and Librarian's apartments. Messrs. Wyatt and Brandon are the architects.

MISCELLANEA.

Improved methods of coating iron, under various circumstances, to prevent oxidation or corrosion, and for other purposes; patented by James Beaumont Neilson, Glasgow, Aug. 29.—The inventor claims the method of coating or covering iron, &c., by means of copper or alloys of copper, with zinc or tin. The copper or alloy is brought to that minute state of division in which it is obtained by precipitation from its solution, or it may be used in a granulated state. In order to cover cast-iron, sprinkle a thin coating of granulated, or other fine copper or alloy over the surface of the mould, to which may be added borax, or other flux, to facilitate the spreading or diffusion of the metal. Thus, when the molten iron is poured into the mould, the copper or alloy will be fused, so as to cover the casting, and render it secure against oxidation or corrosion. If malleable iron is to be coated, put a covering of the pulverised copper or alloy over the upper surface of the iron, while it is being heated, and the borax or other flux will soon cause it to spread over the heated part, which should be plunged into water, to detach the scale of oxide that forms upon it.—*Inventor's Advocate.*

Improvements in apparatus for withdrawing air or vapour; patented by Samuel Carson, Caroline-street, Euston-square, Aug. 5.—The inventor states, that revolving heads with cones have been applied to chimneys, in order to improve the draft thereof, but in such case the cones have not been made of sufficient length to pass beyond the opening of the chimney; hence the same has been of little use, owing to the wind being blown down the chimney. First improvement is for withdrawing heated air from chimneys, by means of the atmospheric air blowing through a cone, situated in a cylindrical box that revolves, at the chimney top, by the aid of a vane or weathercock; the wind passing through this cone, the orifice of which extends beyond the opening of the chimney or shaft, causes by its attraction or draft the smoke from the fireplace, or rarified air of the chamber, to rise with velocity, and pass round the casing connected to the chimney by a revolving joint. Second improvement consists in bringing the pipe that is to carry off the condensed or heated air of an apartment, down to the conical apparatus situated near a jet of steam, or near the waste steam-pipe of a boiler. In place of the atmospheric air passing through the cone, a jet of steam is made to draw off the confined air of the chamber, or from the bottom of a mine. Third improvement is to introduce a jet of steam into a chamber, without the use of a cone, whereby the vacuum is produced, and the confined air passes up from the mine or chamber through the valve at the upper orifice of the tube. This improvement we have examined at the Polytechnic establishment, where it works beyond all expectation, and we have since learned that Mr. Brunel has allowed Mr. Carson to introduce it at the Thames tunnel, where a four-horse engine cannot sufficiently ventilate the shaft: by this improvement, the waste steam alone will perform the whole operation.—*Ibid.*

Materials used in lighting or kindling fires; patented by Richard Edwards, of Fairfield-place, Bow, Middlesex, Aug. 29.—In the ordinary faggots of wood, used for lighting fires, there is not sufficient ventilation to allow the wood to burn, in case it be used in the close form of a bundle, but by this improvement, the pieces of wood are so combined with rope, cotton, paper, or other such like material, as to leave a space between each slip of wood or reed; thus it becomes what the inventor terms a "Ventilated Faggot," which may have its ends dipped into pitch, tar, resin, liquid sulphur, or other inflammable matter. By throwing one of these "ventilated faggots" into a fire-place, the coals may be heaped over it, and the servant, or other individual, will find no difficulty in causing the fire to burn after it is once lighted.—*Ibid.*

An improved method or methods of adjusting, shifting, and working theatrical scenery and apparatus; patented by Rowland Macdonald Stephenson, Upper Thames street, civil engineer, Aug. 29.—The object proposed by the patentee is the greater speed and facility with which stage scenery may be brought forward, shifted, or removed. The arrangement about to be described, provides means for shifting or removing simultaneously, and without noise, 35 distinct pieces of scenery, viz., 10 side scenes removed and 10 fresh subjects brought forward; five sets of clouds removed and five substituted; and five main scenes removed. The general arrangement of the machinery for effecting the above, may be described as follows:—The interior of the house between the basement and the roof may be said to be divided into four floors or compar ments, viz., 1. a raised platform, on which the gearing for working the stage-traps is to be placed. 2nd. The stage with traps of various forms and dimensions, including a considerable portion formed to rise or fall by suitable machinery, and called the sinking stage. 3rd. The lower flats, between which and the stage are placed the wing scenes: between the framing formed by the girders and the supporting columns, and stretching from side to side of the stage, are suspended the border frames, which can be raised or lowered by means of ropes passing over drums and connected with counterpoise weights; and fourthly, the upper flats upon which the inventor places the moving power to communicate motion to the whole. On each side of the stage on the upper flat, are placed a series of frames called main scene carriages, having racks, which can be connected with pinions or long horizontal shafts when required to be moved backwards or forwards: these two shafts are connected at their extremities by a third shaft. From the upper horizontal shafts, by means of bevel gear and vertical rods, on the lower ends of which are drums, an endless chain is driven horizontally in either direction, to which are attached the borders representing clouds, foliage, arches, &c. The side frames, of which the number is limited by the depth of the stage, may be either flat, circular, or triangular; in the present case they are triangular, and receive a forward, backward, or rotatory motion, or both at pleasure, and can be placed at any convenient angle to the audience, so as to represent closed doors, &c.; at every change of the scene they will be moved round 130 degrees, or one-third of a circle; the whole of the side frames may be moved together or separately, by means of gear connected with the moving power on the upper flat. Attached to the centre of the border frames, and revolving on a pivot, are the traversing frames for crossing the stage in any direction, and at any given inclination; these, when ready for use, are raised up and secured at one end so as to form an inclined plane, and the object to be traversed having been attached to a wire passing round a drum fixed in a heavy frame, will descend by its own gravity. The trap-frame consists of a rectangular platform traversing on the lower or fixed platform, and having an upright frame of iron mounted on rollers and capable of being traversed on the lower platform in any direction; when brought under the aperture in the stage, it allows the trap to be sunk steadily by bearing on a disc or square iron plate, counterbalanced by weights. The claim is to the improved mode of shifting and working scenes and theatrical machinery and to the obvious modifications of which the above arrangements are susceptible. —*Ibid.*

Improvements in the stuffing boxes of lift pumps; patented by James Horne, Clapham Common, Esq., March 3, 1840.—These improvements consist in the application of two cupped leathers to the purpose stated, in the following manner: the stuffing-box consists of a metal collar and cap, each having a projecting ring or shoulder on the inside; two pieces of leather are blocked into the form of cones with a horizontal base, having an aperture at the apex just large enough to receive the piston-rod; one of these cones is placed upon the piston-rod with its apex downwards, its base resting upon the shoulder in the collar of the stuffing-box; a metal disc is then slipped on to the piston-rod, and afterwards the second leather cone with its apex upwards, its base resting upon the metal disc: the stuffing-box cap is then put into its place, and screwed down tight. The metal disc becomes a guide for the piston-rod, while the pressure of the fluid below, and of the air above, upon the external surfaces of the two cupped leathers, keeps all tight. The arrangement is doubtless a good one, but we think the patentee would hardly have gone to the expence of a patent, had he been acquainted with the more beautiful, as well as more ingenious mode of constructing stuffing-boxes, employed by Bramah in his hydraulic press half a century ago; and which has proved efficient under greater pressures than a lift pump can possibly be exposed to. —*Mechanics' Magazine.*

Petroleum Oil Well.—About ten years since, whilst boring for salt water, near Burksville, Kentucky, after penetrating through solid rock upwards of 200 feet, a fountain of pure oil was struck, which was thrown up more than twelve feet above the surface of the earth. Although in quantity somewhat abated after the discharge of the first few minutes, during which it was supposed to emit seventy-five gallons a minute, it still continued to flow for several days successively. The well being on the margin and near the mouth of a small creek emptying into Cumberland river, the oil soon found its way thither, and for a long time covered its surface. Some gentlemen below applied a torch, when the surface of the river blazed, and the flames soon climbed the most elevated cliffs, and scorched the summit of the loftiest trees. It ignites freely, and produces a flame as brilliant as gas. Its qualities were then unknown, but a quantity was barrelled, most of which soon leaked out. It is so penetrating as to be difficult to confine in a wooden vessel, and has so much gas as frequently to burst bottles when filled and tightly corked. Upon exposure to the air it assumes a greenish hue. It is extremely volatile, has a strong, pungent, and indescribable smell, and tastes much like the heart of pitch pine. For a short time after the discovery, a small quantity of the oil would flow whilst pumping the salt water, which led to the impression that it could always be drawn by pumping. But all subsequent attempts to obtain it, except by a spontaneous flow, have entirely failed. There have been two such flows within the two last years. The last commenced on the 4th of July last, and continued about six weeks, during which time about twenty barrels of oil were obtained. The oil and the salt water, with which it is invariably combined during these flows, are forced up by the gas, above two hundred feet, into the pump, and thence through the spout into a covered trough, where the water soon becomes disengaged and settles at the bottom, whilst the oil is readily skimmed from the surface. A rumbling noise resembling distant thunder, uniformly attends the flowing of the oil, whilst the gas, which is then visible every day at the top of the pump, leads the passing stranger to inquire whether the well is on fire.—*Silliman's Journal.*

Napier's Patent Shot Machine.—The Board of Ordnance have determined upon employing Napier's machine for making balls by compression at the Royal Arsenal, Woolwich; it is to be worked by steam, as also the turners and borers of cannon. At present, the same system as was in vogue forty years ago, is used in the boring of large guns, horses being employed as the moving power. This alteration will relieve about ten artillerymen who have charge of the horses employed in this duty.

Hint for House Decorators.—The walls had a novelty of decoration not peculiar to Affghanistan, as I have seen it in India, though never so well done as in the rooms I speak of; the chunam or plaster being stamped when moist or plastic, and worked into a pattern, over which a varnish of powdered talc is spread, which more nearly resembles the richness and hue of new and unused frosted silver plate than anything I have seen elsewhere. This might be introduced in London as a very cheap and elegant drawing-room decoration.—*Dr. Kennedy's Campaign of the Army of the Indus.*

Locomotive.—Mr. E. Rudge, of Tewkesbury, tanner, has obtained a patent for a new method or methods of obtaining motive power for locomotive and other purposes, and of applying the same. These improvements are for the construction and application of a new form of atmospheric engine, which may consist of two, three, or more open topped cylinders, placed either vertically or horizontally, the piston rods of which are connected with two or three throw cranks. The air below each piston in the cylinder is condensed by a jet of steam, when the preponderating influence of the atmosphere on the external surface of the several pistons produces the available power. The cylinders are lubricated by means of a small funnel on the top of the piston rod, whence the oil flows into a hollow space within the rod, and thence into a groove turned in the piston. In order to gain a reserve of power, for any particular purpose, a large cylindrical receiver is filled by a condensing air-pump placed on either side, and connected with the main shaft of the engine; thus when the carriage is descending the hill, the air-pumps will compress the air into the large cylinders, which again will supply the air for working the pistons while ascending a hill.—*Gloucestershire Chronicle.*

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 30TH AUGUST TO 26TH SEPTEMBER, 1840.

William Daubney Holmes, of Cannon-row, Westminster, Civil Engineer, for "*certain improvements in naval architecture and apparatus connected therewith, affording increased security from foundering and shipwreck.*"—Sealed September 3; six months for enrolment.

Thomas Horne, of Birmingham, Brass Founder, for "*improvements in the manufacture of hinges.*"—September 3; six months.

James Bingham, of Sheffield, Manufacturer, for "*certain improved compositions which are made to resemble ivory, bone, mother of pearl, and other substances applicable to the manufacture of handles of knives, forks, and razors, pianoforte keys, snuff boxes, and various other articles.*"—September 3; six months.

William Freeman, of Millbank-street, Stone Merchant, for "*improvements in paving or covering roads and other ways or surfaces.*" Communicated by a foreigner residing abroad."—September 7; six months.

Thomas Motley, of Bath Villa, Bristol, Civil Engineer, for "*improvements in apparatus and means of burning concrete fatty matter.*"—September 7; six months.

William Coltman, of Leicester, Framesmith, and Joseph Wall, of the same place, Framesmith, for "*their invention of improvements in machinery employed in framework knitting or stocking fabrics.*"—September 7; six months.

John Whitehouse, the younger, of Birchall-street, Birmingham, Brass Founder, for "*improvements in the construction of spring hinges and door springs.*"—September 7; six months.

Samuel Parker, of Piccadilly, Manufacturer, for "*improvements in apparatus for preserving and purifying oils, and in apparatus for burning oils, tallow, and gas.*"—September 10; six months.

Mark Freeman, of Sutton Common, Gentleman, for "*improvements in weighing machines.*"—September 10; six months.

Paul Hanninc, of Clement's Lane, London, Solicitor, for "*improvements in the construction of governors or regulators applicable to steam engines, and to other engines used for obtaining motive power.*" Being a communication. —September 10; six months.

Charles Delbruck, of Oxford-street, Gentleman, for "*improvements in apparatus for applying combustible gas to the purposes of heat.*" Being a communication.—September 10; six months.

Edward John Dent, of the Strand, Chronometer Maker, for "*certain improvements in clocks and other time keepers.*"—September 10; six months.

Henry Houldsworth, of Manchester, Cotton Spinner, for "*an improvement in carriages used for the conveyance of passengers on railways, and an improved seat applicable to such carriages and other purposes.*"—September 10; six months.

Hugh Lee Pattinson, of Bensham-grove, Durham, Manufacturing Chemist, for "*improvemen s in the manufacture of white lead.*"—September 10; six months.

George Alexander Gilbert, of Southampton-buildings, Gentleman, for "*certain improvements in machinery, or apparatus for obtaining and applying motive power.*"—September 10; six months.

Robert Goodacre, of Allesthorpe, Leicester, for "*an apparatus for raising heavy loads in carts, or other receptacles containing the said loads, when it is required that the unloading should take place at any considerable elevation above the ground.*"—September 10; six months.

James Pilbrow, of Tottenham, Engineer, for "*certain improvements in steam engines.*"—September 10; six months.

William Bedford, of Hinckley, Leicestershire, Frame-work Knitter, for "*certain improvements in machinery employed in manufacturing hosiery goods, or what is commonly called frame-work knitting.*"—September 17; six months.

Henry Fourdrinier and Edward Newman Fourdrinier, of Hanley, Stafford, Paper Makers, for "*certain improvements in steam engines for actuating machinery, and in apparatus for propelling ships and other vessels on water.*"—September 17; six months.

Moses Poole, of Lincoln's Inn, Middlesex, Gentleman, for "*improvements in preparing materials to facilitate the teaching of writing.*" Being a communication.—September 17; six months.

Walter Richardson, of Regent-street, Gentleman, and George Mott Braithwaite, of Manor-street, Chelsea, Gentleman, for "*improvements in tinning metals.*" Being a communication.—September 17; six months.

Samuel Draper, of Nottingham, Lace Manufacturer, for "*improvements in the manufacture of ornamented twist lace, and looped fabrics.*"—September 21; six months.

William Mill, of Blackfriar's-road, Engineer, for "*certain improvements in propellers, and in steam engines, and in the method of ascertaining and measuring steam power, parts of which improvements are applicable to other useful puposes.*"—September 21; six months.

Charles Handford, of High Holborn, Tea Dealer, for "*an improved edible vegetable preparation called 'Eupooi,' and the mode of manufacturing the same.*"—September 21; six months.

Thomas Pain, Junior, of Upper Seymour-street, Euston-square, Student at Law, for "*a plan by means of which carriages may be propelled by atmospheric pressure only, without the assistance of any other power, being an improvement upon the Atmospheric Railway now in use.*"—September 22; six months.

John Maughan, of Connaught Terrace, Edgeware Road, Gentleman, for "*certain improvements in the construction of wheeled carriages.*"—September 24; six months.

George Goodman, of Henley, near Birmingham, Needle Manufacturer, for "*certain improvements in the manufacture of mourning and other dress pins.*"—September 24; six months.

Thomas Muir and John Gibson, of Glasgow, Silk Manufacturers, for "*improvements in cleaning silk and other fibrous substances.*"—September 24; six months.

William Hirst, of Leeds, Clothier, for "*improvements in the manufacture of woollen cloth and cloth made from wool and other materials.*"—September 24; six months.

Henry Pinkus, of Panton-square, Coventry-street, Esquire, for "*improvements in the method of applying motive power to the impelling of machinery applicable amongst other things to impelling carriages on railways on common roads or ways and through fields, and vessels afloat, and in the methods of constructing the roads or ways on which carriages may be impelled or propelled.*"—September 24; six months.

John Johnston, of Glasgow, Gentleman, for "*a new method (by means of machinery) of ascertaining the velocity of a space passed through by ships, vessels, carriages, and other means of locomotion, part of which is also applicable to the measurement of time.*"—September 24; six months.

Pierre Erard, of Great Marlborough-street, for "*improvements in pianofortes.*"—September 24; six months.

Thomas Robinson Williams, of Cheapside, Gentleman, for "*improvements in the manufacture of woollen fabrics or fabrics of which wools, furs or hairs are the principal components, as well as for the machinery used therein.*"—September 24; six months.

Alexander Dean and Evan Evans, of Birmingham, Millwrights, for "*certain improvements in mills for reducing grain and other substances to a pulverised state and in the apparatus for dressing or bolting pulverised substances.*"—September 24; six months.

TO CORRESPONDENTS.

Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," *No.* 11, *Parliament Street, Westminster.*

Books for review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

J. D., *the substance of his communication on Suspension Bridges has appeared in print before.*

"*A Student,*" *his communication will be noticed next month.*

J. I., *his communication dated 18th ult., was not received until the 24th, when it was too late to comply with his request.*

"*A Constant Reader,*" *it is difficult for us to give the names and addresses of the inventors at all times, it would subject us, in many instances, to be charged with the advertisement duty.*

"*A Constant Subscriber,*" *shall be answered next month.*

G.'s *work was not received until near the end of the month, it shall be noticed in the next Journal.*

A Subscriber wishes for the address of the agent for supplying the Porcelain Letters, noticed in our Journal in May last

Books received—Scott's Cotton Spinner; The Process of Blasting by Galvanism; On Excavation and Embankment on Railway; Thoughts on Steam Locomotion; and Experiments on the Compass on Iron-built Ships; they will be noticed in the next Journal. We have been compelled to postpone further notices of Mr. Mushet's valuable work, and also Mr. Bartholomew on Specifications.

Next month we shall give the Plan of the Principal Floor and Section of the Reform Club.

ERRATA.

ON BUTTRESSES, PINNACLES, &c.

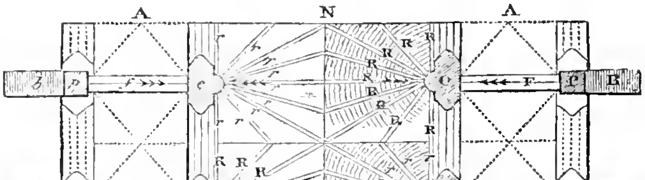
By Alfred Bartholomew, Architect.*

Were it the author's wish to prove by one example more striking than any other, the falling off of science in the absolute practice of architecture, in these times of pretended superiority, in which the ill-taught practitioner who wishes to pursue the integrity of his art, is obliged, after he is turned adrift by his master, to re-educate himself as far as he is able, by picking up whatever scraps of scientific information may fall in his way, instead of receiving from his master at once the full depth of skill which the free-masons for centuries handed down from father to son, from master to pupil, without diminution and without reserve,—he would fearlessly instance the most singular advancement which the mid-eval architects seem, by nothing short of inspiration, to have made in the most delicate acquaintance with *Architectural Dynamics;* a knowledge which taught them at once to unite in their abutments, strength with economy, use with beauty: while in our ignorance we fancy that strength and economy are enemies of each other and that use and beauty are of necessity opposite qualities. This refined intelligence taught them to render every necessary part of their constructions such exquisite ornaments, that the ignorant modern looking at them, without knowing their use, fancies them to be merely ornamental.

They first began in their vaultings with reducing the lateral thrust of the work to the smallest limits, by cutting out all the otherwise more level and hazardous parts of the vaulting, so that what remained scarcely left its perpendicular bearing upon the walls: they next greatly reduced further the weight of the vaulting, by forming it of small stone ribs, with a mere thin cuticle of lighter materials in short and narrow panels between the ribs; and whereas in our modern brick vaultings, the groin-points are weak by their bond, and are still weaker from the soft and inferior nature of the bricks of which they are composed (vulgarly termed "*cutters*," and wholly unfit for the purposes of any *good* work), and we know scarcely any thing of the *dynamics* of such a vault,—the mid-eval builder put all the strength in the ribs, strutted his ribs across as he deemed necessary, and made every strut a beauty, conducted the active force down those ribs as easily as water is conducted down a pipe, and then, instead of leaving the active force within each rib to expend itself in committing unknown and unrestrained damage to the walls of the fabric, he united their force in one point so that he could deal with it as an active power well ascertained; then knowing by the laws of the resolution of forces the way in which the united thrust of the ribs would move, he counter-acted by the



N, nave. A, A, aisles. R. R, &c., ribs of the vaulting, the several thrusts of which all uniting at the centre C; the dynamic action is confined to one point tending to move from C to F. F, flying-buttress, falling against the point C, in the direction exactly suited for opposing the united thrust of the vaulting-ribs. B, wall-buttress from which the flying-buttress springs. P, pinnacle. The small letters indicate the repetition of sets of the same parts belonging to other divisions of the vaulting.

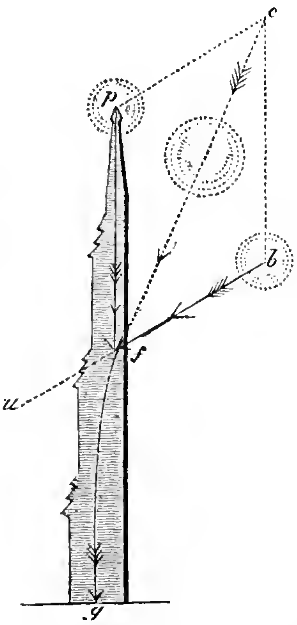
* We have through the kind permission of the author, taken this paper from a work recently published by him, entitled, "Specifications for Practical Architecture; preceded by an Essay on the decline of excellence in the Structure and in the Science of Modern English Buildings."

smallest possible quantity of materials set in the form of flying-buttresses, pinnacles, and wall-buttresses, that force which unrestrained might have endangered the walls. Thus by making use of only a small quantity of materials, every particle of which was brought into active service, he was enabled to carve ornament and enrich every part of his fabric out of those funds which we ignorant moderns expend in raising coarse masses which perform no duty, or ill-directed either waste much of their weight and strength, or else employ it in rending and dilapidating the fabric.

The author comes now to a department of the dynamic knowledge of the Gothic architects, which, as he believes it outstrips in combination of skill and beauty all other efforts of the architectural practitioner, ancient or modern, affords him matter of surprise, that as far as he knows or remembers, it has not been noticed by any previous writer.

The manner in which the Gothic architects conducted the active force of a vault to one place, and then with practical certainty counter-abutted that force by a small quantity of materials placed exactly in the situation proper for the purpose, has just been shown; it is now proposed to show the wonderful manner in which the flying-buttresses, the wall-buttresses from which they spring, and the surmounting pinnacles, are together disposed so as with the most delicate union of the extreme of beauty, to unite the most wonderful economy and such a knowledge of mechanics as will in vain be sought for in any other description of buildings.

Having found out exactly the precise place where the active force of the vaulting was pressing against the wall, they distended the *flying-buttresses* or *arc-boutant* widely at that part, in the same manner as a modern carpenter, in *temporary-shoring*, places a board flat against a dangerous wall; they then gradually concentrated this distention of the wall-thrust into one point, where the flying-buttress joins the wall buttress; thus they concentrated at the head of the wall-buttress, all the active force communicated by the vaulting, in the same manner as in wrestling all the force received by the arms becomes concentrated in the spine, pressing its vertebræ closely together; but then as the operation of this force, would have required the wall-buttress to be made sprawling out to a vast distance from the wall, in order to prevent the active power from throwing it over, they change the course of the active force, simply by running up the head of the wall-buttress in the form of a pinnacle, which, having only a direct downward gravity, by the *resolution of forces*, so changed the course of the active force, that it could be confined within the body of a buttress of comparatively moderate dimensions,—the downwardly-increasing gravity of the wall-buttress in fact mingling with the force communicated to it, curved the direction of the force more and more inwards, till it was eventually re-diffused horizontally over the broad foundation of the buttress, and was from thence communicated to the earth itself. Thus



f—b. Bent of the force communicated to the flying-buttress by the *drift* of the vaulting, which force would proceed unrestrained to *u*, if the pinnacle were removed, and would consequently drive over the wall-buttress in that direction.
p—f. The direct downward force of the gravity of the pinnacle.
—f. The active direction of the two combined forces above-stated, more and more restrained in its downward course, within the body of the wall-buttress, till it reaches the ground at *g*.
f, b, p, c. Parallelogram of forces.

pinnacles, which are vulgarly considered merely as ornaments, became the most refined instruments in the economy and security of ecclesiastical and other buildings, and like the position of the human head, had a most material influence upon the stiffness and activity of the whole frame. With this knowledge, it was, that the Gothic architects proportioned the weight and size of their pinnacles, and when we see them assuming an extraordinary altitude, as at Worcester Cathedral, it is not from idle, wild, or luxuriant caprice, but because extraordinary means were required in order to change suddenly the course of an active power, which would otherwise have expended itself beyond the body of the abutment, and by displacing it, have brought to ruin the whole work.*

They did not always stop here, for knowing that there was a portion of the wall-buttress near the ground and adjoining to the side aisles, which received no thrust, and lay as it were dead, this they cut out altogether, as at Gloucester Cathedral, some of our English Chapter-houses, Westminster-hall, and some of the Continental Cathedrals which have chapels set between their wall-buttresses;† so that in fact, the whole form, position, and management of the counter-abutments of Gothic vaultings, were like those of a human skeleton, placed in a leaning posture, with the bones of the legs away from the base, those of the hands and arms pressing against the moving part of the vault, with the skull erect to confirm and steady the spine, and the whole strengthened by sufficient flesh and muscle.

That the true mechanical office of the pinnacles of pointed architecture is as stated above, appeared to the author to be so evident, that it at once struck him after coming to this knowledge, that the double set of flying buttresses on the south side of Westminster Abbey, must be respectively inclined, so as to receive within their solid substance the pressure of the vaulting; and that on account of the operation of the two sets of pinnacles, the lower flying-buttresses must be set more uprightly than the upper ones; this upon examination proved to be the case, showing that if the original builders were not fully versed in the subject (which may be greatly doubted), Wren, who restored these buttresses, was so, and probably by his great scientific knowledge, was enabled to adjust them more accurately to their proper positions. The great masters who had to do with this fabric, could not avoid the great extra consumption of materials which arose from removing the great buttresses away from the wall out into the cloister-green, in order to leave room for the north avenue of the cloister; but having a difficult task to perform, they performed it with admirable skill, and knowledge greater than is exhibited in many of the Continental Cathedrals, some of which have two sets of buttresses in order to admit side chapels.

With what humility should we look upon our modern use of buttresses, pinnacles and abutments, which we pretend are the results of a far outstripping science, and of an improved taste,—while men whom we have been in the habit of calling barbarians, have in a dark age (more enlightened in many things than the best ages of Greece and Rome) at once mingled in their works, poetry, economy, taste, strength, and invention.

Geometrical Survey.—The officers of the engineers appointed to conduct the survey of the island have been for the last six weeks stationed upon the top of Ben Volich, a high and peaked mountain in Rannoch, east of Lochgarry. They had spent the greater part of the summer on Schihallion, but the severity of the weather of late has both both impeded their operations and rendered the station very uncomfortable. For the last fortnight the snow has been lying some inches deep around their very superficial temporary dwelling, and the carriage of fuel from the surrounding districts is at once expensive and precarious. The view from this moutain, as well as from Schiballion, is very extensive from their commanding altitude, and enables the engineers to take a very wide observation.—*Scotch Paper.*

---

* Rondelet in his "*Traité Théorique et Pratique de l'Art de Bâtir,*" shows that he had sagacity enough to find out the beauty of the whole management of the dome of St. Paul's, and that he saw plainly the consolidating effect which the weight of the covering of the dome has upon the hollow cone; but it is singular that this sagacity did not preserve him from in some sort deprecating the oblique meeting of the cone with its supporting piers; he did not perceive, that besides the enormous collection of surrounding abutments which the great cone possesses, the perpendicular extension of the external peristylum above the foot of the cone, acts so as by the resolution of forces to materially change the direction of any expanding thrust which the base of the cone may possess, and to confine it strictly within the bodies of the first set of piers.

† Mr Savage, at the New Chelsea Church, has omitted the nactive parts of the wall-buttresses in order to admit a free passage in the dry areas which surround the basement-story of the edifice; but he has not changed the *drift* in the flying-buttresses by placing pinnacles over the wall-buttresses; allowing the present wall-buttresses of the church to be sufficient, the present combustible ceilings over the galleries of the church might be exchanged for groined roofs of stone, and the addition of pinnacles would still confine the drift within the present wall-buttresses, notwithstanding the added drift of the new side vaults.

ON CLOTHING OF STEAM BOILERS.

Report upon the advantages to be derived from Clothing Steam Boilers, Pipes, Cylinders, &c., with the Patent Felt, manufactured by Messrs. Borradaile, Whiting, and Company.

By Thos. Wicksteed, Mem. Inst. Civil Eng., Hon. Mem. Roy. Cornish Polytech. Soc., &c. &c.

[We feel much pleasure in being able through the kindness of Messrs. Borradaile and Co., to give to our readers the following very valuable report on Clothing of Steam Boilers and Cylinders, and which we are sure will be perused with much interest. We must here observe that too much praise cannot be given to those gentlemen for the spirited manner they have had the experiments made, which could not have been done excepting at a very large outlay. We think after a careful study of this report by those who have a steam engine not already clothed, they will hesitate no longer in adopting that very essential requisite, which we are sorry to say has been, heretofore, most shamefully neglected. The experiments were conducted under the direction of Mr. Wicksteed, the eminent engineer of the East London Water Works, whose abilities are too well known to the profession to need any praise on our part for the very elaborate manner he has performed his task.]

Upon the 25th of April last, Mr. Francis Whiting called and requested me to give an opinion as to the advantages of using Borradaile's Patent Felt as a non-conductor; and to state what I considered was the actual amount of saving in fuel obtained in the use thereof as a clothing for steam-boilers, cylinders, &c. I stated that, although I never had had the opportunity of trying experiments, I was satisfied it was a good non-conductor, and as the amount of saving stated as having been obtained by those that had used it varied from 6 to 17 per cent., I thought it would be advisable to try a series of experiments upon a large scale, continued for so long a time that the *experience* obtained should put at rest all question as to the actual amount of saving.

Mr. Whiting approved of this suggestion, and gave me instructions to try any experiments I thought proper.

In pursuance of these instructions I determined to ascertain the quantity of water evaporated by a given weight of coals, when the boiler, steam-pipes, and flues were exposed, or not clothed, and also when they were clothed with one, two, three, and four coats of the Patent Felt respectively; having been in the habit also of using hop sacking as a covering for the boilers, I determined to ascertain the evaporative power of the boiler when clothed with three and five coats of hop-sacking respectively, these experiments would give me the proportionate amount of fuel required to evaporate a given weight of water under the different circumstances before stated.

To ascertain the saving obtained by the use of the Patent Felt in clothing the cylinder, nozzle, and steam-pipes, I determined to ascertain the quantity of water that was required to pass through the cylinder in the form of steam, to do the duty of one horse, when the cylinder, steam-pipes, &c., were exposed, or not clothed, and when clothed partially, or wholly, with Patent Felt, as described in Table No. IV. appended to this report.

The boiler on which the experiments were tried was made by Boulton & Watt; it was of that form called wagon-headed, with a flue passing through the centre, the fire being underneath; the dimensions were as follow:

	Ft.	In.
Length of boiler	21	0
Depth	8	8
Width in widest part	5	11
Width of flue passing through the centre	2	6
Depth of ditto ditto	3	0

The engine, which was a single pumping-engine, was made by the same parties, the cylinder 60 inches in diameter, and average stroke 7ft. 11in.; the cylinder had a steam jacket around it.

A long series of experiments was made, the details of which are given in Tables Nos. 1, 2, 3, and 4, appended to this report.

Before commenting upon the experiments, I will give an explanation of the Tables, to show in what way the different results have been arrived at.

Table No. I.

The columns 1 and 2 require no explanation.

Column No. 3, shows the number of hours the engine was at work per diem of 24 hours.

Column No. 4, gives the bushels of coals consumed, which were accurately weighed, each bushel weighing 84 lb., being the weight of the imperial bushel.

Column No. 5, gives the weight of water in hundred weights introduced into the boiler every 24 hours, the way in which this was ascertained was as follows:—There were two cisterns of given dimensions placed one above the other, the top one communicating with the feed pump of the engine, having an overflow, or waste water-pipe attached to it, and a valve in the bottom to let water into the lower cistern when required; the lower cistern communicated with the boiler, supplying it in the ordinary way adopted for low pressure boilers; the lower cistern was gauged, the gauge being divided into hundred weights, the divisions being obtained by actually weighing the water into the cistern; the lower cistern was filled with 21 cwts. of water, and when that was exhausted in feeding the boiler, the feed valve was closed, and the cistern was refilled with 21 cwts. more, so that the actual quantity evaporated was most accurately obtained.

Column No. 6, represents the mean temperature of the water in the lower cistern before evaporation, and was thus obtained: the temperature of the water each time the cistern was filled was taken, and again when it was nearly empty, the mean of all these temperatures is represented in column No. 6. The mean temperature in the line of Totals was obtained by multiplying each weight of water, given in column No. 5, by the corresponding temperature in column No. 6, the products being added together, and divided by the total weight of water, which gives the true mean temperature of the whole water evaporated.

Table No. II

Column No. 1, refers to the totals in Table No. 1.

Columns Nos. 2, 3, 4, 5, & 6, require no further explanation than has been already given.

Column No. 7, represents the pounds weight and decimals of a pound of water evaporated by the consumption of one pound of fuel; the water before evaporation being at the corresponding temperatures given in column No. 6.

Column No. 8, represents the cubic feet and decimals of a cubic foot of water evaporated by the consumption of 112 lb. of coal, under similar circumstances to those given in column No. 7.

Column No. 9, represents the cubic feet and decimals of a cubic foot of water, that would have been evaporated, if the temperature of the water admitted into the boiler had been equal to 212° of Fah., and is obtained thus:* The latent heat of steam was stated by Mr. Watt to be equal to 950°, the sensible heat at the boiling point is 212°, the sensible and latent heat together being equal to 1162°, but as the water to be evaporated (see experiment No. 1,) had already 80·9° of heat in it, the number of degrees of heat required to be communicated to the water to convert it into steam would be 1081·1° only, and if the temperature of the water had been 212°, it would have required only 950° of heat (equal to the latent heat) to be communicated to it to convert it into steam, hence

	Heat.		Coal.		Heat.		Coal.
As	1081·1°	:	112 lb.	::	950°	:	98·4 lb.

Thus if the temperature of the water had been 212° Fah. before it had been admitted into the boiler, 98·4 lb. of coals would have evaporated as much water as 112 lb. of coals would have done, the temperature being 80·9, hence

Coal.		Water.		Coal.		Water.
98·4 lb.	:	13.43 cubic feet	::	112 lb.	:	15·28 cubic feet,

in other words, 112 lb. of coal will evaporate 15·28 cubic feet of water from 212° Fah., and only 13·43 cubic feet from 80·9° Fah.

The object of column No. 9, is to show a fair comparison between all the experiments, reducing them to one standard, which is rendered necessary from the circumstance of the temperatures given in column No. 6, varying in each series of experiments.

Column No. 10, shows the amount of saving in fuel under different states of clothing, or exposure of the boiler, steam-pipes, &c., as described in column No. 11.

Table No. III.

Columns Nos. 1, & 2, require no farther explanation than has already been given.

Column No. 3, represents the weight of water passing through the cylinder, or into the steam jacket in the form of steam, in the time stated in column No. 2.

Column No. 4, represents the number of strokes made by the engine in the time stated in column No. 2, which is necessary to be recorded, that the power of the engine may be ascertained.

Column No. 5, is the pressure under which the engine worked, or the height to which the water was raised, and was obtained by noting down every 15 minutes during the time the experiments lasted, the pressure, indicated by a mercurial syphon-gauge attached to the pump, then taking the mean of the pressures so noted down, and adding to it the height from the level of the water in the engine well to the datum line of the mercurial gauge; the mean pressure in the line of totals was obtained by multiplying the figures in columns No. 4 and 5 together, and dividing by the total number of strokes, which gives the true mean of the observations made every 15 minutes.

Table No. IV.

Column No. 1 refers to the totals in Table No. 3.

* Vide Mr. Parke's paper on the evaporation of water from steam boilers. Transactions of the Institution of Civil Engineers, vol. 2. page 172.

Columns No. 2, 3, 4, 5, and 6, require no farther explanation than has been already given.

Column No. 7, shows the average number of strokes made by the engine per minute during the time of the experiments.

Column No. 8, shows the effective power of the engine, and is obtained by multiplying the weight of water lifted each stroke (which was equal to $1920\frac{52}{100}$) by the pressure shown in column No. 6, and by the strokes per minute shown in column No. 7, the product being the number of pounds weight raised 1 foot high per minute, which, divided by 33,000lb., will give the horses' power indicated in column No. 8.

Column No. 9, shows the quantity of water (in decimals of a cube foot) required per hour to pass through the cylinder and steam jacket in the form of steam to produce one horse's power, and is obtained by reducing column No. 4 to cubic feet, and dividing by the hours given in column No. 3, and again dividing the quotient by the horses' power represented in column No. 8.

Column No. 10, shows the proportional quantity of water in the form of steam required per horse's power under different states of clothing or exposure of the cylinder, &c., as described in column No. 12.

Column No. 11, shows the proportionate saving of water by clothing the cylinder as described in column No. 12.

Upon examination of the results shown in the Tables, a description of which has just been given, it will be seen in Table No. 2, that when the boiler was clothed with *one* coat of Bo radaile's Patent Felt, that the evaporation was a little greater than when clothed with five coats of hop sacking. When clothed with *two* coats of felt it was not superior to *one* coat of felt, but when clothed with *three* coats, the evaporation was $1\frac{4}{10}$ per cent. greater; and when one coat of felt had been laid on the top of the flues, on the flag stones round the boiler, the evaporation was increased $3\frac{9}{10}$ per cent., and when the boiler was clothed with four coats, and the top of the flues with two coats, the evaporation was increased $\frac{5}{10}$ per cent. only; from this it would appear that to produce a considerable saving in fuel, it is necessary to have at least three coats of felt, and that the top flues should be coated with at least one coat of felt.

Upon examination of Table No. 4, it will be seen, that to obtain the greatest effect of saving from casing with Patent Felt, that not only the steam-jacket and steam-pipes should be clothed, but also the cylinder-cover, and steam-nozzle. The result of these experiments, which an examination of the tables will prove to have been carried on upon a large scale, each trial being continued for several days, shows that by properly clothing the boilers, steam-pipes, and flues, with Borradaile's Patent Felt, a saving of fuel of $10\frac{8}{10}$ per cent. may be effected; and by properly clothing the cylinder-steam-jacket, steam-pipes, nozzle and cylinder-cover, a saving of 15 per cent. is effected in the quantity of water converted into steam to produce a given effect: and consequently, the combined result is equal to a saving of fuel of $25\frac{8}{10}$ per cent.

Although the saving in fuel effected may be considered as the greatest advantage in using the Felt, yet there are others of no slight importance which should be noticed.

1st. The saving in the repairs of the boilers; supposing two boilers equally well made, of equally good materials, under which the same quality of coals is burnt, and in which the same quality of water is used, it is very certain that the wear and tear of the two boilers will be in proportion to the quantity of fuel burnt under them; now if the same effect can be produced by using 25 per cent. less fuel under one than under the other, the wear and tear will be 25 per cent. less in one than in the other; now although the actual amount of saving cannot be estimated, as it must depend upon the quality of materials and workmanship employed, which varies in almost every boiler, nevertheless, that it is a matter of importance will strike every one who has had to do with repairs of boilers.

2ndly. In steam-vessels it must be remembered that a reduction in the weight of coals is equivalent to an increase of tonnage, or in other words, supposing a foreign vessel whose cylinders, steam-pipes, and boilers are unclothed, carries in the course of twelve months 4000 tons of coals as fuel for the engines, a reduction in the fuel of 25 per cent. will enable them to carry 1000 tons extra weight of cargo.

3rd. Reduction in the cost of labour in working the engines, especially on board steam-boats. Upon this point it is not necessary to say more than that, by reducing the quantity of fuel to be used, and reducing the temperature of the engine room, and stoke hole, the labour of the engine men and stokers will be considerably less, and it is very evident a considerable saving may be made in this item of expenditure.

4th. If judiciously applied, the felt will prove a great safe-guard against fire, as it will be seen, by reference to Mr. Aikin's experiments, an account of which is appended to this report, that it may be exposed to a temperature of 400° Fahr. without being affected.

EXPENCE OF CLOTHING.

This, of course, must vary according to the size of the engine and boilers, whether land or marine, engines, &c. &c.; the cost, however, of clothing the engine upon which the trial was made, and *two* boilers with four coats of felt, the engine work covered with green baize oil-cloth, and the boiler with canvas, as herein before described, was £96; the engine working 12 hours per day exposed, or not clothed, would consume 1100 tons of small Newcastle coals per annum, which, at 17*s*. per ton would be equal to £935; 25 per cent. saving on this would be £233 15*s*. or 251 per cent. profit upon the outlay of £95.

DURABILITY OF THE FELT.

It has been the general practice to coat the boilers, pipes, and cylinders with a mixture of white lead, alum, Paris white, and linseed oil, before the first coat of felt is laid upon it, with the intention of preventing the felt from being scorched from direct contact with the heated metal; and it has been said that the fire which occurred in the Great Western steam ship when in the Thames, on her first voyage, was occasioned by the oil in this composition catching fire; to ascertain how far the use of this paint was necessary, and also what heat the felt would bear without being injuriously affected, I requested Mr. Arthur Aikin to try some experiments, and favour me with his opinion on this matter, and beg to refer you to his letter, which is appended to this report, and which to me appears most satisfactory; I also beg to draw your attention to his valuable suggestion of a new mixture to be applied in the place of that used at present in places where it may be found necessary, as being much more efficacious. With a view of showing the saving which may be effected by the use of the patent felt, I have calculated the Table No. V., shewing the saving in annual expence in proportion to the consumption of coals per annum, and the price per ton.

In conclusion, I beg leave to say that I had not, before I tried these experiments, an idea that the saving would be so great as it proves to be; the experiments have been, however, conducted with so much care, each series has been continued for so long a time, and the coals used having been from the same cargo, that I have not the slightest doubt any person clothing their boilers and engines in the *same manner, and to the same extent hereinbefore described*, will at once effect 25 per cent. saving in fuel, or in case of a boiler and steam pipes alone where an engine is not used, a saving of 10 per cent.

THOMAS WICKSTEED,
Civil Engineer.

Old Ford, August 14th, 1840.

REPORT OF ARTHUR AIKIN, ESQ., F.L.S., F.G.S., &c.

MY DEAR SIR—You inform me that it is customary to cover the outside of steam boilers with a paint composed of lead, oil and alum previous to applying the coating of felt. This you say is done with the intention of preventing the felt from being scorched by direct contact with the heated metal of the boiler. You require my opinion if it is necessary to interpose any substance in order to avoid injury to the felt, and likewise inform me that in one instance a fire was said to have originated from the oil paint becoming overheated.

With the view of answering your inquiries in a satisfactory manner, my first object was to ascertain the utmost degree of heat which felt is capable of bearing without injury. For this purpose I put several pounds of mercury in an iron basin, and then placed another smaller basin on the mercury—in the smaller basin I put a layer of felt, and applied pressure to the upper surface of the felt sufficient to force the bottom of the iron basin in which it was contained, so deep in the mercury that there was only about half an inch of mercury between the two basins. A pot of burning charcoal was then placed below the larger basin, and a mercurial thermometer graduated to 600 Fah. was dipped from time to time in the mercury to ascertain the temperature. When the heat had risen to 300 Fah. a small piece of felt was immersed in the mercury between the two basins, and was withdrawn occasionally as the heat increased, in order to observe the effect produced on it. Up to the temperature of 440° or 450°, the felt appeared to suffer no injury, the colour remaining unaltered; but from 450° to 480° the colour first became deeper, the elasticity of the fibre was destroyed, it then became nearly black, and at the same time gave out the odour of burning hair. The hot charcoal was then removed, and on examining the felt which was in the small basin, it gave out, while warm, a burnt odour, and the surface in contact with the iron had become of a dark brown colour, as you may see in the specimen which accompanies this report. I consider therefore the heat of 440 Fah. as the highest to which felt can be exposed without injury, even for a short time (for my experiment did not continue above an hour), and if the heat were continued for several days, it probably ought not to exceed 400 Fah. If therefore the external heat of a steam boiler is liable to rise to 400 Fah., it would be prudent to interpose some substance between the surface of the boiler and the felt, but for this purpose oil paint with a basis of litharge, red lead or white lead is not to be recommended; for the oxides of lead are, all of them, especially the second, very easy of decomposition when mixed with oil and heated. While decomposing, that is, while the oxygen of the lead is combining with the combustible ingredients of the oil, a considerable increase of heat is excited, and this may, under favourable circumstances, be so great as to produce actual combustion of the oil.

In making experiments with the intention of discovering a composition free from the objections to oil paint, and at the same time cheap, the following occurred to me, and I find on trial that it adheres perfectly well when dry to the surface of iron, and will bear a heat of between 500° and 600° without material injury; it also retards considerably the efflux of heat, and will therefore, I think, be found a very good protection for the felt. It is made as follows:—

Take very stiff clay and sand (that of a bright yellow colour is best), dry them separately at a heat not much exceeding that of boiling water; reduce them to powder and pass them through a moderately fine sieve. Of the sand take four measures, and of the clay two measures, and mix them well; then add one measure of linseed meal, and one measure of horse dung, mixing them with the other ingredients as accurately as possible. Pour into any convenient vessel boiling hot water, and shake into it the above composition by small quantities at a time, observing that the last added quantity is thoroughly soaked before another is put in; there will thus be obtained a slippery semi-gelatinous mass which is best applied to the surface of the boiler by means of a trowel.

The first layer should be very thin, and care must be taken that it does not slip down while wet, when it has become dry it will adhere firmly, and if its surface is left rather rough, the second layer may be applied without any hazard of its slipping.

A. AIKIN.

7, *Bloomsbury Square*, *Aug.* 6, 1840.

TABLE No. I.

Detail of Coals consumed and water evaporated in the course of 72 experiments, during which there were 4275 bushels of coals consumed, 1287 tons and 8 cwts. of water evaporated.

COMPETITION DESIGNS.

MR. SPARKE IN REPLY TO K. P. S.

SIR—In your number of this present month appeared a letter signed K. P. S., containing a charge against the persons who are engaged in building a New Church in this town. I have to request that you will give insertion in your forthcoming number to some observations in reply to those charges.

Your correspondent K. P. S. refers to a letter, dated Oct. 29, 1839, addressed by the Subscribers to the New Church to six Architects, inviting them to send designs for the proposed building, upon certain terms therein specified.

This letter is designated by K. P. S. as "most offensive." But surely it is impossible to conceive that the subscribers* *intended* an offence to the gentlemen with whom they sought communication. The letter indeed contained a clause, obliging the architect, whose design should be selected to carry the work into execution for the specified sum of £3,000, if required by the subscribers so to do. The subscribers, however, learnt that this arrangement was contrary to the practice of the profession, and therefore they at once altered the terms of the proposition to meet the wishes of the architects, who [so far as the subscribers are informed] were perfectly satisfied with the terms as amended, to which they all assented.

Let me now address myself to that point which has led the subscribers to think it proper to take notice of this letter of K. P. S., namely, the charge of bad faith towards the architects.

The substance of this complaint is, that the subscribers selected a

* K. P. S. criticizes the expression "Subscribers," and says "the business was of course onducted by a committee." He is as ill informed on this as on other points connected with this church. The subscribers at large, and not a committee transacted the business K. P. S. speaks of. The building committee was not appointed till after the design was selected.

design, the execution of which will cost £700 or £750 more than the sum mentioned in the instructions given to the architects.

Your correspondent K. P. S. says, "having selected the design, the subscribers proceeded to receive tenders for its execution; and it having been whispered that the estimates of the builders greatly exceeded the stipulated sum, the result was—not that the subscribers rejected the design and chose another—but that the tenders were returned to the builders unopened, and the designs referred back to the architect, for the purpose of being altered, so as to bring it within the means of the subscribers."

This statement is totally at variance with the truth. The first tenders were not returned to the builders, and the design was not referred back to the architect for the reason stated. This course was taken solely on account of an objection to the mode of constructing the roof, made by the Incorporated Society for building Churches; and the objection of the Society was communicated to the subscribers after the first tenders were received.

Your correspondent proceeds, "how the subscribers have fulfilled the conditions they dictated, may be seen by the following statement: The accepted tender amounted to £3550 in round numbers."

This Sir, is not in accordance with the fact: the sum for which the Church is to be completed is £3,353.

K. P. S. continues, "in addition to this, extra foundations, to the amount of £150 to £200, were found to be necessary, not in consequence of any unforeseen difficulty, such as might arise from the nature of the soil, &c."

The fact, Sir, is, that the "extra foundations were required by the nature of the soil." It was necessary to remove a very considerable body of earth for every part of the foundations, and in the site of the tower, the ground was excavated to the depth of 13 feet: and the foundations was made of the best concrete, comprised of lime and gravel, brought from a distance of nearly 3 miles.

"The cost of the building," continues K. P. S., "is therefore to be from £3,700 to £3,750."

This inference is very far from the truth. The sum for which the Church is be completed is, as I have before observed, £3,353. But from this gross sum is to be deducted the amounts of the drawback on the duties upon the customable and exciseable materials used in the building, as was expressly stated in the directions to the architects in the letter dated Nov. 30, 1839. This drawback is estimated at £350.

The cost of the Church, therefore, will amount as nearly as possible to £3,000, the sum which the subscribers have always stated that they intended to expend.

K. P. S. continues, "neither plastering nor painting are included in the contract."

This is opposed to the fact. The walls indeed are not to be plastered, but all the plastering which the subscribers think fit to do, *is included* in the contract; and so also is the painting.

K. P. S. continues, "instead of 650 sittings in pews on the ground floor, there are but 360; 180 more in open seats, and the remainder on benches."

The subscribers have thought fit to substitute for pews of three different widths, seats of uniform width throughout the body of the Church, some close pews, some open pews, and along the middle aisle, benches.

K. P. S. continues, "instead of stone quoins, there is not an atom of stone in the building but what may be indispensable."

This statement also is opposed to truth. There is much more stone in the building than would have been indispensable in making stone quoins: all the weatherings are of stone, as are also the string courses.

K. P. S. continues, "the window jambs, &c., are of moulded brick, not gauged brick, but bricks from the kiln, with good ⅜ joints between them. The side roofs are to be covered with zinc."

I have only to observe that there was nothing in the instructions to the architects which rendered it improper to build in the way that has been adopted.

K. P. S. continues, "the side walls are 2½ bricks thick, but, to save materials, are built hollow, the construction of the rest of the building being in strict keeping."

The inference which an incautious reader might be induced to adopt from this statement, would perhaps be this—that the walls are hollow throughout. Nothing could be further from the fact. There are no chambers, but in those parts of the walls where there is little weight to be supported. In the latter part of the last clause, K. P. S. has been more guarded and prudent than in the rest of his letter, because it is only an insinuation, and therefore does not admit of any direct contradiction.

K. P. S. continues, "whether all this is quite acting up either to the letter or the spirit of the instructions of the Incorporated Society, may admit of a doubt at least."

The doubt, Sir, is soon resolved; for the subscribers have the approbation of the Incorporated Society testified by the signature of their secretary upon the plans; and indeed the quantity of materials used in the walls is greater than is required by those approved plans.

"It will admit of a doubt," continues K. P. S., "whether a building with bare walls of ordinary brick, and fittings of naked deal inside, can be exactly said to maintain an ecclesiastical character."

How far the New Church can be said to maintain an ecclesiastical character, must be a matter of taste of opinion; but it is believed that no one has seen the designs of Mr. Ranger, the architect, without admiration of their beauty and their perfect adaptation to the purposes for which the building is required; and that no one has seen the building itself, so far as it has already been executed, without approbation of the mode in which the work is done.

So great a discordance between the statements of K. P. S. and the facts of the case, the subscribers conceive can only have arisen from this cause—that K. P. S. has seen neither the contract nor the building, and therefore neither knows what has been done, nor what it is intended to do. He might have seen both by applying either to me, or to the clerk of the works, and he is quite welcome to do so whenever he pleases.

I am, Sir, your obedient servant,

J. SPARKE, *Hon. Sec.*

Bury St. Edmund's, Oct. 19, 1840.

RANGELEY'S SAFETY ROTATION RAILWAY.

(With an Engraving, Plate XVII.)

IN the September number of our Journal we gave a short description of this invention, and also in the present number will be found an abstract of a paper read at the British Association, but as we thought many of our readers might feel interested in the proposed novel mode of transit, we have prepared the accompanying plate illustrative of the subject, and which, with the following description, will fully enable our readers to judge of its practicability.

This system consists in the adoption of two parallel lines of fixed wheels along the proposed road, at any moderate gauge, and at a short distance longitudinally from centre to centre of each wheel. These are termed the bearing wheels, which, together with a double pulley, are cast or keyed on to a common axle marked *d* and *e* in the engraving. The axles of these bearing wheels and pullies work in plummer blocks *c*, fixed on to cast-iron beds or bearing frames *b*, which are proposed to be in 12 feet lengths, and secured to three wood sleepers and to each other in the way shown in fig. 3; but to prevent elevating these iron beds much above the surface of the ground, a chamber of masonry or iron is necessary to enable the bearing wheels to revolve free from obstruction. Over every pulley is passed an endless band working into the adjoining pulley each way, so that for any distance that the road may be carried there would be an equal distance of band, but in a series of lengths, equal to the distance from each other, of pulley from pulley. Having proceeded so far in our description, we will now explain the method of action:—A steam engine, water wheel, or other motive power being connected with the pullies at each end of such a series of wheels, and motion given thereto, it would in a short time communicate it throughout; and each wheel revolving in the same direction, it is evident that any body placed on the upper periphery of the wheels, so that it could not quit the track, would be in a short time carried from one end to the other, and in greater or less time according to the greater or less rapidity with which the wheels revolve.

By referring to figs. 1 and 2, it will be perceived that the carriage is without wheels, and in fact a kind of sledge; an iron rail is fixed in the underside of the bearing frame to prevent the rapid wear which would otherwise take place from the friction of the wheels in progressing the carriage.

The safety of this mode of transit arises from a considerable portion of the carriage depending between the wheels, and which is termed the baggage box *k*, and the steady motion of the carriage will in a great measure depend on the load which may be stowed therein. To prevent lateral friction against the wheels on beds, guide wheels are fixed at each end of the baggage box, which will prevent the carriage at any time from quitting the track, and also assist in its passage round corners; a break at each end (for regulating the speed, or stopping the carriage, by slightly raising it, and of course diminishing the friction or bite of the wheels on the carriage), is shown in figs. 1 and 2.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XX.

"I must have liberty
Withal, as large a charter as the winds,
To blow on whom I please."

I. It is somewhat odd that those who profess so greatly to admire St. Paul's, Covent Garden, should not have cared to aim at the same kind of effect, as regards one peculiarity in it. It is almost doubtful, however, whether the circumstance alluded to has been taken into account at all, since it has never been especially pointed out, as deserving to be noted and studied. What I mean is, the projection of the pediment as seen in profile, and the bold shadows—or rather depth of shadow in the tympanum of the pediment. Perhaps I shall be told that this is a circumstance attending the peculiar kind of entablature and cornice there employed, and that consequently the same effect cannot be obtained in the pediment of a portico whose columns are of the Grecian Doric, or Ionic order. Most undoubtedly not, if we are determined merely to copy Grecian authorities, yet not only so slavishly, but so blindly, as not to study such modifications of the originals as shall in some degree give us a tolerable equivalent for what is unscrupulously abandoned in the professed copy, however essential it may be to resemblance. There is no occasion whatever for impoverishing Grecian architecture, yet we do so continually without the slightest compunction, making naked entablatures and pediments, with scanty cornices, absolutely *starving* our buildings, yet congratulating ourselves all the while on the classicality and purity of our taste, and fancying that we are perfectly Grecian, whereas we are no better than architectural paupers, dressed up in old finery of which the trimmings and embroidery have been cut away.

II. Should future generations form their ideas of Grecian architecture from our modern English imitations, prodigious will be their wonder at the praises bestowed upon it; for they will be greatly puzzled to discover in them any of its spirit, or any adherence to its principles—aught of refined taste and artistical feeling. In his recent work on *Kunst-Sinnbilder*, Menzel makes some remarks on the ancient orders and the modern versions of them, that architects would do well to take into consideration. He condemns the recipes and prescriptions for making Doric, Ionic, &c., given by Vignola, Palladio, Serlio, Scamozzi and others, as leading only to the most servile and blind imitation of the patterns so set, and which are certainly not the very best in themselves. Of even the very best examples, too, the continual repetition not only becomes wearisome in itself, but also tends to check all invention in design,—at least as regards detail, and so far degrades the architect from an artist to a mere parrot or automaton. Yet in this as in other matters over-strictness is apt to lead to the opposite extreme of licentiousness: and those who would be shocked at the idea of any innovation in Greek detail, even though it were perfectly in accordance with Greek feeling, feel no scruple whatever in reverting for the sake of variety, to such deformities as the Italian Ionic,—which would be reckoned positively detestable after Greek, were it not, that there is precedent for it, and it is not an invention of our own. Out upon the *servum pecus* of pedants, whose dislike to originality arises from their own incapacity to originate any thing whatever, and who therefore bolster up their own imbecillity by a most convenient veneration for precedent.—In the grounds of Mr. Anderson's villa in the Regent's Park, there has lately been executed a small building, the capitals of whose columns would scandalize such *pseudo-legitimates*, for the very reason that they must charm every one whose taste is any thing better than mere prejudice. Ionic in character, though unlike any existing example, they display genuine artistical feeling, and a perfect knowledge of architectural principles with a thorough contempt for ready-made architectural patterns, and for those who make use of them. By all means, let the Institute procure a cast of that capital; and were the two Professors of Architecture to do so likewise, they might get from it something they now seem to be terribly in lack of.

III. In an article on Modern Churches, British Critic, No. LII, there are many remarks worth attending to, and among others what is there said in regard to the excessive quantity of light admitted into churches generally, in consequence of painted glass having been destroyed or removed from the windows of the older buildings, and its not being introduced into those of modern ones, notwithstanding that the apertures are made as large, and the spaces between them as narrow, as if it were intended to damp the light, and hinder the effect of rawness generally, by glazing the windows with rich material. "Nearly all our ancient churches," says the writer, "from the cathedral to the smallest oratory are now considerably *overlighted*. They are not now seen in their proper dress; but are like the face of nature in winter without leaves or flowers. Thus the interior of Salisbury Cathedral is as light as the open air: nay, in a sense, it is lighter; for out of doors, there is an infinite variety of light and shade, and still greater variety of hue; but in that building, as reformers and puritans have left it, there is no relief, no repose: with inconsiderable exception, all is one equally monotonous, shadowless, colourless medium: nothing recedes, nothing stands out. The proportions suffer: for neither height nor length are felt in the glaring mass of day-light.—The cathedral is reduced to one great airy room. The aisles are no longer depths of shade: the lofty pillars and arches no longer stand out in bold relief, bathed in copious streams of light and colour from the high clerestory windows, every stone from the vaults above to the pavement under our feet seeming instinct with life."—"Our churches having been nearly all built or altered with a view to painted glass, as soon as this essential part of their plan was destroyed, there was immediately found to be double or treble the quantity of aperture sufficient for light. In spite of bad glass, windows wholly or partially blocked up, curtains, galleries, and staircases, lofty screens, and all the other numberless accretions of the last three centuries, they are still greatly too light. The restorations of the present age, by opening windows, substituting larger panes of clear white glass, clearing away heavy screens and partitions, and lowering pew-walls, have in fact accidentally increased the evil, and rendered the glare of our churches, especially those of the later styles, quite intolerable, not only to the mental feeling, but to the bodily eye."

IV. In speaking of Vestries, the writer just quoted is of opinion there is little occasion for them in country churches. Such a place "is useful of course to the *crack* preachers of the metropolis, some of whom sit there and *comfort* themselves during the service, that they may come forth fresh as giants to the event of the day—the sermon." It is said also that Dr. Parr used to illustrate his attachment to rural psalmody, by "*smoking in the vestry* during the performance of the choir"! Considering the character of the publication in which the article appears, these remarks are somewhat freely satirical, though certainly not without foundation; for I myself have been in an exceedingly snug vestry, where there was a delightful blazing fire, and every thing vastly *comfortable* indeed, so much so that I should have mistaken it for the parson's own parlour, had not the sash windows been much higher up from the floor than they are in modern houses; which certainly did not diminish the appearance of comfort, inasmuch as it afforded comfortable assurance that there was no danger of any one's accidentally peeping in.

V. Whether I be censured or not for my last comment, the passage which I shall now quote from the same writer, is so excellent, that I shall be thanked for here introducing it.—"Mere novelty is not *originality*. Many things have never been done; some things have never been thought of, simply because they are unnatural and out of the way. *True originality* is a power of invention or discovery; but whether employed in the regions of science or of poetry," (or of art) "it only discovers or invents what is, in some sense, natural and true. It does not so much *make* new ideas, as *find* what have escaped the minds of others. It conceives ideas which strike us at once as having a sort of self-evident propriety and beauty. Its creations are at the same time like and unlike what we know already,—like, in that they accord with our existent taste and notions;—unlike, in that they seem each to have an individual essence."—This last expression, indeed, is not altogether a happy one: perhaps it would be better to say—unlike, in that some new modification is presented to us, for which there is no actual precedent, but which recommends itself so strongly, and withal appears so obvious that we wonder no one should have hit upon it before.

VI. Shall I venture to quote another observation from the same source? Yes; for what the writer says in regard to the notion of Grecian architecture requiring greater attention to study and rules than Gothic does, is well worthy of attention. "There cannot be a greater mistake. Gothic architecture *appears* less formal and less regular than its ancient rival, only because it embraces *more* elements of calculation,—because it has *more forms and rules of art*." True, most true! A person may go through the whole of Grecian architecture—may learn all the Five Orders, *secundum artem*, in less time than he can make himself acquainted with the varieties of Gothic doors or windows, or any other single feature belonging to that style. Carpenter's Gothic indeed,—or even the Jemmy-Wyatt Gothic is a different matter;—that is *regular* enough, all done *by rule* without any study, and therefore regularly bad, or at least insipid.

ON LONG AND SHORT STROKE STEAM ENGINES.

By John Seaward, C. E.

A popular notion has for a considerable time past prevailed, that a long stroke engine is much superior to a short stroke engine; and it will consequently be found that the practice of most, if not all engineers, is greatly regulated by this idea. On very careful consideration, however, it does not appear that this alleged superiority can be satisfactorily proved. That a long stroke engine, under certain circumstances, may be much more advantageously employed than a short one, is undoubtedly true, but considering the steam engine *per se*, that is without reference to adventitious or extraneous circumstances, it would be difficult to show that the former has any advantage whatever over the latter.

For let a careful comparison be made of a long stroke engine with a short stroke engine; let there be two beam engines of thirty horses power each, both equally well made, but the one having a stroke of eight feet, while the stroke of the other is only four feet, the cylinder of the latter being double the area of that of the former; it being understood that both engines shall make the *same* number of revolutions per minute; the steam passages and valves to be of the same area and capacity; and the two engines in all other respects to be well proportioned and made without any limitation as to space or weight.

Now as regards the mere mechanical effect of the moving power (*i. e.* of the steam) it is perfectly clear that it must be precisely the same in both engines, because the same volume of steam must produce the same mechanical effect whether it is let into a long narrow cylinder or into a short wide one; therefore, if there be found any difference in the efficient duty or economical working of these two engines, that difference must arise from circumstances quite unconnected with the mechanical effect of the steam power.

The only circumstances which really can make any essential difference in the efficient duty or economical working of these two engines are these:—First, the greater or smaller quantity of friction in the various parts of the machines. Second, the greater or lesser radiation of heat from the cylinders and passages; third, the greater or smaller loss of steam by the clearance of the piston at the top and bottom of the cylinder. Fourth, the *inertia* and the impulse of the parts of the machine in motion on the surrounding air.

First, then of the *friction*. It will be found in the working of a well made engine of the proportions of the short stroke engine under comparison, that more than four-fifths of the whole friction are due to the packings of the piston and air pump bucket, and of the piston rod and bucket rod,* and less than one-fifth to the main gudgeons, the end gudgeons, the crank pin and other moving joints about the engine. But the friction of the piston packing will vary as the circumference of the piston, multiplied into the distance which the piston travels. Now in the long stroke engine the piston supposing it to be 30 inches diameter, will move eight feet, and the friction of the packing be therefore as 24, while in the short stroke engine the piston will be about 42·4 inches diameter, will move only four feet, while the friction of the packing will be only as 17. In the same way it can be shown that the friction caused by the packing of the air pump bucket, of the piston rod, and of the bucket rod, is also respectively in the ratio of 24 to 17, in the two engines. With respect again to the friction due to the main and end gudgeons, &c., it is clear that it will be less in the long stroke engine, because in the latter engine, the force acting upon these parts will be one-half what it is in the short stroke engine. Assuming therefore 100 to be the whole quantity of friction in an ordinary engine then, 80 of these parts in the short stroke engine, will be due to the piston, air pump, bucket, &c., while in the long stroke engines the friction of these parts will be as 113 that is $= \frac{24}{17} \times 80$, but the friction on the main and end gudgeons in the former engines will be as 20, and in the latter only 10, making the total friction in the short stroke engine 100, and in the long stroke engines 123, or one-fourth more.

Second.—The *radiation of heat* will be in proportion to the extent of surface, but the surface of the long stroke cylinder, is much greater than that of the short cylinder, whence it follows that the loss by radiation in the former, must be greater than in the latter.

Third.—The *clearance of the piston* at the top and bottom of the cylinder, which will evidently be greater in the short stroke engine than in the long stroke engine. Because the area of piston in the former is double that of the latter, some persons would be disposed to say, that the loss by clearance in the former must be double what it is in the latter; but this is not quite certain, for it is not required to give so much clearance in a 4 feet stroke cylinder as it would be advisable to give in an 8 feet stroke cylinder, the reason of which is obviously that the spring and elasticity of the parts in the long stroke engine, must be much greater than in the short stroke engine, and that they must therefore require more clearance. However, it is probable that there would be more loss in the latter engine than in the former.

The loss of steam by filling the passages and nozzles, as also by the radiation of heat from those parts, must evidently be the same in both engines.

Fourth.—*The inertia and impulse of the moving parts on the surrounding air.* The loss in a steam engine occasioned by these two causes may not be very considerable; indeed as regards what is called the *inertia* of matter in the moving parts, it is doubtful whether any such source of loss really exists; however if it does exist, it is clear that the amount of loss must vary in proportion to the *momenta* of those parts of the machine which are in motion, but as the *momenta* must be as the mass of matter in motion multiplied by the velocity, and as these are evidently much greater in the long stroke than in the short stroke engines, (because the parts in the former, are if any thing, of greater weight than in the latter, and also move at a double velocity,) it follows that whatever loss may arise from the *inertia*, must be much greater (double?) in the long stroke engine than in the short stroke engine. With regard to the loss occasioned by the impulse of the moving parts on the air; it must be admitted that in very slow motions it cannot be very important; nevertheless with a material increase of velocity this source of loss becomes serious; it varies as the extent of surface of the moving parts multiplied into the *square* of the velocity. It is tolerably manifest however that the surface of the moving parts in the long stroke engine, will be, if any thing, greater than in the short stroke engine, and that the velocity of the former will be twice that of the latter; therefore the loss by impulse on the air in the long stroke engine, must be four times that in the short stroke engine.

Beside the foregoing causes, it is doubtful whether there are any others that can produce any material difference in the efficient duty or economical working of a steam engine; at least none that can in any way influence the question now under consideration. In estimating therefore, the advantages of the short and long stroke engines, we have in favour of the former a diminution of loss occasioned by friction, by radiation, by *inertia*, and by impulse on the air; while on the other hand, we have in favour of the long stroke engines, a diminution of loss in the clearance of the piston at the top and bottom of the cylinder. It may be difficult to strike an exact balance between these several sources of loss; but there can be no doubt that in a steam engine the loss by friction is much greater than the loss by all the other causes before mentioned put together; and it is past dispute that the balance of loss as regards these causes, is decidedly against the long stroke engine. (The advantages offered by the short stroke engine as regards diminution of space and weight, although of vast importance, are not here adverted to, because they form no part of the immediate inquiry.)

It may be objected that to select an engine with an 8 feet stroke and a cylinder of only $2\frac{1}{2}$ feet diameter for comparison, is not a fair proceeding, because an engine of such proportions is unusual; and it may be also asked whether, if the principle is further extended by making the stroke only 2 feet, and again doubling the area of the piston, whether the advantage would still be in favour of the short stroke engine?

To this it may be answered that although an engine of 8 feet stroke and $2\frac{1}{2}$ feet diameter of cylinder, may be unusual in this country, it is not so in America; in that part of the world, many engines are employed of very nearly the above proportions, for purposes of steam navigation; and in which engines it is not unusual for the piston to travel at the rate of 300 or 400 feet per minute. Again, as regards the carrying out of the principle by still farther reducing the length of stroke, say to two feet, and increasing the diameter of cylinder proportionately, say to 5 feet; there is no doubt whatever that such an engine would have precisely the same mechanical effect as either of the other two; but the balance of advantages would be against an engine of such proportions; because it would be verging to an extreme on one side as much as the 8 feet stroke engine may be thought extreme on the other side. It may, however, be safely affirmed that the principle applies most powerfully to the case where the diameter of cylinder is the same as the length of stroke; because in that case the proportions are most favourable for the diminution of friction and of radiation, and offer the minimum of disadvantage under the several heads of loss above enumerated.

As it is manifest, therefore, that in all particulars which more immediately affect the beneficial employment or working of a steam engine, the long stroke has no manifest superiority over the short stroke; it may appear strange that so decided a preference should have hitherto been given to the former by the generality of engineers.

* The friction of the slide is not included, as that will obviously be the same in both engines. See remarks on Friction at the end.

Perhaps this is chiefly to be attributed to the circumstance of the long stroke offering on most occasions greater convenience than a short stroke. Much may be due also to fashion. The earliest application of steam power was for the purpose of pumping water in the course of mining operations, and in this sort of work a good long stroke was found to be attended with considerable convenience and advantage. In blast engines, and many other of the earlier applications of steam power, the same result was manifest; the earlier habits and ideas of engineers were therefore naturally associated with long stroke engines. Moreover, the earlier manufacturers of steam engines had neither good machinery nor good workmen; they could neither depend upon the correctness of their proportions, nor upon the exactness of the workmanship; besides, timber and other inefficient materials were formerly employed to a considerable extent in the construction of engines; from all which causes imperfections and irregularities were numerous in the earlier engines, and they were consequently very inefficient. As all these sources of imperfection and inefficiency operated much more extensively against short stroke engines than against long, it is no wonder that the latter soon obtained a preference, and that the prejudice should still continue to exist, notwithstanding the same causes are no longer in operation. At the present day, with our good materials and workmanship, exact proportions and adjustments, a short stroke engine will be found to work as accurately and as perfectly as a long stroke engine.

There is one very important circumstance to be kept in view as regards long and short stroke engines; which is, that whenever an engine of the latter description has hitherto been made, it has always been considered necessary to keep the cylinder nearly of the same diameter, as in the long stroke engine, and to cause the engine to make a greater number of revolutions in proportion to the shortness of the stroke, so that the piston in every case might travel at a nearly uniform speed of about 200 feet per minute. Now, to a short stroke engine, made on this plan, there may undoubtedly be many objections. The more frequent alternation of the stroke—the greater loss of steam by the more frequent filling of the passages and nozzles, and the clearance at the top and bottom of the cylinder—the much greater angular motion of all the bearings and moving joints, thereby materially increasing friction and wear—are all circumstances tending to lessen the efficiency of a short stroke engine made upon this plan. It is clear however that an engine made upon the principle, herein before laid down, is not open to the same objections.

And, as regard the speed of the piston in engines, whatever may be the length of stroke, being regulated to the uniform standard of about 200 feet per minute, there can be no valid reasons given for such rule; no one can prove that double the above speed, or only one-half that speed, might not be employed with equal or greater advantage; it is certain that in many steam engines of the transatlantic world the pistons move at a speed of 300, 400, and even as much as 500 feet per minute, and no substantial reason can be alleged why such engines should not do good duty; indeed it may be safely affirmed, that whether the speed of an engine be 100 feet, 200 feet, or 300 feet per minute, it matters nothing; provided all the parts of the engines are well proportioned for the proposed speed, the efficient duty and economical use of the engine will be much the same; keeping this always in mind, that *the slow speed will be more favourable for the easy and pleasant working of the engine, and for durability.*

This question may however be asked—Since it is shown that the long stroke has no superiority over a short stroke, but on the contrary that the balance of advantage is rather in favour of the latter, is it intended to recommend the invariable adoption of a short stroke engine to the total exclusion of a long stroke? By no means. All that is contended for is, that in every case a length of stroke should be adopted whether long or short that shall prove to be most convenient, and best adapted to the object for which the engines are to be employed; and that an engineer should not be fettered and cramped by any fallacious abstract notions, that what is termed a long stroke engine must necessarily be more efficient than an engine with a short stroke; and that he should not therefore be obliged to sacrifice many other far more important considerations, for the sake of obtaining in every case the longest possible stroke.

The application of steam power for the purpose of navigation has had such wonderful results, the character of the steam engine has become so greatly changed, and the proportions so altered, that a marine engine of the present day, and a land engine of former times can scarcely be recognised as belonging to the same class of machines. The length of stroke of marine engines is probably not more than half what used formerly to be given to engines of similar power for mining and manufacturing purposes, but still no one can say that this departure from old rules and maxims has been attended with any disadvantage; on the contrary, it can be shown to have been most beneficial and glorious in its results; and if a still further departure from old established notions can be proved advantageous for steam navigation, we can have no reason whatever to regret the change.

There is no question that the ordinary beam engine as employed in steam vessels has proved most efficient, and that in its application it has been productive of vast benefit. If however, by a modification of the existing steam engines, these benefits can be still further augmented, and that in an eminent degree, no consideration ought to stand in the way of the proposed improvements. The great and paramount objects to be aimed at in the construction of steam engines for navigation are the following, viz., the greatest saving of fuel, the greatest saving of space, the greatest saving of weight, and the greatest durability of the machinery. The more eminently the marine engine shall combine the above important qualities, the more nearly will it have arrived at perfection; and much as may be advanced in favour of the beam engines generally used for marine purposes, it cannot be considered presumptuous to declare that the system of engines employed in the "Cyclops" and "Gorgon" Frigates is far superior in all the qualities before enumerated.

It only remains to be stated, that the real question is, not whether the stroke of an engine shall be 8 feet or 4 feet; but relates to a difference of stroke, of probably from 7 feet to 6 feet: that is, whether the reducing of the stroke of a 200 horse engine *one foot*, with a proportionate increase of diameter in the cylinder, can be attended with such injury and inefficiency as shall wholly neutralise or outweigh all the important advantages of the Gorgon Engines.

In conclusion, it should be observed that as regards the ordinary beam engines, there are many circumstances of convenience which render it advisable to make the stroke as long as practicable, *i. e.*, the adopting a tall narrow cylinder instead of a short and wide cylinder; for in the arrangement of the ordinary beam engine for marine purposes, it is evident that a considerable space lengthways is required for conveniently placing the slide jackets and passages, the condenser, the hot-well, and the air pump; this necessarily causes a great elongation of the side levers or beams; there is therefore much local convenience in making the stroke long, and thereby having a tall narrow cylinder instead of a short wide cylinder, less strain is thrown upon the beams; the beams become more close and compact, and afford more space for a passage between and on the off-sides of the pair of engines: the cross-heads and fork-heads become shorter, and have much less strain thrown upon them; these are all very important considerations which clearly indicate the convenience and possible advantage of having as long a stroke as possible in the ordinary beam engine. But in the Gorgon Engine none of these considerations have any influence whatever; here there are neither beams nor cross heads; we can increase the diameter of the cylinder to almost any extent without any local inconvenience whatever.

We shall conclude these observations with the remark, that as it cannot be proved that there is any superiority in a long stroke engine, over a short stroke engine, and as it is also evident that there is no disadvantage whatever in employing a short connecting rod, it is therefore clear that the two objections are decidedly absurd and groundless.

Of the Friction in Steam Engines.

In the preceding pages we have offered an investigation of the comparative merits of the Gorgon, and of the common beam engine; in the course of our remarks it became necessary to advert to the important subject of friction; it will not therefore be deemed misplaced to add a few general remarks upon the nature of the friction, which occurs in a steam engine of the usual construction.

To attempt anything like a correct estimate of the absolute quantity of friction in an engine, would we conceive be very fallacious, because there are so many circumstances which affect the quantity of friction, which are quite beyond the reach of calculation; as for example, the uncertain degree of tightness to which the several bearings or packing may be screwed down—the state of the rubbing surfaces, as to smoothness, polish or roughness—the perfect or imperfect state of the lubrication, &c., all of which are circumstances which have a vast influence on the quantity of friction in a steam engine. From observations which the writer has made he is induced to believe, that in a well made engine, in good working condition, the total amount of friction does not exceed five or six per cent. on the whole power of the engine; but that with no very great change of circumstances this quantity may be increased readily to as much as 10 or 12 per cent.

It happens however that in the preceding investigation, the consideration of the absolute quantity of friction in the engine, is not required; all that is wanted is an estimation of the relative proportions of friction which are due to the several parts of the engines; now this sort of estimation is not very difficult, at all events we can arrive at an approximation sufficiently near for practical purposes.

For, if we assume that all the moving or rubbing surfaces throughout the engine are equally smooth, that all the packings and bearings are uniformly screwed down, that all parts are well lubricated; then the comparative quantity of friction in the several parts will be, as the area of one of the rubbing surfaces, multiplied into the distance which it moves up on the other rubbing surface.

We obtain thus the following rules:—

1. For the relative quantity of friction due to the piston, multiply the circumference of the piston by the depth of the packing, and by the distance which the piston moves up and down in the cylinder.

2. For the friction of the main shaft bearings, multiply the square of the circumference by the length of the bearing.

3. For the friction of those bearings which do not revolve entirely round, but oscillate backwards and forwards, as the beam, gudgeons, &c., multiply the area of the bearing into the angular distance moved backwards and forwards during one revolution of the engine, &c.

4. It should be observed, however, that when one of the two rubbing surfaces is hemp packing, the amount of friction will be at least double what it will be when both surfaces are metal.

5. Furthermore, there are certain bearings which receive the direct strain of the engine, while others do not. The following receive the direct strain, viz.; the crank pin, the fork head gudgeons, the main gudgeons, the upper and lower bearings of the side rods; now the quantity of friction upon these several bearings will be considerably more than that which is simply due to the tightening down of the bearings, as before assumed; it is difficult to say what may be the increase of the friction from this cause, but it will be safe to assume that the friction on these bearings will be three times greater than what is due to the other bearings.

Upon the foregoing principles therefore, is calculated the following table of the comparative friction of the different parts of an engine, having a 40-inch cylinder, a 3½-feet stroke, and furnished with the common D slide.

Table of Comparative Friction of the moving parts of a Steam Engine.

2 (rule 4) 125½ in. circum. 4 in. deep. 84 in. dist.	81·336	Piston, with hemp packing 4 in. deep, moving a distance of 84 in.
2 13 in. circum. 4½ in. deep. 84 in. dist.	9·828	Piston rod, hemp packing 4½ in. deep, moving 84 in.
2 82 in. circum. 3 in. deep 42 in. dist.	20·262	Air pump bucket, hemp packing 3 in. deep, and moving 42 in.
2 8 in. circum. 3½ in. deep 42 in. dist.	2·352	Bucket rod, hemp packed 3½ in. deep, moving 42 in.
2·2 12 in. circum. 3 in. deep 42 in. dist.	6·048	Two plunger poles, with hemp packing 3 in. deep, moving 42 in.
15 in. wide 8 in. 2 faces deep 14 in. dist.	10·059 (Flat face 1·680)	The slide face metal and metal back hemp packed, 6 in. at top, 6 in. at bottom, moving 7 in. each way.
2 24 in. circum. 12 in. deep 14 in. dist.	(Back, hemp 8·064)	
2 4½ in. circum. 2½ in. deep 14 in. dist.	(Slide rod ·315)	
2 25 in. circum. 9 in. length 25 in. dist.	11·250	The two main shaft bearings moving entirely round metal and metal.
18 in. circum. 9 in. deep 18 in. dist.	2·268	The bearing at outer end of paddle shaft
3 (rule 5) 15½ in. circum. 6 in. long 15½ in. dist.	4·323	Crank pin. moving entirely round and receiving the direct strain of the engine.
3-2— 10 in. circum. 3½ in. long 2½ in. dist.	·525	The two fork head joints moving at an angle of 45° each way, but receiving the direct stain of the engine.
3-2— 10 in. circum. 3½ in. long 2½ in. dist.	·525	Two lower bearings of side rods same as fork head joints.
3-2— 18 in. circum. 7 in. long 9 in. dist.	6·804	The two main gudgeons receiving the strain of the engines and moving 90° each way.
45 in. circum. 13¼ in. deep 45 in. dist.	3·543	Eccentric ring moving quite round.
	1·000	Sundry small joints.
	163·123	

Therefore, if it be assumed that the total quantity of friction in a steam engine is as 163·123, then will the relative quantity of friction in the several parts be nearly as is represented by the numbers in the preceding table.

ON THE THEORY OF TOLLS UPON CANALS AND RAILWAYS.

SIR—As I am aware that Mr. Ellett's remarks on Canal and Railway Tolls, extracted in your Journal for September, have attracted some attention, and have been received as sound and judicious principles by some persons, who are in a position which enables them to carry out these principles into practical operation, I beg to offer a few observations, with the view of pointing out what I conceive to be erroneous in Mr. Ellett's statement.

Mr. Ellett's object is, so to regulate the charge of toll upon a canal or railway, as that every part of the country through which the line passes, near or remote, may derive from the improved mode of conveyance the same advantage, an equal share of trade. And he contends that this cannot be effected by the system of tolls that generally prevails, namely, a fixed mileage, or a certain rate per ton per mile; and he therefore recommends the adoption of the directly opposite method, viz., that the lowest charge should be levied on the trade that is brought from the greatest distance, and increasing gradually as we approach nearer to the mart or place of consumption, that the heaviest toll should be charged on that which comes the shortest distance. And Mr. Ellett then proceeds to show that this plan would produce the largest trade, (that is, would command the largest extent of country,) and the greatest amount of revenue.

Now all Mr. Ellett's argument depends upon one little assumption, which he quietly introduces, without remark or explanation, quite unconscious that it contains the grossest fallacy. The market price of any commodity at the place of consumption may be said to be fixed, (for our present purpose,) and, in order to obtain a sale for this commodity brought by the canal or railway, the cost of production and the expense of conveyance must not exceed the fixed market price. Mr. Ellett takes for granted that *the cost of production* is fixed also, and on this rests the whole theory of tolls. "Let us also assume that the cost of producing this article (lumber) is 6 dollars per ton," and the market price being fixed (10 dollars,) he consequently assumes that the extreme cost of carriage which the article can bear, so as to be sold in the market, is fixed too, that it must not exceed 4 dollars, in the instance given. But he assumes also, and it follows in like manner from the preceding assumption, that *the cost of production is fixed*, that the article can always bear this fixed charge of 4 dollars, that whether the commodity be brought from near or far, whether it is carried 100 or 400 miles, it can always bear the full charge of 4 dollars for carriage, and cannot, in any case, afford more. And on this assumption Mr.

Ellett builds his theory,—that as the cost of carriage consists of two parts, the actual expense of conveyance, including the maintenance of the canal or railway, called *the freight*, and the profit of the canal proprietors, called *toll;* and as the freight must necessarily be directly proportional to the distance, the toll (their sum being fixed) should be inversely proportioned thereto.

Even were this principle correct in theory, it would in practice be exceedingly unjust, and therefore injurious. For nothing can be more unreasonable than that the trade which passes along the canal but 50 miles, should pay three times as much toll as that which comes 150 miles, thus paying actually *nine times* its due proportion. Let it be observed also that Mr. Ellett's system is one that can be fully carried out only on such a canal or railway, as has to sustain no competition with common roads. On the latter the charges of conveyance will always be directly proportioned to the distance, and being lowest for the nearest parts, will of course successfully compete with the canal or railway, whose toll is *here* the highest. The maximum charge for conveyance being 4 dollars, and supposing with Mr. Ellett that land carriage is five-fold more expensive than by the "improvement," it will, according to the scale given by him, be cheaper than the canal for the first 40 miles, (one-tenth of its whole length,) and from so much of the country, therefore the canal will derive no trade. With us the proportion of the cost of land and canal carriage is much nearer, perhaps greater than two to one; and the portion of the country commanded by the superior cheapness of land carriage, under Mr. Ellett's system of tolls, will be proportionately larger. Wherever there is the competition of another conveyance, on which the charges are made according to the distance, the inverse system of toll will be impracticable.

Leaving, therefore, for the present, the practical objections to Mr. Ellett's proposed system, I turn again to that which forms the basis of his whole theory, and which I conceive to be a most fallacious assumption. I am indeed surprised that any one writing upon such a subject, who ought to have some acquaintance with the principles of Political Economy, should hazard, or should carelessly make, an assumption so opposed to the mere elements of that science, as well as to ordinary experience. So far from *the cost of production* of any article being a fixed sum, throughout an extensive district of country, it is dependent upon, and varies exceedingly with, a great many circumstances. Every one knows that there is a difference of prices in many markets throughout the kingdom, and the price *at the place of production* is, *generally*, the actual cost of production, added to the usual profits. For reasons which will be noticed hereafter, the cost of production, and consequently, prices differ less in an improved country like England, than in one possessed of fewer artificial advantages, such as America or Ireland. But the fact is notorious to every one, that differences do exist in the expenses of production, at different places, of commodities of the same quality, and of equal value at the place of consumption.

The cost of production is made up chiefly of rent, the wages of labour, and the profits of the producer, (and, in manufactures, of the price of the raw material.) *Rent* is well known to vary exceedingly in different parts of the country, even for lands of the same kind, and equal fertility. *Wages* differ too, not only between the manufacturing and agricultural districts, but also between different districts engaged in the same occupations. Profits differ likewise, but being nearly in a fixed proportion to the total cost, they need not be considered separately. As, then, the component parts of the cost of production thus vary throughout the country, their sum, the total cost, cannot be said to be fixed. Yet Mr. Ellett seems to have forgotten these facts, palpable as they are to every man's observation.

There are, however, certain articles whose value is very small, and the cost of production of which consists merely of the wages of the labour employed upon it; and this labour being of the coarsest kind, its wages vary but little. Of such commodities the expense of production cannot differ much, and may be said to be fixed. Such are stone, lime, and, in a wooded country like America, timber, and perhaps coal, ores, &c. It is to such products Mr. Ellett chiefly applies his theory, but he does not confine it to them. He intimates that some other principles come into operation with reference to the more valueable articles of trade. But as I have not seen his observation on that part of the subject, and as it appears to me that his principle, if correct, must be equally applicable to every branch of trade, and as I know that it has been so interpreted and applied by some of his readers, I have discussed the subject generally, endeavouring to refute the theory in its application to either division of canal trade. In certain cases, then, it would appear that Mr. Ellett's assumption is correct, that the cost of production is fixed (or nearly so). But it so happens, that in these instances, our author's system of tolls would be altogether impracticable. The commodities are of such little value as to be scarce worth removing, unless at a very small cost; they cannot, in general, be brought from a distance, the necessary charge for freight, even if there be no toll, acting as a prohibition; and to have any trade, even from the nearest places, you must levy only the lowest rate of toll. Thus on the Irish Grand Canal the toll on stone is 6*d.* per ton, and on manure 1*d.* per ton for any distance,—because at higher rates they would scarcely be carried at all. And here, it is evident, there is no room for graduation according to Mr. Ellett's plan.

But resuming the consideration of the cost of production, where it is not fixed, let us examine into the causes of the differences that exist; why rent is high in one district, and low in another, and why wages vary so much as they are found to do in different parts of the country. Of course they all depend upon the economical principle of the relation of supply and demand. But in the same country, all parts of which are subject to the same laws and conditions of trade, and all contribute to the supply of the same great market, this relation between the supply and demand, that is the different values of rent and wages in the various parts of this district, depends mostly upon their respective distances from the place of consumption, and the facilities of conveyance thither. Near a large town, rent and wages, and consequently the cost of production, are high, because there the great demand can be most easily supplied, and with very little expense for carriage. Farther off, as the cost of conveying the products to the markets increase with the distance, both rent and wages are lower. And if a canal or railroad be made into the country, as it cheapens the cost of conveyance, and thereby facilitates its supplying the market, it raises rent and wages, or the cost of local production. Thus the true state of the case is very different from Mr. Ellett's theory. The cost of production is not fixed; it is found to depend on the charges for conveyance, varying inversely with them, (not in the same ratio,) that is, with the distance. Of course I speak here of the natural charge for conveyance, which consists of *freight* only, and is always proportionate to the distance. Such is the cost of carriage upon common roads, and as these are generally the first modes of conveyance, and the most universal, it is by the principles and circumstances that relate to them the cost of production is generally governed. In England the facilities for transport are so great, and so equally diffused throughout every part of the country, that the difference in the cost of production in different places is small, as I before mentioned. But in countries where the improved methods of conveyance are few, the difference of price, or the cost of production, at places at unequal distances from the market, or not having the same facilities, is often very striking. In Ireland, the price of potatoes, for instance, is frequently found to differ to an astonishing degree, in various parts more or less remote from the large towns; and the only cause appears to be the expense of carriage, which being in proportion to the distance, increases or diminishes the cost of production and the facility of removal.

If, then, the cost of production is found to vary, and inversely with the distance, the difference between it and the market price is not fixed, but varies directly with the distance; and the total sum which the commodity will bear as the cost of conveyance to the market is a varying quantity, increasing with the distance. The freight, one of its parts, is proportioned to the distance, and the other portion, the toll, should also, in general, be regulated by the same proportion. There are, of course, many circumstances which modify this law, at least in practice; but looking at the abstract question, I think that the theory of tolls, which the principles of economy and the laws that govern the relations of value and price indicate, is the simple, natural, and just system of charging according to the distance, in proportion to the benefit conferred, or to "the value given."

This is not only the true theory, but it is also the only system that is practicable, wherever there is the competition of common roads; it is easy to show that, in all cases, it would be the most profitable system also,—the most productive of revenue to the proprietors of the canal or railway; and at the same time the most impartial, and the most equally advantageous to every part of the country. Each district has its own advantages, in which it is superior to the others, and, under a natural system, its facilities for production and transport are proportioned duly to its means; while the retrograde principle must have the effect of encouraging the remoter districts, and depressing the nearer,—by destroying the natural and equable balance, which prevails in the social commonwealth.

I cannot trespass on your space, Sir, by entering further on the proofs that the natural system is also the most productive; neither could I do so without introducing diagrams, which would be found to differ very much indeed from those of Mr. Ellett. I shall only add, that I hold the true and most effectual mode of gaining for a canal or railroad the largest amount of trade and revenue to be MODERATE TOLLS, charged fairly according to the distance. I am convinced that the charges upon most canals and railways are much too high; that considerably lower rates would greatly increase their prosperity, and add vastly to the resources and commercial facilities of the country. Wherever the experiment of reduction has been tried, I believe it has proved successful, in augmenting the trade and its profits; and I have no doubt that soon the proprietors of many public works will be compelled, for their own sakes, to resort to such measures: and it is, therefore, of much importance that the principles of "the theory of tolls" should be clearly understood; and, conceiving that those advocated by Mr. Ellett are fallacious, unjust, and injurious, I have endeavoured to refute them,—and regret that the task has been so feebly and hastily performed.

C. E. B.

ON COMPETITION DESIGNS.

We receive many letters on the subject of Competition, which are almost unanimous in complaining of the UTTER WANT OF GOOD FAITH on the part of those who invite architects to send in designs. And though we are sorry there should be room for such complaint in any instance whatever, we are glad to find that the evil itself prevails to so shameful an extent, because it is now likely that the profession will be stirred up to adopt some decisive measures to correct it. They certainly ought to do so: and we should advise a public meeting to be convened by them for that purpose. In the meanwhile our own pages shall be open to the exposure of the impositions now practised under the mask of Competition; and no doubt, many a strange tale might be unfolded that would open the eyes of the public to the mysterious doings of those Secret Tribunals which exercise an arbitrary and irresponsible power, and generally no less injuriously to the interests of architecture and good taste, than unjustly towards individuals in the profession.

From among the letters addressed to us on the subject, we give the three following as being well worthy of the attention of our readers, though we dare not promise the writers that their remonstrances will produce any effect.

Sir—The exposure made by your correspondent K. P. S. relative to the Bury St. Edmund's affair, ought to produce some good effect, yet that any is likely to result from it is more than can reasonably be anticipated; for not only are committees—even though composed of "all honourable men," perfectly callous to any thing like shame, but there is a sad want of energy in architects themselves, or they would even now have taken some decided steps to check the scandalous abuses—I may say, the barefaced impositions and deceptions attending competitions.

If there is positively no remedy for the evils complained,—why then in the name of common sense let them be endured, without any pitiful whining on the part of those who choose to lend themselves to a system of humbug.—Well, I have said *humbug*, and although that word is certainly not the most delicate, there is hardly another in the language that would be so appropriate, unless it were one more offensive still.—But remedy I am persuaded there is—at least to a very great extent, provided we choose to adopt such measures as will secure it. No doubt, there are many difficulties to be first overcome; but that, I conceive is a reason the more, why they should be boldly encountered, and the task of reform be set about with fearless resolution. Such reform ought to have been carried through by the Institute; because that Body might have taken up the matter actively without incurring the invidiousness and risk to which individuals might expose themselves by so doing. There was, indeed, an attempt of the kind, and a most feeble one it was,—amounting to nothing more than a little *palavering*. It would therefore have been greatly more to the credit of the Institute, had the subject never been brought forward at all; because now it looks as if the present vile system of competition was formally acquiesced in by those who ought to leave no stone unturned until they correct it. But there have been two other opportunities which, had they been properly turned to account, might have gone far towards bringing about the so-much-desired reform. As you will perhaps anticipate, I allude to the Nelson Monument and Royal Exchange Competitions, in both of which those who engaged in them, suffered themselves to be more injuriously and contemptuously treated, without venturing to protest against it. With regard to the first one, nothing could be a more insulting piece of mockery than the pretended Second Competition—without any warning on the part of the Committee, that they were decidedly in favour of some kind of Column;—although the result too plainly shows that they were predetermined to adopt Railton's design;—for had they not been so predetermined, they would at least have decently expressed their regret that they should have been driven into so particularly awkward a situation, being under the necessity of confirming their first choice, though aware that it would be in opposition to public opinion. No explanation, however, was offered—and what is much more, none was demanded by the Competitors.—Pity would be thrown away upon such pusillanimous creatures; for they have shown that they deserved to be kicked.

Had a bold and resolute stand been made then,—and the public would almost to a man have supported them;—had they called the Nelson Committee to account, and let the latter know that they were not wholly irresponsible; there can be no doubt but that it would have served as a most wholesome warning to the Gresham Committee, and the Royal Exchange competition would have been conducted very differently from what it has been. But in that, too, the Competitors have allowed themselves to be kicked like spaniels; and the authors of the Eight Designs which obtained the approbation of the professional umpires, suffered themselves to be set aside, and not permitted to try their strength again!

Tame, spiritless, pluckless! they have been served rightly, but THE CAUSE!—that has been most cowardly betrayed. Had those competitors been firm, the Committee would have chaunted *Peccavimus* in full chorus. Had not those Competitors been milk-livered the Committee would have blushed like boiled lobsters. But now, *Actum est! Perii!* And with such a memorable example—such a fatal precedent before them, future Committees may laugh at both competitors and the public.—There is but one chance left: and that is to urge Reform in Competition, incessantly; to discuss it in every possible shape, and without intermission:—and, not least of all, to insist in future upon Pre-exhibition of Designs,—not for merely a day or two, but for sufficient length of time, according to the number of drawings.

I remain, &c.

P. S.

Sir—Apropos to the subject of Competition there is an anecdote now circulating of so extraordinary a nature that it ought to be either publicly confirmed, or publicly contradicted. Reporting it, just as I heard it, the case is this: from among the designs sent in for the Protestant Memorial at Oxford, that by Mr. Blore was *unanimously* chosen, consequently whether such selection was actually the very best or not, it is evident that it was judged to be so by those who made it. But they afterwards discovered to their astonishment and mortification that they had clapped the saddle on the wrong horse, for misled by the name, they had decided in favour of that design, taking for granted that it was by *the* Mr. Blore who has been employed at Buckingham Palace, &c. As soon therefore as they detected their error, and ascertained that *their* Mr. Blore was a different individual, and one comparatively unknown in the profession, they came to the worthy resolution of setting aside the design, which had previously been approved of by them merely through *mistake!* Is not this a most delicious anecdote? Does it not speak volumes as to the sort of discrimination, and the kind of integrity and good faith, displayed by *gentlemen* on such occasions? And mark you, I pray, this extraordinary tergiversation was not manifested in a paltry hole-and-corner competition in some obscure town and village, but in—Oxford!—the seat of learning, and of orthodoxy.

Unless the matter is altogether misrepresented—in which case it becomes the duty of those who are concerned in it, to clear themselves from so highly injurious a charge,— Mr. Blore has sufficient grounds for bringing his action for damages against his quondam judges; and would no doubt obtain them to a very heavy amount, because he has not only suffered pecuniarily, but may be said to have been stigmatised in his professional character, having been formally set aside as incompetent, consequently placed in a very different situation from the other unsuccessful competitors.

Delenda est Carthago: the Humbug and Deception now attending Competition must be blown up,—the present system must be entirely reformed; and as the Institute will not exert itself at all in the cause, so much the more manfully must individuals do so. The pen and the press must bring the subject continually before the profession and the public, until both shall be completely roused: and then, perhaps, when the needed reform shall have been commenced by others, the Institute will valiantly profer their services, and come forward to share in the merit of the victory.

I remain, &c.

J. P. M.

Sir—In the No. for this month of your excellent Journal, there is an article on Architectural Competition signed "K. P. S," in which some "facts" are detailed relative to that subject, especially as relates to a church to be built or now building at Berry.

If "K. P. S." was aware of how these matters are managed with us in Ireland, it might excite his honest indignation still more, as the system generally adopted here is to place all the competition designs submitted into the hands of a favoured architect, from which to choose and model such plans as the committee may direct, who *kindly* indulge the favourite with the necessary time.

It may be supposed that the writer is a disappointed candidate, and that this is merely the ebullition of his chagrin and mortification from defeat. Not so; for having had the benefit of seeing the fate of others on these occasions, he has invariably steered clear of this species of competition.

An instance of the flagrant injustice done in this way took place a short time since, wherein architects were invited by public advertisement to send in plans for an edifice to be erected near Dublin, to be appropriated as a place of worship. After the plans, &c., had been sent in, considerable shuffling took place on the part of the committee. At length, after frequent postponements and delays, it was announced that none of the designs, in their judgment, were suitable to the required building, although they numbered upwards of a dozen designs, some of which were shown to me previously, and possessed (in my opinion) very great merit, and were in strict accordance with the rules laid down in the advertisement. In a short time afterwards the building was begun, after the design and inspection of an architect who had not competed, and as the building is now nearly completed, I can, without fear of contradiction, assert that it is a "fac simile" (as far as I have been able to examine it) of one of the designs I had been shown, and which was sent in to the committee.

The profession of an architect is completely degraded in Ireland; for instance, in the erection of any county public building (the architect, if indeed any be engaged at all) is merely a subordinate to the county surveyor, who, with very few exceptions, know nothing of our profession, and until the clause which relates to this subject in the present Grand Jury Act is remedied, things must remain in this state. At present every public work is placed in their hands, and, generally speaking, when anything architectural (or at least what should be architectural) is to be done, they attempt it themselves, and a pretty finish they make of it, instances of which are but too numerous.

Again, a paragraph is now going the round of our papers, eulogizing a new Saving's Bank erected in Limerick, *"by Sir Thomas Deane, the* EMINENT ARCHITECT, *the progress of the work was superintended by William H. Owen, Esq.*, CIVIL ENGINEER, *whose professional taste and skill are so highly appreciated."*

Not wishing to occupy too much space in your valuable journal, I have merely glanced at some of the strange doings perpetrated here, which, if properly "*shown up*," would undoubtedly throw the grievances complained of by K. P. S. into the shade.

I am, Sir,
Your very obedient servant,
Dublin, Oct. 12, 1840. J. A., Architect.

LAND SURVEYING.

SIR—I should not trespass on your very valuable time, and on the pages of your most deservedly popular Journal, did I not know that you make it your study to give publicity to every thing, however trifling, which may be of use to any member of the profession, whose interests you so very ably advocate on all occasions. Should this obtain your approval, your insertion of it will much oblige the writer.

It has, I dare say, occurred to every one engaged in an extensive survey, that there is a great danger of mistakes taking place in the change of pins in a long chain line; as the number of changes or removes must be kept in memory, and one is very likely to become confused if there are a great many of them. To obviate this inconvenience, I would beg to propose a very simple plan, viz., that the leader should be provided with a small bag, containing a number of common marbles, such as school-boys employ in their games; and that on giving up his pins to the follower, or hind chainman, at every remove, he should give him one of these marbles, to be kept by the follower in another bag provided for the purpose, until they arrive at the end of the line; when each marble will stand for 10, and the pins in the follower's hand, as usual, for single chains.

By this method nothing is left to the memory, and of course a greater degree of certainty is obtained.

I have the honour to remain, Sir,
Your most obedient servant,
Dublin, Oct. 3, 1840. E. WILLIAM MANSELL.

LAND SURVEYING.

SIR—I observe in your last Number an extract from Mr. Bruff's Treatise on Engineering Field Work, wherein he says, in describing the new instrument for measuring the contents of maps, that "the principle of the plan has been long known to some few suveyors, but that they prudently kept it to themselves, &c." Now, Sir, I should very much like to know the names of any surveyors to whom the instrument was known before its introduction into the Tithe Office, and perhaps Mr. Bruff will be good enough to afford this information through the medium of your Journal, as it is certainly important to know to whom surveyors are indebted for the invention of this instrument, which most justly deserves all the praise that can be bestowed upon it.

I beg it to be understood, that in seeking this information from Mr. Bruff, I am actuated by no hostile or cavilling spirit, on the contrary, I think generally the contents of his work are most valuable, and strictly to be depended on; in this instance, however, I think he is misinformed, and believing that Mr. Bruff would not wish to deprive the inventor of his due share of credit, I trust he will have no hesitation in stating publicly, who are the parties to whom he alludes, as having long known the principle of the plan.

I am, Sir, your obedient servant,
AN OLD SURVEYOR.
London, Oct. 15, 1840.

THE NELSON AFFAIR.

MR. EDITOR—I send you some stanzas which you may, if you like, suppose were intended to have been put into the foundation stone of Railton's Column, but somehow or other escaped that honour; allow them therefore to be preserved in one of your columns.

ANTI-STYLITES.

NELSON *loquitur*:—

You see that I stick to my *post*,
Stuck up here on the top of a peg,
And having before but one arm,
I am now left to stand on one leg.

Though not on a leg made of wood,
Oh no!—'tis a leg built of stone;
And so wondrous tall too it is,
That I stand "all aloft and alone,"

Just after that whimsical fashion
Old Simeon adopted of yore;
But then he was a saint most sublime,
And his practice a bit of a bore.

Yes, my case is confoundedly hard,
Tho' some other folks' heads are quite soft,
So I wish they had left me *alone*,
Before they had left me *aloft*.

For Wightwick I see there is sneering,
While others are laughing outright,
And folks seem myself to be queering,
While they gape at my pitiful plight.

O! were but the stick I am stuck on,
A good walking-stick—by my fay,
I would not stand here to be quizzed at,
But with stick and all *walk away*.

PNEUMATIC OR ATMOSPHERIC RAILWAY.

SIR—The fairness that should guide a public Journalist, and a scientific one especially, will doubtless induce you to afford me a place to reply to an invidious article contained in your Journal for July, which does me great injustice—has an injurious tendency, and at the same time confers approbation on Messrs. Clegg and Samuda, who are endeavouring to avail themselves of the result of information communicated to them, whilst they were confidentially employed by me in 1836-7-8, in the construction of works and machinery designed for carrying into practical operation the pneumatic or atmospheric railway, which was intended to be applied on the Birmingham, Bristol, and Thames Junction Railway at Wormwood Scrubs, as the first prospectus of that railway (1835) will show, and on which line my invention is now pirated by Clegg and Samuda.

The article in your Journal appears intended as a disparagement of my invention. I have before publicly accused those persons of the conduct complained of in the Sun newspaper of the 17th and 19th June last. I am preparing to stop their proceedings through the medium of a court of justice, but that is no ground for my sustaining in the mean time injurious remarks, and the public mind abused through the columns of public journals.

I am prepared to prove that the system carried into effect, even in all its minute details, is wholly my invention; as well as the more improved applications of the same principle, as specified in my patents of 1834 and 1836, all of which are legally held by me under the authority of the Patent Laws, which forbid those persons or others from using any portion of that which is described in the article inserted in your Journal.

In regard to the remarks that "the idea of employing the power of the atmosphere against a vacuum created in an extended pipe laid between rails, and communicating the moving power thus obtained to propel carriages travelling on a road, we believe originated with Mr. Medhurst, in 1827, and that in 1812 he published some ideas on this method." And that "about 1835 some experiments were made with a model in Wigmore-street, by Mr. Pinkus, very similar to those described by Mr. Medhurst: these experiments, however, failed from the same cause probably, which prevented Mr. Medhurst from carrying his into effect, viz., the impossibility of making an air tight communication from the inside of the pipe to the carriage, tight enough to allow a useful degree of rarefaction to be produced."

Now, Sir, I have to complain that not even so much as one particular of all the allegations in the above quotations is true, and declare that I can disprove them all by documentary evidence of record, and printed publications of old dates. Myself an humble labourer in the field of science, I trust I shall never be guilty of that meanness of mind that would detract from another the merit justly due to him for any mental production, and I will contend for equal justice to myself.

First, then, the merit, and it is a high one of "employing the power of the atmosphere against a vacuum," and transmitting that power, as well as the suggestion of obtaining a similar power by plenum (the latter though impracticable) is due to the celebrated Papin, who suggested them 120 years ago, and not Mr. Medhurst.

Second. The suggestions and the experiment "employing the power of the atmosphere against a vacuum, and by impelling a piston through a tunnel," is due to Mr. Valance, who did it at Brighton in 1824, and not to Mr. Medhurst, who in 1810 only proposed the *impractical part of Papin's plan of forcing air under the compression of many atmospheres*, as several others before him had done; and added at a subsequent date the idea of moving a piston through *an underground tunnel*, by forcing in *air behind it*, from distances of 20 miles apart, and so impel goods and passengers therein. In 1824 Mr. Valance took out a patent for his method of an *underground tunnel*, and the *more correct and practical principle* of rarefaction and atmospheric pressure.—Mr. Medhurst, who held no patent, made claim to Mr. Valance's invention of transmitting a piston through an underground tunnel.—Mr. Valance in a pamphlet of that date, answered Mr. Medhurst, and pointed out in what his invention differed from the other's claims; thus both Papin and Valance went before Mr. Medhurst.

In 1825, not 1835 as is alleged, I proposed to apply Papin's principle by a new method, combination of apparatus and machinery, whereby I was enabled to transfer the power generated under *partial vacuum to the exterior of extended* mains or pipes laid on the margin of a canal or railway, and transmitting the power so generated along such main. I combined the main with a canal, and proposed to use Brown's Gas Vacuum Engine as the prime mover, my plans and specifications were recorded, my models constructed and exhibited: these contained such a mechanical arrangement for effecting a propelling power under rarefaction, *as alone admits of its application at all;* subsequently they became the subject of the first patent (1834) ever taken out for that object. As I was for the first time informed in 1836, Mr. Medhurst in 1828 reprinted his pamphlet of 1810, for the Underground Tunnel and the application of a *Plenum*, and with it, now for the first time proposed to transfer the power to the outside of the underground tunnel, and to have stationary engines 20 miles apart for forcing in air, he shewed a lithographic drawing of the method, and having 4 years before claimed the plan of Valance, and 3 years before of my method of transferring the power of partial vacuum to the exterior of a main, he proposed a long box and a pipe suspended over a channel of water in order to make a water-joint; these suggestions made at that late date, were nevertheless so crude and undigested, as to be utterly impracticable as they show. His calculation based upon them he can in no way obtain. He never made an experiment, as I am well informed, and his pamphlet was in the hands only of private friends; I saw one, for the first time, in 1836. Having been engaged until 1830, I in that year again prepared fresh plans and specifications, such as are now enrolled, and exhibited them to friends. In 1833 I commenced my patent, sealed in 1834, and in that year constructed a large working model that was publicly exhibited, *and upon its success in* 1835 an association for working my system was formed, which is now extant; contracts were made for works to demonstrate the principle with my subsequent improvements, for which patents also were taken out in various countries. The works were designed to be applied on the Birmingham Bristol and Thames Junction Railway, at Wormwood Scrubs; those works were nearly completed, the line half a mile in length formed on the margin of the Kensington Canal, which was united with that line of railway. Samuda and Hague were the contractors for the engines, the former as well in the construction of the pneumatic mains and valve, and Samuel Clegg was confidentially employed and consulted, and witnessed the progress of the experiments during such employment, learned from me all the minute details that they have now carried into effect, but which are nevertheless held by me under patents. Clegg and Samuda saw my experiments in 1835-6 made upon rough models, but which were attended with perfect success, only some of the details were purposely omitted until further patents were sealed.

Not only, therefore, is the invention in all its details my own, and legally held by my patents, which embrace such mechanical combinations, as without which that well known principle cannot possibly be carried into effect, but I shall, when my interest best requires it, stop their further progress.

I am, Sir, your obedient servant,

H. PINKUS.

11, *Panton Square*, *Aug.* 20, 1840.

MUSEUM OF ECONOMIC GEOLOGY,

CRAIG'S COURT, CHARING CROSS, LONDON.

(Extract from the President's Address of the Geological Society of London.)

Among the most important of the remarkable events of the past year, we recognise with gratitude and confident anticipation of great advantage, both to science and the arts, the establishment by her Majesty's government of an institution hitherto unknown in England, namely, a Museum of Economic Geology. This is to be freely accessible to the public at stated periods, in the department of her Majesty's Woods and Forests, and Public Works, for the express object of exhibiting the practical application of geology to the useful purposes of life. In this Museum, a large store of valuable materials has already been collected and arranged, chiefly by the exertions, and under the direction of Mr. De la Beche. In it will be exhibited examples of metallic ores, ornamental marbles, building stones and limestones, granites, porphyries, slates, clays, marls, brick earths, and minerals of every kind produced in this country, that are of pecuniary value, and applicable to the arts of life. Information upon such subjects, thus readily and gratuitously accessible, will be of the utmost practical importance to the miner and the mechanic, the builder and the architect, the engineer, the whole mining interest, and the landed proprietors. The establishment will contain also examples of the results of metallurgic processes obtained from the furnace and the laboratory, with a collection of models of the most improved machinery, chiefly employed in mining. A well-stored laboratory is attached to this department, conducted by the distinguished analytical chemist, Mr. Richard Phillips, whose duty it already is, at a fixed and moderate charge, to conduct the analysis of metallic ores, and other minerals and soils submitted to him by the owners of mines and proprietors of land, who may wish for authentic information upon such matters.

The pupils in this laboratory are already actively employed in learning the arts of mineral analysis, and the various metallurgic processes.

A second department in the Economic Museum, will be assigned to the promotion of improvements in agriculture, and will contain sections of strata with specimens of soils, sub-soils, and of the rocks from the decomposition of which they have been produced.

To this last-mentioned collection, proprietors of land are solicited to contribute from their estates labelled examples of soils, with their respective sub-soils; and all persons who wish for an analysis of any sterile soil, for the purpose of giving it fertility, by the artificial addition of ingredients with which nature had not supplied it, may here obtain at a moderate cost, an exact knowledge of its composition, which may point out the corrective additions which it requires. This portion of the Museum will more especially exhibit the relations of geology to agriculture, in so far as a knowledge of the materials composing the sub-strata may afford extensive means of permanent improvement to the surface.—*Phil. Mag., October*, 1840.

St. James's Park.—An ornamental building in the Swiss style, consisting of council-room, bridge, and keeper's cottage, is now building in St. James's park for the Ornithological Society of London. The site is nearly opposite the Horse Guards, and the design, approved by the Board of Works, has been prepared by Mr. Watson, under whose direction it will be completed.

AN ACT FOR REGULATING RAILWAYS.

PASSED AUGUST 10, 1840.

No railway to be opened without notice to the Board of Trade.—Whereas it is expedient for the safety of the public to provide for the due supervision of railways: be it therefore enacted by the Queen's most excellent Majesty, by and with the advice and consent of the Lords spiritual and temporal, and Commons, in this present Parliament assembled, and by the authority of the same, that, after two months from the passing of this Act, no railway, or portion of any railway, shall be opened for the public conveyance of passengers or goods until one calendar month after notice in writing of the intention of opening the same shall have been given, by the Company to whom such railway shall belong, to the Lords of the Committee of Her Majesty's Privy Council appointed for trade and foreign plantations.

Penalty for opening railways without notice.—And be it enacted, that if any railway, or portion of any railway, shall be opened without due notice, as aforesaid, the Company to whom such railway shall belong shall forfeit to her Majesty the sum of 20*l.* for every day during which the same shall continue open, until the expiration of one calendar month after the Company shall have given the like notice as is herein-before required before the opening of the railway; and any such penalty may be recovered in any of her Majesty's courts of record.

Returns to be made by railway companies.—And be it enacted, that the lords of the said committee may order and direct every railway company to make up and deliver to them returns, according to a form to be provided by the lords of the said committee, of the aggregate traffic in passengers, according to the several classes, and of the aggregate traffic in cattle and goods respectively, on the said railway, as well as of all accidents which shall have occurred thereon, attended with personal injury, and also a table of all tolls, rates, and charges from time to time levied on each class passengers, and on cattle and goods conveyed on the said railway; and if the returns herein specified shall not be delivered within thirty days after the same shall have been required, every such company shall forfeit to her Majesty the sum of 20*l.* for every day during which the said company shall wilfully neglect to deliver the same; and every such penalty may be recovered in any of her Majesty's courts of record; provided always, that such returns shall be required, in like manner and at the same time, from all the said companies, unless the lords of the said committee shall specially exempt any of the said companies, and shall enter the grounds of such exemption in the minutes of their proceedings.

Penalty for making false returns.—And be it enacted, that every officer of any company who shall wilfully make any false return to the lords of the said committee shall be deemed guilty of a misdemeanor.

Board of trade may appoint persons to inspect railways.—And be it enacted, that it shall be lawful for the lords of the said committee, if and when they shall think fit, to authorize any *proper* person or persons to inspect any railway; and it shall be lawful for every person so authorized, at all reasonable times, upon producing his authority, if required, to enter upon and examine the said railway, and the stations, works, and buildings, and the engines and carriages belonging thereto: *provided always, that no person shall be eligible to the appointment as inspector as aforesaid who shall within one year of his appointment have been a director or have held any office of trust or profit under any railway company.*

Penalty on persons obstructing inspector.—And be it enacted, that every person wilfully obstructing any person, duly authorized as aforesaid, in the execution of his duty, shall, on conviction before a justice of the peace having jurisdiction in the place where the offence shall have been committed, forfeit and pay for every such offence any sum not exceeding 10*l.*; and on default of payment of any penalty so adjudged, immediately or within such time as the said justice of the peace shall appoint, the same justice, or any other justice having jurisdiction in the place where the offender shall be or reside, may commit the offender to prison for any period not exceeding three calendar months, such commitment to be determined on payment of the amount of the penalty; and every such penalty shall be returned to the next ensuing court of quarter sessions in the usual manner.

Copies of existing bye-laws to be laid before the board of trade; otherwise to be void.—And whereas many railway companies are or may hereafter be empowered by Act of Parliament to make bye-laws, orders, rules, or regulations, and to impose penalties for the enforcement thereof, upon persons other than the servants of the said companies, and it is expedient that such powers should be under proper control; be it enacted, that true copies of all such bye-laws, orders, rules, and regulations made under any such powers by every such company before the passing of this Act, certified in such manner as the lords of the said committee shall from time to time direct, shall, within two calendar months after the passing of this Act, be laid before the lords of the said committee; and that every such bye-law, order, rule, or regulation, not so laid before the lords of the said committee within the aforesaid period, shall, from and after that period, cease to have any force or effect, saving in so far as any penalty may have been then already incurred under the same.

No future bye-laws to be valid till two calendar months after they have been laid before the board of trade.—And be it enacted, that no such bye-law, order, rule, or regulation made under any such power, and which shall not be in force at the time of the passing of this act, and no order, rule, or regulation annulling any such existing bye-law, rule, order, or regulation which shall be made after the passing of this Act, shall have any force or effect until two calendar months after a true copy of such bye-law, order, rule, or regulation, certified as aforesaid, shall have been laid before the lords of the said committee, unless the lords of the said committee shall, before such period, signify their approbation thereof.

Board of trade may disallow bye-laws.—And be it enacted, that it shall be lawful for the lords of the said committee, at any time either before or after any bye-law, order, rule, or regulation shall have been laid before them as aforesaid shall have come into operation, to notify to the company who shall have made the same their disallowance thereof, and in case the same shall be in force at the time of such disallowance, the time at which the same shall cease to be in force; and no bye-law, order, rule, or regulation which shall be so disallowed shall have any force or effect whatsoever, or, if it shall be in force at the time of such disallowance, it shall cease to have any force or effect in the time limited in the notice of such disallowance, saving in so far as any penalty may have been then already incurred under the same.

Provisions of Railway Acts requiring confirmation of bye-laws repealed.—And be it enacted, that so much of every clause, provision, and enactment in any Act of Parliament heretofore passed as may require the approval or concurrence of any justice of the peace, court of quarter sessions, or other person or persons, other than members of the said companies, to give validity to any bye-laws, orders, rules, or regulations made by any such company, shall be repealed.

Board of trade may direct prosecutions to enforce provisions of Railway Act. Notice to be given to the company.—And be it enacted, that whenever it shall appear to the lords of the said committee that any of the provisions of the several Acts of Parliament regulating any of the said companies, or the provisions of this Act, have not been complied with on the part of any of the said companies, or any of their officers, and that it would be for the public advantage that the due performance of the same should be enforced, the lords of the said committee shall certify the same to her Majesty's attorney-general for England or Ireland, or to the lord advocate for Scotland, as the case may require; and thereupon the said attorney-general or lord advocate shall, by information, or by action, bill, plaint, suit at law or in equity, or other legal proceeding, as the case may require, proceed to recover such penalties and forfeitures, or otherwise to enforce the due performance of the said provisions, by such means as any person aggrieved by such non-compliance, or otherwise authorized to sue for such penalties, might employ under the provisions of the said acts: provided always, that no such certificate as aforesaid shall be given by the lords of the said committee until twenty-one days after they shall have given notice of their intention to give the same to the company against or in relation to whom they shall intend to give the same.

Prosecutions to be under sanction of board of trade, and within one year after the offence.—And be it enacted, that no legal proceedings shall be commenced under the authority of the lords of the said committee against any railway company for any offence against this act, or any of the several Acts of Parliament relating to railways, except upon such certificates of the lords of the said committee as aforesaid, and within one year after such offence shall have been committed.

Punishment of servants of railway companies guilty of misconduct.—And be it enacted, that it shall be lawful for any officer or agent of any railway company, or for any special constable duly appointed, and all such persons as they may call to their assistance, to seize and detain any engine-driver, guard, porter, or other servant in the employ of such company, who shall be found drunk while employed upon the railway, or commit any offence against any of the bye laws, rules, or regulations of such company, or shall wilfully, maliciously, or negligently do or omit to do any act whereby the life or limb of any person passing along, or being upon the railway belonging to such company, or the works thereof respectively, shall be, or might be injured or endangered, or whereby the passage of any of the engines, carriages, or trains shall be or might be obstructed or impeded, and to convey such engine-driver, guard, porter, or other servant so offending, or any person counselling, aiding, or assisting in such offence, with all convenient despatch, before some justice of the peace for the place within which such offence shall be committed, without any other warrant or authority than this act; and every such person so offending, and every person counselling, aiding, or assisting therein as aforesaid, shall, when convicted before such justice as aforesaid, (who is hereby authorised and required upon complaint to him made, upon oath, without information in writing, to take cognizance thereof, and to act summarily in the premises), in the discretion of justice, be imprisoned, with or without hard labour, for any term not exceeding two calendar months, or, in the like discretion of such justice, shall for every such offence forfeit to her Majesty any sum not exceeding 10*l.*, and in default of payment thereof shall be imprisoned, with or without hard labour as aforesaid, for such period, not exceeding two calendar months, as such justice shall appoint; such commitment to be determined on payment of the amount of the penalty; and every such penalty shall be returned to the next ensuing court of quarter sessions in the usual manner.

Justice of the peace empowered to send any case to be tried by the quarter sessions.—Provided always, and be it enacted, that (if upon the hearing of any such complaint he shall think fit) it shall be lawful for such justice, instead of deciding upon the matter of complaint summarily, to commit the person or persons charged with such offence for trial for the same at the quarter sessions for the county or place wherein such offence shall have been committed, and to order that any such person so committed shall be imprisoned and detained in any of her Majesty's gaols or houses of correction in the said county or place in the mean time, or to take bail for his appearance, with or without sureties, in his discretion; and every such person so offending, and convicted before such court of quarter sessions as aforesaid (which said court is hereby required to take cognizance of and hear and determine such complaint), shall be liable, in the discretion of such court, to be imprisoned, with or without hard labour, for any term not exceeding two years.

Punishment of persons obstructing railway.—And be it enacted, that from and after the passing of this Act every person who shall wilfully do or cause to be done any thing in such manner as to obstruct any engine or carriage using any railway, or to endanger the safety of persons conveyed in or upon the same, or shall aid or assist therein, shall be guilty of a misdemeanor, and being convicted thereof shall be liable, at the discretion of the court before which he shall have been convicted, to be imprisoned, with or without hard labour, for any term not exceeding two years.

For punishment of persons obstructing the officers of railway company, or trespassing upon any railway.—And be it enacted, that if any person shall wilfully obstruct or impede any officer or agent of any railway company in the execution of his duty upon any railway, or upon or in any of the stations or other works or premises connected therewith, or if any person shall wilfully trespass upon any railway, or any of the stations or other works or premises connected therewith, and shall refuse to quit the same upon request to him made by any officer or agent of the said company, every such person so offending, and all others aiding or assisting therein, shall and may be seized and detained by any such officer or agent, or any person whom he may call to his assistance, until such offender or offenders can be conveniently taken before some justice of the peace for the county or place wherein such offence shall be committed, and when convicted before such justice as aforesaid (who is hereby authorized and required, upon complaint to him upon oath, to take cognizance, thereof, and to act summarily in the premises,) shall, in the discretion of such justice, forfeit to her Majesty any sum not exceeding 5*l*, and in default of payment thereof shall or may be imprisoned for any term not exceeding two calendar months, such imprisonment to be determined on payment of the amount of the penalty.

Proceedings not to be quashed for want of form, or removed into the superior courts.—And be it enacted, that no proceedings to be had and taken in pursuance of this Act shall be quashed or vacated for want of form, or be removed by certiorari, or by any other writ or process whatsoever, into any of her Majesty's courts of record at Westminster or elsewhere, any law or statute to the contrary notwithstanding.

Repeal of all provisions in railway Acts that empower two justices to decide disputes respecting the proper places for openings in the ledges or flanches of railways.—And whereas many railway companies are bound, by the provisions of the Acts of Parliament by which they are incorporated or regulated, to make, at the expence of the owner or occupier of lands adjoining the railway, openings in the ledges or flanches thereof (except at certain places on such railway in the said Acts specified), for effecting communications between such railway and any collateral or branch railway to be laid down over such lands, and any disagreement or difference which shall arise as to the proper places for making any such openings in the ledges or flanches is by such Acts directed to be referred to the decision of any two justices of the peace within their respective jurisdictions: and whereas it is expedient that so much of every clause, provision, and enactment in any Act of Parliament heretofore passed, as gives to any justice or justices the power of hearing or deciding upon any such disagreement or difference as to the proper places for any such openings in the ledges or flanches of any railway, should be repealed; be it therefore enacted, that so much of every such clause, provision, and enactment as aforesaid shall be repealed.

Board of Trade to determine such disputes in future.—And be it enacted, that in case any disagreement or difference shall arise between any such owner or occupier, or other persons, and any railway company, as to the proper places for any such openings in the ledges or flanches of any railway (except at such places as aforesaid), for the purpose of such communication, then the same shall be left to the decision of the lords of the said committee, who are hereby empowered to hear and determine the same in such way as they shall think fit, and their determination shall be binding on all parties.

Communications to the board to be left at their office.—Communications by the board how to be authenticated. What shall be deemed good service on railway company.—And be it enacted, that all notices, returns, and other documents required by this Act to be given to or laid before the lords of the said committee shall be delivered to or sent by the post to the office of the lords of the said committee; and all notices, appointments, requisitions, certificates, or other documents in writing, signed by one of the secretaries of the said committee, or by some officer appointed for that purpose by the lords of the said committee, and purporting to be made by the lords of the said committee, shall, for the purposes of this Act, be deemed to have been made by the lords of the said committee; and service of the same upon any one or more of the directors of any railway company, or on the secretary or clerk of the said company, or by leaving the same with the clerk or officer at one of the stations belonging to the said company, shall be deemed good service upon the said company.

Meaning of the words "railway" *and* "company."—And be it enacted, that wherever the word "railway" is used in this Act it shall be construed to extend to all railways constructed under the powers of any Act of Parliament, and intended for the conveyance of passengers in or upon carriages drawn or impelled by the power of steam or by any other mechanical power; and wherever the word "company" is used in this Act it shall be construed to extend to and include the proprietors for the time being of any such railway, whether a body corporate or individuals, and their lessees, executors, administrators, and assigns, unless the subject or context be repugnant to such construction.

Act may be repealed this session.—And be it enacted, that this Act may be amended or repealed by any Act to be passed in the present Session of Parliament.

THE THAMES EMBANKMENT.

Abridgement of the Evidence.

(Concluded from p. 360.)

Mr. *Stephen Leach* stated, that he is clerk of the works on the river Thames, from Staines to Yantlet Creek; 39 years in all he has been in the service of the corporation: nine years assistant to his predecessor, and 30 years since. Very considerable improvements have taken place under his direction in the navigation of the Thames between Putney and Staines; when he came into the office, the navigation there was in a very bad state; it was no unusual thing for 50 or 60 barges to be aground in one place, and some of them he has known to be a fortnight working through the city jurisdiction. At present they get up with tolerable certainty, from the Pool to Staines, in 16 or 18 hours, and down from that place in less time; those improvements have been made under his direction. The improvements consist of the building of six pound-locks and five weirs, in different places, where the impediments were the greatest; the removal of a number of shoals, and the raising of towing-paths with the ballast so removed. He has considered the plan now before the Committee for embanking the river Thames from Vauxhall Bridge to London Bridge, on the north side; he considers it certainly as calculated to effect an indispensable improvement, by a very obvious and usual mode of improving river navigation, namely, by contraction; it is much too wide in several places to preserve a uniform depth, and a convenient one for navigation. The object of this embankment would be to equalize the section of the river, to regulate the velocity, and thereby to displace and enclose the large quantities of mud which are at present on the shores, and which receive the noxious contents of the sewers. The embankment begins at Vauxhall Bridge, where there is a short length, not very important. With regard to the navigation that joins from Vauxhall Bridge to Millbank, opposite the Penitentiary, there the embankment is complete, which is carried out to the full extent; there is no intention in that part of carrying it further out; he considers it as a specimen of what the embankment would be if it were continued in a similar way. The line is taken to the Horseferry-road, Horseferry-stairs, in front of the Marquess of Westminster's property; that would be a very beneficial improvement in his opinion. No part of that is embanked at present; the proposition is, to come flush with a very old wharf, which has been there for many years, now in the possession of Mr. Johnson, a stone wharf, in a line with the embankment at the Parliament Houses, which completes it to Westminster Bridge; below Westminster Bridge the embankment is proposed to be continued to Scotland-yard; and there, on account of the particular nature of the business, and the number of coal barges, it is proposed to discontinue the embankment, and adopt a low embankment of some two or three feet above low water, so as to form a dock for the more convenient carrying and entering those barges; that is Mr. Walker's plan, and it is one in which he (Mr. Leach) quite concurs, according to the present occupation. From Scotland-yard, in front of the Hungerford Market estate, the York-buildings' estate, the Savoy, and so on, he thinks there is a length of about 1,400 feet, and an average width of about 300 feet; the mud on part of this ground is already so grown up as to have a pretty large vegetation upon it in front of York-buildings, already embanked with an accumulation of mud. From Waterloo Bridge the embankment is proposed to be continued in front of Somerset House and King's College, about 600 feet in length, and an average width of 130 feet; and at no place, in his opinion, is an embankment so much needed as in front of Somerset House, where there is a very lofty heavy pile of building immediately on the brink of the river, and he thinks it wants something to defend it in front of it, which would be a protection to the building; there is a depth of water in front of it, at the upper end of it particularly; the set of the current is immediately in that direction: that violent current has so deepened the water at Waterloo Bridge, that the late Sir Edward Banks recommended a deposit of about 3,000 tons of stone to protect the Bridge. From King's College the embankment proceeds about 460 feet in length, with an average width of about 190 feet to Water-street, from whence, the occupation of the wharfs being principally by coal merchants, the open-dock system of low wharfing is proposed; there must be an open dock there to accommodate the coal trade; then the embankment would be continued to the end of Temple Gardens; it is then intended to adopt the open-dock system and the low wharfing below the Temple, from Whitefriars-dock to Blackfriars Bridge. There is nothing particular between Blackfriars and Southwark Bridges, only to correct the present irregularities, and make a fair and straight line. It goes on to London Bridge; at the bridge it wants no contraction whatever, it is already quite small enough.

Mr. *James White Higgins* was examined; he is a surveyor of long standing; has been engaged both in the service of the Commissioners of Woods and Forests, and of the City of London, on very many occasions. The quantity of land to be embanked is 595,400 feet, that is, reclaimed by solid embankment; that I have from Mr. Walker's estimate, and that is independent of the Crown property. The amount of Crown property is 436,150 feet. With reference to value, it is an exceedingly difficult question to deal with, and one that does not often occur: and as practice and experience are the best test of value, he has felt a good deal of difficulty in dealing with it. He has made it a matter of inquiry, and having had a great deal to do with wharf property, perhaps more than most professional persons he has endeavoured to bring the experience he possesses and the information he could gain to bear upon the subject; the conviction of his mind is, that 2*d*. a superficial foot, which was talked of, the property could not bear; he thinks it would be excessive; but he thinks 1*d*. a foot superficial might be borne, which would yield nearly 2,500*l*. per annum upon the solid embankment; he thinks so, as he has already stated, from the experience he has, from the advantages it is calculated to afford. It involves the improvement of the navigation of the river, which the persons using the wharfs would be benefited by; it gives them an increased quantity of freehold property; and with regard to that freehold property, if, as was done in a former case, he believes, and that to some considerable extent, at the time of building Blackfriars Bridge, the freehold property was made also free from rates and taxes, it would afford another advantage. That property so reclaimed at Blackfriars Bridge was charged at 1*d*. a foot, he finds; as far as he has been able to learn, it was found to work well; and one advantage that would be afforded here is, that in some cases persons with bad wharf walls would get good ones. In other cases, the general property would be secured by this embankment, and a great public highway, the Thames, would be benefited, and persons using it. Persons possessing themselves of freehold land, he thinks, would have no just ground of complaint in paying 1*d*. a foot for the property reclaimed; but there would be this difficulty about it, and one which the honourable Committee will feel perhaps to be considerable, a penny a foot on some portion of the property would be much too little, and on others it would be too much: in some cases persons would get the more valuable part of the property in Thames-street; he knows that they would be very glad to pay 2*d*. a foot: but in other cases he knows persons would not be willing to pay a penny per foot. The honourable member for Lambeth has alluded to cases in which the advantages now possessed by individuals would be lessened. Those points all want consideration. Every individual case, to do what he is quite sure the Committee are desirous to do, viz. to do justice, would require a matter of consideration; that is an affair which he has not entered upon except in this way, he has judged from his own experience. He has valued a good deal of wharf property; he has lately had to buy a good deal for the Crown at the enormous price that was invariably asked; we were then told that a few feet were worth nobody knows what money. He has also had to value with reference to a good deal of the parish assessments along the river, Hungerford Market and other parts; now he is quite satisfied that in some cases it would be an extraordinary boon at a penny per foot; but in others 1*d*. per foot could not be borne. How the separate cases are to be met he must leave to the Committee; but, in going from wharf to wharf, (he does not mean the Committee to understand that he has been on every wharf, he has been on many), he has put down what each wharf would bear, and that comes nearly to 1*d*. per foot, so that he feels warranted in saying that 2,500*l*. a year might be charged for the whole line of embankment, from one extremity to the other, where a solid embankment exists; but it is a matter of considerable difficulty. He has endeavoured to do it as honestly and impartially as he could, and bring all the experience which he has to the subject. Then as regards the dwarf piling, that is 725,700 feet; the superficial quantity enclosed by the dwarf piling, a halfpenny per foot has been talked of for that; he has more difficulty in this than in the other case, in saying what is right. There are advantages with reference to the navigation and security of buildings, and the possession of freehold instead of what, so far as he has heard of the evidence, appears to be a doubtful property, the city claiming a right over it, which would be abandoned, he takes it, in this case. But he has not, as in the case of Blackfriars Bridge, any test here, and after thinking of it a good deal, he has taken an annual sum for it of 1,133*l*., that is, between a halfpenny and a farthing, the intermediate sum, as an annual sum; a halfpenny per foot was mentioned; he thought it too much, for it gave larger rent in some places than it appeared to me they could bear, though they have advantages in this case; by becoming their own freehold they would have a right to embank at any future period; but it is a matter of so much difficulty, that to give his evidence as he could upon some subjects, to say that he knows from experience that the property would produce such results, he could not pretend to do. It is open to much doubt. His impression is, that in both cases he has been moderate; he intended to be so. It would be worth to sell, twenty-five years' purchase. He would not be warranted in putting it at 25 years' purchase unless it was connected with the other portions of the property. Freehold land connected with buildings is generally at 20 years' purchase only. A ground-rent, amply secured, has sold for 30 or 31 years' purchase. This is an intermediate case of 25 years' purchase. He thinks 30 years would be too much, as there is some speculation in it, or else it is a ground-rent, and therefore he thought 25 was safer.

The following is the Report of Mr. Walker made in 1821, referred to in his evidence given in the last month's Journal.

"From the recent, and, we believe, accurate surveys that have been made, it appears that the difference of level in the water above and below bridge, towards the latter end of the ebb of a spring tide, is from 4 feet 4 inches to 5 feet 7 inches; the water is therefore at present dammed up to that extent at the bridge; we find, by calculation, that this pen will be reduced from, say 5 feet, to about 3 inches, by the proposed alterations; and the water above bridge, at low water, will therefore be 4 feet 9 inches lower than at present. But as the velocity of the stream above bridge will be increased by a greater quantity of water having to run through in the same time, both on account of the water flowing higher at high water, and ebbing lower at low water, the inclination of the surface will also be increased; and this lowering of 4 feet 9 inches, above referred to, will decrease as the distance from the bridge increases. Now, by the survey above referred to, the present rise in the surface of the water from London Bridge to Westminster Bridge, at low water, is 12 inches, being 6 inches, per mile; and supposing the velocity, after the alterations, to be increased so as to produce twice the inclination, or 12 inches per mile, the surface of the water at Westminster Bridge will be lowered, at low water, 4 feet 9 inches, less one foot (the increase of fall), or 3 feet 9 inches below its present level at spring tides. Again, from the best information we can collect, the rise of surface from Westminster to Fulham is about 8 inches per mile; and as the effect of the alterations of London Bridge will be less sensibly felt here than nearer the bridge, we assume that the inclination, after the alterations, will be 12 inches per mile, and the distance being nearly 6 miles, the water at Fulham will be lowered at low water 3 feet 9 inches less 2 feet, or 1 foot 9 inches, which will increase as we descend towards Westminster Bridge, when (as before stated) the depression will be 3 feet 9 inches. Again, as at Fulham, the surface will be lowered 1 foot 9 inches, this depression will decrease upwards: but as in any given length upwards, the effect of the proposed alterations will also decrease, this depth (1 foot 9 inches) will be felt a considerable way up the river; for we think it probable that the effect of the alterations may be sensible, in point of the navigation, for 6 miles above Fulham Bridge, or at Kew Bridge; and that though it will really extend higher, we apprehend that its effects will not be of any consequence above that point. We believe there is no speculation in any of the above numbers, excepting in the assumed increase of declination of surface; for the correctness of which we cannot vouch, but we have been guided by the consideration that 4 feet 9 inches at low water, and about 9 inches at high water, making together 5 feet 6 inches, will be added to the depth of water which will pass through the bridge at every spring tide; and by allowing an increase of fall in proportion to the square of the increase of velocity or quantity, and also by referring to the inclination in the upper part of the river, say between Mortlake and Teddington, as shown upon Mr. Whitworth's survey, and making such allowance as from the difference of situation appeared to us reasonable, we apprehend that we are not far from being correct, particularly between Fulham and London Bridge; and it is hardly necessary, after the above, to say that we agree in opinion with Mr. Smeaton, that, by this reduction of fall at the bridge, 'the navigation of that part of the river will be materially affected.' It appears to us, from our own knowledge, and from the statements that have been given to us, that although the increased velocity of the river would have a tendency to restore the river to its ancient depth, and in course of time would probably effect that object, yet that so great a lowering at once would be productive of great temporary inconvenience, unless artificial means were resorted to, to deepen the shoals, which, even in the present state of the river, are attended with considerable hindrance to the navigation. Mr. Smeaton's opinion on this subject goes beyond our ideas of time; but, as great respect is due to his opinion, we extract it in his own words: 'If this difference of bed,' that is, the difference above and below bridge, 'is original, we must expect it to remain after the bridge is taken away; but if an effect, the cause being removed, the river would gradually restore itself; but as this might probably take up 700 or 800 years (the time it has probably been gathering), the work of restitution would go on far too slowly to answer the demands of the present generation.' Our opinion is, that the difference of level in the bottom of the river, above and below bridge, is caused, in a great measure, by the pen of the bridge; and although we think that the work of restitution would be complete in less time than stated by Mr. Smeaton, unless where the accumulation has got cemented into a solid mass, which we have no doubt is in many places the case, yet, both for the purposes of present trade, and to prevent the shoals from being moved down the river by the current, and forming obstructions lower down the river or below bridge, we think that ballasting to a great extent will be expedient and requisite; as, in addition to the above reason, the stuff that is excavated from the upper part may be applied to raise the towing-paths and banks, so as to meet the increased height of the high water, which will occasionally be from 1 to 2 feet above the present level. One principal shoal is close above London Bridge, on the Surrey side; it extends almost half-way across the river, and is even now occasionally above low water. This must therefore be deepened to a considerable extent; and to prevent the opening of any of the proposed widened arches, which will be opposite to it, from washing any part of it into the Pool, and settling upon the shoals below bridge, it, as well as the other shoals, ought to be ballasted away before the proposed arches are opened. In regard to the navigation through London Bridge, we are of opinion that it will be very essentially improved by the proposed alterations, and that the cause of the losses, accidents, and dangers to which the passage is at present subject, from the great fall or shoot in the arches, will be almost entirely removed. We have mentioned, that the velocity of the current above bridge will be increased. This will take place during both the flood and ebb tide, but will be greatest in the latter; and the increase of velocity will, as before stated, be greatest between Westminster and London Bridges. In our calculation of the fall, we have supposed that the increase of velocity will amount to one-half of the present velocity. This will, in many cases, be important, not only as regards the velocity itself, (as to which it will sometimes be found of advantage to craft and sometimes probably otherwise), but as the water will ebb sooner from all the wharfs, the time in each tide during which the barges are afloat at the wharfs and when they can float to and from them, will be decreased. This will, so far, be a disadvantage, but will occur only during the ebb of tide. It is evident, however, that it will not be compensated by the increased velocity of the flood-tide bringing the barges sooner to the wharfs above bridge, as the velocity of the flood will not be so much increased as that of the ebb-tide, and although barges may come up opposite to the wharfs sooner in the tide than they do at present if the channel is deep enough, they will not be able to get close to the wharfs until about the same time of tide they do at present, unless a general artificial deepening takes place opposite to each wharf. In some cases, however, barges which may get opposite to the wharfs early in the tide, will be enabled by having done so to draw in to the wharfs so soon as there is depth enough of water to float them in, and, so far as this goes, the effect of this proposed alteration will be useful. The great cause of shoals is the unequal velocity of currents, and this inequality increases as the velocity increases; for therefore it is that floods, or great velocities, are always found to add to the shoals of navigable rivers, and to deepen what was too deep before. The increased current through the narrow parts disturbs and carries down the materials of the bottom through those narrow parts or deeps, and they are lodged upon the shoals below, where the decreased velocity, caused by the widening of the river, has not force enough to carry them along with it. There can be no more striking illustration of this general theory, than the effect of floods upon the river near London Bridge, which is invariably to deepen between the arches, and at the same time to raise the shoals below the bridge: therefore, although the natural effect of the increase of current is upon the whole to deepen its channel, it does it so partially that it has also the effect, in rivers of unequal current, such as the Thames is, of forming and increasing shoals, and unless guarded against by proper means may therefore be injurious to the navigation. Now the effect of opening London Bridge will be, that the ebb-tide and land-floods, not being checked by the pen of London Bridge, will increase in velocity to the extent *up the river* that the effects of this pen are felt, and produce the consequences we have mentioned, so that an increase of expense in deepening the shoals after floods, and a greater inequality of level in the bottom, will be the consequence, and this will be a lasting expense unless means are taken to prevent it. The means we should recommend are, the nearer approximation to an *uniform velocity*, which would best be accomplished by producing an *equality of area*, such as contracting the *width* of the river abreast of the shoals, *by means of embankments or otherwise*: as this cannot, however, be done in many places to the required extent without enormous expense, ballasting must be had recourse to until a new regimen corresponding to the existing circumstances is obtained. Finally, although we think it might have been desirable that the great change, which the proposed opening of the arches in London Bridge will certainly produce in the navigation, had been made, so that their effects might have been felt, and things conformed to the new state by degrees, yet when called upon to give an opinion without these experiments, we feel little hesitation in saying that if effectual means are taken for preventing the evils to which we have referred, then the proposed alterations will be beneficial to the navigation above bridge, but that without those effectual means they will be injurious."

Now, the fact is, that the alterations have been made to the full extent stated in this report, and the consequences have been to the full extent of what is stated, but as yet no means have been taken to remove the evil which was anticipated, and is now felt.

A Statement showing the Sectional Areas of the River Thames, taken in the Years 1823 and 1831.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

INSTITUTION OF CIVIL ENGINEERS.

April 14.—The President in the Chair.

"*Description of a Dynamometer, or an Instrument for measuring the Friction on Roads, Railways, Canals, &c.*" By Henry Carr, Grad. Inst. C. E.

The object of Mr. Carr's modification of the dynamometer is to obviate the irregularity of the common indicator arm, caused by the jerking motion of the tractive power or any inequality of resistance. The instrument consists of a cylinder half filled with mercury, and containing a piston connected with the spring of the dynamometer, so as to be lowered or raised as the tractive power is increased or diminished. Two tubes of glass, connected by a passage with a regulating valve, stand in front of the cylinder, one of them communicating freely with it, and in this tube the mercury is raised or lowered proportionally to the power applied; while in the other, an average of the variations is obtained as the facility of communication between the tubes is increased or diminished by the opening or closing of the stop-valve. The instrument must be graduated by actual experiment, and the results of the average power may be read off from the scales placed behind the tubes. The paper is illustrated by a detailed drawing of the machine.

"*An account of a proposed Suspension Bridge over the Haslar Lake at Portsmouth.*" By Andrew Burn, Jun., Grad. Inst. C. E.

The usual calculation for the maximum load on each superficial foot of the platforms of suspension bridges is 70 lb.; but, as in the event of a crowd of persons assembling the pressure may increase to nearly 100 lb. per foot, and by the passage of soldiers marching in regular time the strain may be greatly augmented, the projector assumed 200 lb. per superficial foot as the amount of load to which the platform might be subjected. The peculiar feature of this bridge is the substitution of cast-iron chains for the wrought-iron ones generally used. This deviation from the usual practice is adopted as a measure of economy, and with a view of increasing their stability and durability, cast-iron being much less influenced by atmospheric action than wrought-iron. Cast-iron beams, when well proportioned, will bear a very considerable tensile strain. As these chains would be proved beyond the weight they are intended to bear, no doubt is entertained by the author of their security. The platform, which is formed of transverse iron girders carrying cast-iron plates $\frac{3}{4}$ of an inch thick, with dovetails falling into holes cast in the girders, is suspended by wrought-iron rods $1\frac{1}{2}$ inch square from two lines of chain only, as the strain is more easily brought to bear on them than on a greater number of chains. They are trussed laterally to prevent oscillation, and the balustrade is so constructed as to prevent the undulation so prejudicial to suspension bridges generally. To insure a perfect bearing, each pair of links of the chains are in manufacturing cramped together, and the holes bored out to receive the pins which are turned to fit them accurately; they are of a larger size than usual, being 4 inches diameter, and a less number are employed. The piers on which the chains pass are of cast-iron, 33 feet high above the level of the roadway.

	Feet.
The extreme length of the bridge is	632
The breadth of the roadway	$17\frac{1}{2}$
The clear waterway between the piers	300
The clear headway of the platform above the high water line	$18\frac{1}{2}$
Ditto ditto above low water line . .	33

The tension on the chains is calculated as equal to 991·4143 tons. To sustain this tension, the section of the chains is 256 square inches, and taking 7 tons per square inch as the elastic limit of cast-iron, the resistance of the chains will equal 1792 tons, leaving a surplus of 800·6 tons after the calculated strain has been deducted from the real strength of the chains. Three elaborate detailed drawings accompany this paper.

Mr. Smith, of Deenston, *explained a new system of Lockage for Canals proposed by him, a model of which he presented to the Institution.*

To avoid the present expensive construction of locks and their waste of water, the author proposes to divide the canal into a series of basins, the water levels of which should be from 12 to 18 inches above each other. The extremity of each basin is so contracted as to permit only the free passage of a boat; in this is placed a single gate, hinged to a sill across the bottom, the head pointing at a given angle against the stream, and the lateral faces pressing against rabbets in the masonry. The gate is to be constructed of buoyant materials, or made hollow so as to float and be held up by the pressure of the water in the higher level; on the top is a roller to facilitate the passage of the boats. When a boat is required to pass from a higher to a lower level, the bow end, which must be armed with an inclined projection, depresses the gate as much as the depth of the immersion of the boat, and as much water escapes as can pass between its sides and the walls of the contracted part of the basin. The same action takes place in ascending, except that a certain amount of power must be expended to enable the boat to surmount the difference of level between the basins. The quantity of water wasted by each boat would be in proportion to its immersion and the speed at which it passed over the gate. In case of different sized boats passing along the same canal, it is proposed to have a small gate forming part of the main gate, so as to avoid the loss of water which would ensue from the whole width being open for the passage of a small boat.

This system has only been tried by models; but it is proposed to make an essay on an extensive canal next summer, when the results will be communicated to the Institution.

May 5.—The President in the Chair.

The following were balloted for and elected :– Angier March Perkins, St. George Burke, and Beriah Botfield, as Associates.

"*Description of the Engines on board the Iron Steam Tug, the Alice.*" By J. Patrick, Inst. C. E.

The speed of this boat having far exceeded the constructor's expectations, induced the author to send a description of her proportions, and of the construction of the engines. The chief peculiarity in the engines is their being placed in the centre of the vessel, with the two cylinders in a line with the keel, and placed at an angle of 45°, inclining inwards towards the paddle shaft, to which the motion is communicated direct (without the use of side beams) by long connecting rods attached to the cross heads, which are placed at the lower ends of the cylinders, instead of being on the top as in the usual manner; the connecting rods are thus enabled to be three times instead of twice the length of the stroke, as is usually the case. The framing is entirely of wrought-iron on the tension principle, and appears to resist the tendency to vibration better than cast-iron framing. For the two cylinders of 31 inches diameter, there is only one air pump of 22½ inches diameter, with 19½ inches length of stroke, instead of the usual complement of two air pumps, 18 inches diameter each; this is found to be sufficient, as a vacuum of 13¾ lb. per square inch is maintained. One of the advantages proposed by this mode of construction is the reduction of weight; these engines only weighing 9 cwt. per horse power. The small space occupied leaving more room for passengers, they are particularly adapted for river navigation, where the breadth of beam must be limited. The simplicity of their construction renders them less liable to expensive repairs.

The principal proportions of the Alice are—

	Feet.	Inches.
Length between perpendiculars	95	
Breadth of beam	20	
Draft of water	4	6
Diameter of wheel	14	
Size of engines	two 30 horse power	
Diameter of cylinder	0	31 inches
Length of stroke	3	3

The engines were constructed by Messrs. Davenport and Grindrod, of Liverpool. Drawings of the boat and engines accompany this communication.

"*Description of an Apparatus for preventing the Explosion of Steam Boilers.*" By Robert M'Ewen.

The frequent explosions of steam boilers, caused in many instances by the steam being confined until it acquires a density greater than the boiler can resist, induced the author to invent a simple, self-acting apparatus, intended to warn the engineer whenever the pressure exceeded the proper degree of safety.

The apparatus under consideration is constructed on the principle that steam, in proportion to its density, will support a column of water or mercury, of a given height, and that any fluid will find the same level in two or more vessels, provided there be a free communication between them. It may be called a mercurial safety valve, and consists of a cylinder, within which are two cups, with two pipes dipping into them of a length proportioned to the pressure of the steam; these pipes are connected at the top with two valves on one spindle, so arranged, as that when one is open the other must be closed. On the top is a waste steam pipe open to the atmosphere. One pipe being filled with mercury, and the valve connected with it being open, the mercury remains stationary until the pressure of the steam exceeds its proper point. It will then be blown out and fall into the empty cup, allowing the steam to escape by the waste pipe, and giving warning to the engineer by its noise. When the pressure is again reduced to its proper point the valve is reversed, and the mercury will, on the next occasion of an increase of pressure, be blown back again, still giving warning on either side.

Plans and sections of this apparatus accompanied the paper.

"*On setting out Railway Curves.*" By Charles Bourns, Assoc. Inst. C. E.

Mr. Bourns having been engaged in setting out the Taff Vale Railway through a country presenting circumstances of more than ordinary difficulty, which rendered it necessary to vary the radii and the flexure of the curves frequently, his attention was particularly directed to the subject; and he has treated it in this paper clearly and successfully, demonstrating the several cases geometrically, and generally in a plain and satisfactory manner. He calls attention to the inaccuracy of applying a square to the setting out of segmental curves, particularly those of short radii, and recommends an offset staff as theoretically correct and practically much more convenient. The general rule to find the offset is—"Divide the number of inches in the chain used by the number of such chains in the radius of the required curve, the quotient is the offset in inches." The paper is accompanied by a table of offsets for curves of different radii; which the author found extremely convenient for use in the field.

The paper being altogether mathematical is not adapted for publication in abstract; but it will be given at length, with examples and diagrams, in the Transactions of the Institution.

"*Description of an Instrument for describing the Profile of Roads.*" By Henry Carr, Grad. Inst. C. E.

The object of the author was the construction of a machine, which, being drawn along any road of moderately even surface, should describe the section of the line over which it passed. It is evident, that if a pendulum be suspended from a frame standing perpendicularly when the machine rests on a horizontal plane, on passing over a plane inclined at any angle with the horizon, the pendulum must form the same angle with the frame the tangent of which angle in terms of the radius will be the rise or fall of the plane. The duration of the tangent will be determined by the paper on which the section is drawn being made to traverse at a speed proportionate to the distance passed over; and the extent, by the difference of the speeds of a nut and screw which are made to revolve in the same direction—the nut turning at a constant velocity, and the screw at a speed differing from that of the nut in proportion to the tangent, slower or faster as the tangent is *plus* or *minus*, raising or lowering the nut according to the deviation of the plane from the horizontal line.

The machinery is set in motion by the wheels of the carriage, and a series of wheels and pinions of given diameters cause the ground line and datum line to be drawn simultaneously by two pencils on a paper which gradually unfolds itself from one drum, and is transfered to another at the rate of 16 inches per mile passed over, or on a scale of 5 chains to the inch. A profile of a line of country may thus be obtained with sufficient accuracy for a preliminary survey.

A comprehensive perspective drawing accompanies the paper, and explains the construction of the machine.

May 12.—The President in the Chair.

"*Photography, as applicable to Engineering.*" By Alexander Gordon, M. Inst. C. E.

The object of the author in this paper is to direct general attention to the advantages which may be expected to result to the profession of the Civil Engineer from the discoveries of Mons. Daguerre and others, in enabling copies of drawings, or views of buildings, works, or even of machinery when not in motion, to be taken with perfect accuracy in a very short space of time and with comparatively small expense. This system of copying not only the outline, but the tints of light and shade, united with accurate linear perspective, he contends may be easily adapted to the purpose of the engineer, as well as to all those professions in which the art of drawing is used. The photographic apparatus has already been employed to bring before us exact copies of the most interesting monuments of antiquity, the French antiquarians and artists having found it more easy and correct to Daguerreotype the Egyptian monuments and decipher the hieroglyphics at their leisure, than to labour over the originals.

The subject is divided into two branches: the first being the art of copying drawings and plans by the transmission and absorption of light by prepared paper. The drawing to be copied is placed between two pieces of plate glass, held down in close contact with a sheet of photogenic paper, prepared by being washed over on both sides with a neutral solution of nitrate of silver of a specfic gravity of 1·066, and afterwards with a solution of common salt and water (1 lb. of salt to 25 pints of water). The paper thus prepared must be dried and kept in the dark, on account of its peculiar delicacy. The rays of the sun are then permitted to pass through the white portions of the drawing or print, while they are interrupted by the black lines, and more or less by the tinted portions. The rays of light thus act upon the prepared paper, and produce, in a few minutes, a reversed copy, reproducing the lights of the original in shadows; this can be remedied by taking a second copy from the first, and thus the shadows are restored to their original positions. To destroy the sensitiveness of the prepared paper, and preserve the copy, it is soaked in pure water, which carries off the excess of nitrate of silver, then covered with a solution of hypo-sulphite of soda of a specific gravity of 1,055, and again washed in pure water, so that when dried it is permanently fixed. It is evident that a copy thus obtained must be exactly like the original, and the value of such a process may be readily estimated by engineers.

The second branch, which is named "Daguerreotype," after the distinguished artist who brought it to its present state of perfection, is of a much higher order. This is the art of fixing and preserving on the surface of a polished silvered plate the images collected in the focal plane of a camera obscura.

The process is rather complicated, but may be thus briefly described. The surface of the silvered plate being cleaned and polished very perfectly by means of finely levigated pumice stone, olive oil, and cotton, is rubbed lightly over with diluted nitric acid, in the proportion of 1 pint of acid to

16 parts of distilled water; it is then subjected to the heat of charcoal or a spirit lamp until a firm white coating is formed all over the surface of the silver. The plate is then suddenly cooled. This process is repeated three times. It is placed in a dark chamber with the face or silver surface downwards, where it is acted upon by the spontaneous evaporation of iodine; this condenses upon the silver, and produces a fine gold-coloured surface, extremely sensitive to the impressions of light. It is then placed in a camera obscura, the light having been until then perfectly excluded from it. It there receives the impression of any images brought within the focal plane; and by subsequently exposing it in a dark, close chamber, with its silver surface downwards, to the fumes of heated mercury, the images are rendered visible; to fix the images so received, the iodine is removed by dipping the plate in pure water, and then washing it either with a weak solution of hypo-sulphite of soda or a saturated solution of common salt, and finally dipping it in distilled water and drying it. It should then be framed and glazed to preserve it from external injury, and the picture will remain unchanged.

Attempts have been made to use this process for preparing the plates for engravers, as much time and cost would thereby be saved, but hitherto it has not been done to any extent.

The author presses upon the Institution the applicability of these processes to engineering uses, and quotes the remark of Mons. Arago—"That photographic delineations having been subjected during their formation to the rules of geometry, we may be enabled, by the aid of a few simple data, to ascertain the exact dimensions of the most elevated parts of the most inaccessible edifices."

Mr. Cooper, Senior, introduced the subject of photography by explaining, and illustrating by instruments and diagrams, the principles of the division and dispersion of the rays of light, according to the Newtonian theory, as well as the most recent researches into the subject. He described the chemical properties of light—its affinity for certain combinations, such as chloride of silver—its heating powers—the different effects of the rays on vegetation—and the application of these known principles to photography. He then explained the chemical properties of the chloride of silver, iodine, and other substances used in the process. In alluding to the probable uses of the Daguerreotype, he observed that the process might be employed to make drawings of machinery, as graduated scales might be fixed to certain parts of the objects, and they would be copied in their relative proportions to the machine.

Mr. Cooper, Junior, illustrated Mr. Gordon's communication by explaining the photographic apparatus, and the process of obtaining a specimen of Daguerreotype by means of the oxy-hydrogen light. He described, among other points, the difficulty of obtaining pure silver upon the copper plates, as, for the advantage in rolling, the manufacturer will introduce an alloy of ½ to 1½ per cent. On this account, acid is used so repeatedly in cleaning the plates, that any particles of copper which have been rolled into the surface may be carried off. He explained his improvement to the iodine box, which consists in spreading the iodine all over the bottom of a tray lined with glass, and covering it with a piece of card-board, which becomes saturated with the fumes of the iodine, and on the silvered plate being placed over it, acts equally over its surface, instead of partially, as in the old system of placing the iodine in a mass in the centre of the tray. He had found this to be a great improvement. The shortest time in which he had obtained a photographic picture in England was 11 minutes; while, during a gloomy day in November, it took an hour and a half to procure a moderately good one.

"*An Universal Screw-Jack.*" By George England.

This machine, a model of which was presented to the Institution, is intended for raising heavy weights and moving them in any required direction; the vertical motion is similar to that of a common screw-lifting jack, and the lateral motion is communicated by a ratchet lever to a horizontal screw, working in bearings on a strong cast-iron bed with planed surfaces through a double nut attached to the base of the jack. The jack has been found useful for erecting heavy pieces of machinery, and for replacing railway carriages and locomotives on the rails when they have been accidentally thrown off.

"*Description of a Traversing Screw-Jack.*" By W. J. Curtis.

The screw-jack is attached to a plank with a rack in it, and slides in a groove in another plank which is placed beneath it, across the railway; in the lower plank is a rack, by means of which and a hooked lever, the jack, with the engine or any other weight resting upon it, is drawn easily across the rails and lowered to its proper position. By this apparatus, engines and carriages of considerable weight have been replaced on a railway by two men in a very short space of time.

A model of the machine was presented to the Institution.

May 19.—The President in the Chair.

Peter Bruff was balloted for and elected an Associate.

"*Description of a new Gas Regulator.*" By James Milne.

The object of this instrument (which the inventor exhibited in action, and presented to the Institution) is to regulate the supply of gas to burners, so that any variation in the pressure, arising from extinguishing the adjacent lights along the line of the street main, or in the different floors of manufactories, shall not affect those lights which are supplied through the regulator.

The regulator consists of a cylindrical outer case, to which is affixed a water gauge to show the pressure; to the top is attached an inner cylinder, open at the lower end and reaching nearly to the bottom of the outer case; the gas is introduced from beneath by a tube in the centre, terminating in a conical valve at the top; the male part of the valve is fixed by three arms to the top of a float, which moves freely in the space between the inner cylinder and the centre tube; the areas between the outer case and the inner cylinder, and between the inner cylinder and the centre tube, being alike, the pressure of the gas acts upon the water within the inner cylinder, and causes it to rise in the outer case just as much as it is depressed in the inner space. This depression carries down the float with the male part of the valve attached to it, and thus diminishes the aperture of the supply pipe, until the pressure is relieved by other burners being lighted, and enables the supply of gas to be in proportion to the demand. The pressure may be regulated at will by increasing or diminishing the quantity of water in the cylinders, and it is shown correctly by the graduated glass gauge. This apparatus has been found, in an experience of two years, to effect a saving of about 20 per cent., independent of its ensuring a perfect equality to all the burners in action. Drawings of the instrument accompanied this communication.

Mr Lowe believed the "gas regulator" to be an efficient instrument. It was of the utmost importance that the light from gas should be steady and equal, as the nerves of the eye were more injured by an unsteady than by an intense light. In large establishments, the greatest care would scarcely prevent constant variation in the lights, so that an efficient means of producing regularity must be valuable.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Tenth Meeting.—*September*, 1840.

(From the Athenæum.)

Section G.—Mechanical Science.

Mr. Dircks gave an account of *a railway wheel with wood tyre*, which was exhibited in the museum. It was one of a set which had been in use for two months, carrying five tons each day. The construction of the wheel will be understood by imagining an ordinary spoked wheel, but with a deep-*channelled* tyre. In this channel is inserted blocks of African oak, measuring about 4 × 3½ inches, prepared by filling the pores with such unctious preparations as counteract the effects of capillary attraction in regard to wet or damp. The blocks are cut so as to fit very exactly, with the grain placed vertically throughout, forming a kind of wooden tyre. There are about thirty blocks of wood round each wheel, where they are retained in their places by bolts, the two sides of the channel having corresponding holes drilled through them for this purpose; each block of wood is thus fastened by one or two bolts, which are afterwards well rivetted. After being so fitted, the wheel is put into a lathe, and turned in the ordinary manner of turning iron tyres, when it acquires all the appearance of a common railway wheel, but with an outer wooden rim, and the flange only of iron. Mr. Dircks proposes the use of either hard or soft woods, and of various chemical preparations to prevent the admission of water into the pores of the wood: he also contemplates the using of wood well compressed.

Mr. Jeffrey *on a New Hydraulic Apparatus.*—It comprised an improvement on the ancient endless chain of buckets, which he considers of Egyptian origin. This apparatus has hitherto never acquired the value it admits of, on account of a defect having remained in its construction, opposed to geometrical principle—the buckets which bring up the water being fixed outside instead of within the rope. The effect of this is such an acceleration of the bucket, when it is carried round the wheel at top, as causes it to overtake the water and carry much of it down again. But, by placing the buckets on the centre side of the ropes, that is, within them, the bucket when passing round the wheel, being very near the centre, is much retarded, and the momentum of the water causes it to ride out of the bucket very effectually into the trough. A peculiarity in the form of the bucket also prevents the spilling of the water in cases where the motion is very slow.

Sir J. Robison stated that, although the methods in India are rude, yet they give a greater return of work done for power applied than other methods known.—Mr. Jeffrey stated that he had tried this method on a large scale, each bucket containing 1½ cwt. of water. A small valve at the bottom of the bucket allows the air to enter, and the bucket is thus quickly emptied.

"*Additional Notice concerning the most economical and effective proportion of Engine Power to the tonnage of the hull in Steam Vessels, and more especially in those designed for long voyages.*" By Mr. Scott Russell

Large power or small power? has always been a disputed question. The early steam boat engines had but a small power proportioned to the tonnage. The *Comet* had 25 tons burden, and only three horses power—being a proportion of power to tonnage amounting to ⅛. On this subject modern practice and opinion seem to offer no guide. The East India Company have used low proportions of power to tonnage, and in this they appear to have adopted the general maxims of Southern engineers. The Government appear also to have followed the same course, but without going to the same extreme. The Clyde engineers adopt the opposite maxim, and place as much power in their vessels as can be conveniently applied. There appears at present to be a feeling in favour of a high proportion of power to tonnage. It has been found by some of the best mercantile companies that a high proportion of power to tonnage is not only better for expedition, but also more economical of fuel and of capital: and instances are frequent of an increase in the power of a steam vessel, producing a diminution in the consumption of fuel. As this question is becoming every day of greater importance, it is proper to examine it carefully. In the first place, it is known that the proportion of power must be very much increased to gain a given increase of speed;—thus, if ten horses power propel a vessel through water five mile an hours, it will require forty horses power to propel the same vessel ten miles an hour; since it will require a quadruple power to obtain a double speed, in like manner it will require a ninefold power to triple the speed. A large power of engine, it may be said, occupies much useful space which might be filled with cargo. It consumes much coal, and the speed is by no means proportioned to the expense of fuel and machinery. But this is a limited view of the subject. If time, as an element, and a very important one in the value of mercantile conveyance, be calculated, then it will be found that in many cases the effects of high speed, at any expense of fuel, will compensate for that expense. But it is not on the value of speed at the present day that we proceed in this inquiry. We are to ascertain what may be the best proportion of power to tonnage in sea-going vessels. We have seen that the lowest speed is the most economical, and that it requires expensive additions to give high velocities. But in arriving at this conclusion, we have taken only the case of smooth water: here it is obvious that the smallest power will be most economical. But it should be remembered that the great purposes of steam are generally of a different nature from the mere generation of motion through a quiescent fluid. The force of adverse winds, waves, and tides are to be overcome,—and it is the success of steam in obtaining regularity and speed, in spite of these, which constitutes its superiority. Now, if we take a simple case of one of these, we shall soon find that a higher proportion of power to tonnage may be essential not only to speed but even to economy. Suppose, a steam-boat with a small proportion of power, capable of propelling the vessel at the velocity of three miles an hour through still water, to be applied to stem a current of three miles an hour, or a proportionately strong breeze,—is it not plain that the vessel would make no headway? This extreme case of too little power shows that there is at least one proportion of power which is too small for economy of fuel. We may now proceed to investigate the question of best proportion, or the point where the attainment of high speed is accompanied by absolute saving of fuel, as compared to lower velocity. For this purpose we merely take it for granted, that the speed through the water will be nearly as the square root of the former, according to the general law of the resistance of fluids; that the resistance offered by adverse winds, &c. has been ascertained, and is determined on a particular station, that is, that it is known that on a given station, a given vessel, with a given power, makes a voyage in adverse circumstances in, suppose, double the time of her most prosperous voyage, say her prosperous voyage in fourteen, and her adverse voyage in twenty-four days, being a retarding power of ten days out of twenty-four; we take this retardation of ten days as the measure of the retarding power of adverse weather in the given circumstances. By working out the result, we obtain the very simple rule for finding the best proportion of power to tonnage: from the square of the velocity of any given vessel in good weather, subtract the square of the velocity of the same vessel in the worst weather, divide the difference by the square of the velocity in good weather, and the quotient multiplied into double the horses' power of the said vessel, will give the power which would propel the same vessel in the same circumstances, with the smallest quantity of fuel. It further appears, that the consumption of fuel in the worst voyage, will not exceed that of the best voyage, in a greater proportion than 10 to 7—that is to say, for 70 tons of fuel burnt on a good voyage, it will not be necessary to carry more than 100 tons, in order to provide against the worst. Let us take, as example, a Transatlantic steam-ship, which has a proportion of 1 horse power to 4 tons of capacity; her unfavourable voyage being, between England and America, twenty-two days, and her favourable voyage fourteen days, being a comparative velocity 7 and 11.

$$\text{Then } h' = 2\,h'\,\frac{v^2 - v'^2}{v^2} = 2.\ \frac{121 - 49}{121} = 2\ \frac{72}{121} = \frac{12}{10} \text{ nearly.}$$

Hence the power should be increased in the ratio of 6 to 5—that is to say, the engines at present capable of exerting a power of 500 horses should have been capable of exerting a power of 600 horses, and would, in this case, consume less fuel, as well as produce greater regularity. The following result also follows:—The vessel of less power burns 30 tons per day, performs the distance in fourteen days, consuming 420 tons of coal in fair weather. The vessel of less power burns 30 tons, performs the distance in twenty-two days, consuming 660 tons in foul weather. The vessel of greater power burns 36 tons, performs the distance in twelve and a half days, consuming 468 tons in fair weather. The vessel of greater power burns 36 tons, performs the distance in 17·5 days, consuming 630 tons in foul weather; being a consumption of 64 tons less fuel, and performing the journey in four and a half days less than the other. It is manifest, that the store of fuel carried in the vessel with less power, must, on all occasions, be equal to the greatest consumption, that is to say, at least 660 tons, whereas 630 tons will be sufficient for the vessel of greater power, and, as in all vessels for long voyages, coals carried are much more costly than the mere price of coals, or as the freight of the vessel is more costly than the fuel, coals carried are to be reckoned at least as expensive as coals burnt. Moreover, as the gain in time is 4½ out of 22, being 20 per cent., it is plain that the vessel may be calculated to do the distance oftener in a year, because, as the times of starting must be regulated not by the shorter, but by the longest period of a voyage, seventeen and a half days in the one case, stand in the place of twenty-two in the other. It appears, therefore, that, for long voyages especially, there are great advantages in point of economy, certainty, and speed to be obtained by the use of vessels of a higher power than usual; and that in a given case, the best proportion of power to tonnage may readily be determined from the rules already laid down. In regard to absolute or definite proportion, it may be stated, as the result of the best vessels, that the proportion of power to tonnage should not be greater than one horse power to two tons, nor less than one horse to three tons; the greater proportion holding in the smaller, and the less proportion of power in the greater vessel.

Mr. Fairbairn agreed, that the horse power should be increased, but that in bad weather the consumption of fuel was not so great as in fine weather.—Mr. Russell said, that practically in good weather the engines are worked expansively. There are two systems. The south engineers are afraid of using full powers: they use smaller proportions of power to tonnage, and slack the power in head winds. The north engineers always set head to wind in bad weather, and work full power; and in good weather work expansively. In steamers worked on the south system, the advantages would be as Mr. Fairbairn stated; in steamers worked on the north system, the advantages would be as he stated.—Mr. Fairbairn was of opinion, that three tons to one horse power were better than four to one.—Mr. Russell said, that it was safe to give more power than the rule gives; that on the introduction of longer and sharper vessels less power would be required.—Mr. Fairbairn observed, that the goverment post-office steamers, in the Mediterranean, were so bad, that the French vessels constantly pass them.

Mr. Smith made some observations "*On the Drainage of Railway Embankments and Slopes.*"—Mr. Vignoles observed, that had Mr. Smith had as much experience on railways and their construction as himself, he would have known that all he had recommended had been done on various occasions, whenever the expense could be justified.

Mr. Mallet "*On the Action of Air and Water on Iron.*"—Mr. Mallet stated, generally, the nature of the principal practical results obtained by him, with respect to the durability and modes of protecting cast iron, wrought iron, or steel, under various conditions, when exposed to the corroding or chemical action of air and water, whether fresh or salt. These researches have been made under the sanction of the Association, and are still in progress. Numerical results have already been obtained of the absolute and relative durabilities of about 100 different varieties or makes of cast iron and of wrought iron, in each of the following conditions as to water,—viz. In clear sea or ocean water; in foul sea water, as in the harbours of large cities; in clear river water; in foul river water; in sea water at high temperatures; in sea water at various depths; in sea water of variable saltness. The results in all these cases are given in voluminous tables, so arranged as to enable the engineer to predict with confidence the durability of a given scantling of iron of a given sort, under given circumstances. The conditions of corrosion of iron, in contact with copper, with zinc, and with tin, and with various atomic alloys of these, have been determined, and printed tables of the results distributed to the Section. Results are also given as to the relative protecting power of several paints or varnishes, to the surface of iron exposed as above. The specific gravities of all the irons experimented on, have been taken by a new method, and the increment of specific gravity due to increased depth (or head of metal) in castings determined, and also the decrement of specific gravity due to increased bulk or scantling of castings determined. These are necessary data to the foregoing investigation, and are in themselves of importance to the engineer, with reference to the ultimate cohesion of cast iron, which seems to be related, and probably is some function of the specific gravity in any given case. The experiments are now extended to wrought iron and steel; a final report is proposed, to consider the nature of the chemical changes induced on cast and wrought iron by the action of sea water, and to complete the numerical results now given, which have lately been in several instances submitted to control, or tested by the actual corrosion of castings recovered from the wrecks of the *Edgar* and *Royal George*, &c., and found strikingly to coincide.

Mr. Grimes described Dennett's Rockets for preserving lives from shipwreck, and read a letter from Capt. Denham, stating that the range of these rockets exceeded that of the mortar by 100 yards, the range of the rockets being about 350 yards, while that of the mortar was but about 250.

Dr. Wallace on Arches. The object of this paper was to exhibit a method for geometrically constructing a catenary. After explaining his method, Dr. Wallace stated that he was about to publish a set of tables for constructing the catenary, and also for suspension bridges.

Mr. Wallace exhibited and explained his smoke protector.—Mr. Hawkins exhibited and gave an account of Mr. J. R. Bakewell's instrument for measuring the angles of the dip of strata.—Mr. Rayner exhibited a machine for regulating the speed of machinery in cotton-mills, &c.—Mr. Smith, of Deanston, exhibited a model of a new canal lock, the advantages of which he stated to be, that the descent in each lock would not be more than twelve to eighteen inches—that the locks were opened by the passage of the vessels—that the locks shut of themselves—that the vessels did not require to stop —and that little or no water was lost. The lock gate is hinged at the bottom, the upper portion, which is round, floats at the level of the higher part of the water, and is pressed down by the bow of the vessel in passing, and when it has passed, rises to its former position.

"*Experimental Inquiry into the Strength of Iron, with respect to its application as a Substitute for Wood in Ship-building.*" By Mr. Fairbairn.

The number of vessels which of late years have been made entirely of iron, and the probability of the greatly extended use of this metal in ship-building, renders it desirable to attain additional knowledge as to its power to resist these strains to which it is subjected, in its application to the purposes above stated. Mr. Fairbairn's experiments have convinced him, that in proportion as the public become better acquainted with the valuable properties of this material, and its fitness for almost any purpose of naval architecture, they will be convinced that it is safer, and, perhaps, more durable than timber, and that confidence in it will be completely established. To meet the requirements for this purpose, the following series of experiments have been undertaken, and in a great measure completed. Part only, however, could at present be laid before the Section. 1st. A eries of experiments on the strength of plates of iron, as regards a direct tensile strain, both in the direction of the fibre and across it. 2nd. On the strength of the joints in plates rivetted together, and on the best modes of riveting. 3rd. On the strength of the various forms of ribs or frames used in ship-building, whether wholly composed of iron, or of iron and wood. 4th. On the resistance of plates to compression and concussion, and on the power necessary to burst them. The experiments were superintended by Mr. Hodgkinson, to whom Mr. Fairbairn acknowledged himself indebted for many of the results.

On Strength of Iron Plates.—In these experiments all the plates were of uniform thickness. Their ends had plates rivetted to them on both sides, with holes bored through them perpendicular to the plate, in order that they might be connected by both, with shackles to tear them asunder in the middle, which was made narrower than the rest for that purpose. The results were as follow:—Mean breaking weight in tons per square inch, when drawn in the direction of the fibre.

		Tons.	
Yorkshire	plates	25·77	Mean 22·52 tons.
Do	do.	22·76	
Derbyshire	do.	21·68	
Shropshire	do.	22·83	
Staffordshire	do.	19·56	

Mean breaking weights in tons per square inch, when drawn across the fibre:—

Yorkshire	plates	27·49	Mean 23·04 tons.
Do.	do.	26·04	
Derbyshire	do.	18·65	
Shropshire	do.	22·00	
Staffordshire	do.	21·01	

The foregoing experiments show that there is little difference in the strength of iron plates, whether drawn in the direction of the fibre or across it. Mr. Fairbairn then gave the results of a long series of experiments on the strength of riveted plates. The same description of plates was here used, as in the previous experiments; the plates were however, made wider than the former, in order that they might contain (after the rivet-holes were punched out) the same area of cross section as the previous ones. Mean breaking weights in pounds, from four plates of equal section, rivetted by a single row of rivets:—

20127	Mean 18590 lb.
16107	
18982	
19147	

The mean breaking weights in pounds from four plates of equal sections to the last, but united with a double row of rivets:

22699	Mean 22258 lb.
23371	
20059	
22902	

Whence the strength of single to double riveting is as 18590 : 22258. But from a comparison of the results taken from the whole experiments, the strength derived from the double rivetted joints was to that of the single as 25030 : 18591, or as 1000 to 742. Comparing the strength of plates alone with that of double and single riveted joints, Mr. Fairbairn gave their relative values as under:—

For the strength of the plate	100
For that of double riveted joints	70
And for the single riveted joints	56

Hence the strength of plates to that of the joints, as the respective numbers, 100, 70, and 56. Mr. Fairbairn then gave a table containing the dimensions and distances of rivets for joining together different thicknesses of plates.

A discussion ensued as to the comparative strength and safety of iron boats. Mr. Fairbairn stated, that from the manner in which the sheathing is rivetted, the whole vessel becomes one mass; and though he did not come forward as the advocate of iron against wood, he would state that he considered iron as one-third stronger than wood, weight for weight.—Mr. Grantham knew iron boats that had lasted 28 years in fresh water.—Mr. Taylor built an iron boat for a canal in 1805, and it was now in good condition.—Mr. Mallett had found, from his experiments on the action of sea water upon iron, that the duration of a half-inch plate in sea water would be about 100 years.

Mr. Hodgkinson read a paper "*On the Strength of Pillars of Iron.*" This was an abstract of a paper by Mr. Hodgkinson, read at the Royal Society, of which we gave an abstract at the time.—(See Journal, No. 34, page 248.)

Mr. Fairbairn "*On raising Water from Low Lands.*" The commissioners for draining the Lake of Haarlem having applied to Mr. Fairbairn on the subject, he proposed a method where the water is raised by a large scoop, which rises on the descent of a weight, which weight is raised by steam power, on the Cornish principle. It is calculated to raise 17 tons at each stroke. Mr. Fairbairn exhibited a model in illustration.

Mr. Taylor mentioned, that he had that morning received a letter from Mr. Enys, stating that commissioners from the Dutch government had visited Cornwall, to ascertain the duty done by the Cornish engines. Several experiments had been made at their request, and the following was the result.

			Feet stroke.	Lifted one foot.
Wheal Vor, Borlase's engine..	80 in.	single	8·0	123,300,593lb.
Fowey Consols, Austin's	80	„	9·0	122,731,766
Wheal Darlington Engine ..	80	„	8·0	78,257,675
Charlestown United Mines ..	50	„	7·5	55,912,392
Ditto Stamping engine......	32	lifting 66 stamps		60,525,000
Wheal Vor, ditto	36	dble. lifting 72 stamps		50,085,000

Mr. Glynn stated, that by a scoop wheel 25 feet diameter, and 80 horse power, used by him in Lincolnshire, 4½ tons of water were raised in a second, the difference of level being about five feet.

Mr. Hawkins exhibited a Model of a Railway and Carriage, recently patented by Mr. Rangeley, and by him called *the Safety Rotation Railway;* which is an inversion of the ordinary construction, inasmuch as wheels are made to revolve on fixed bearings, placed in two parallel lines along the road; and the carriage, without wheels, is built upon a pair of running rails, carried along upon the peripheries of the train of wheels kept in revolution by steam-engines fixed at every mile or two of the road. It is intended to have the wheels three feet diameter, and three feet apart, which will give 1760 wheels on a mile. They are to be driven by a succession of endless bands, one band in every case passing around two pullies attached to every two contiguous wheels. The carriages are designed to hold forty passengers each, with their luggage; the whole, including the carriage, not to exceed five tons: the running rails always to bear on eight or ten wheels, so that no wheel shall have to support more than about ten or twelve hundred weight. The wheels, therefore, need not weigh more than half a hundred weight each, to be sufficiently strong for supporting the carriage. It is found by experiment, that three ounces suspended from the periphery of such a wheel, causes it to revolve. Any weight that sets a wheel in motion, will, if continued, cause the same to revolve with accelerated velocity, until the resistance of the atmosphere becomes equal to the accumulated force, after which, a steady speed will be kept up. It is inferred from observation, that the wheels driven with a continued force of three ounces each, would acquire a constant speed of about thirty miles an hour. It is also ascertained from experiment, that eight pounds would draw a ton weight on four three-feet wheels running on level rails, and thus that a force of forty pounds would draw the carriage. The following table is constructed from data, by which it is found that seventeen horse power of steam-engine is required to turn each mile of wheels, and two horse power to drive each carriage. The power to turn the wheels, is neither increased by additional carriages nor by acclivities; each carriage added, taking only two horse power more to carry it along upon a level; and an acclivity of 1 in 180 doubling, 1 in 90 quadrupling, and 1 in 45 octupling only the tractive force, without in any case requiring more than the seventeen horse power to turn the wheels.

Carriages Every 2 Minutes.	PASSENGERS.		HORSE POWER. Per Mile in 2 Minutes.			
	Every 2 Minutes	In 12 Hours.	On a Level.	Up 1 in 180.	Up 1 in 90.	Up 1 in 45.
1	40	14,400	19	21	25	33
2	80	28,800	21	25	33	49
3	120	43,200	23	29	41	65
4	160	57,600	25	33	49	81
5	200	72,000	27	37	57	97

The Britannia.—This steamer has brought to Havre from London an iron steamer in 372 pieces. The vessel, which is destined for the Lake of Geneva, will be 135 feet long, and these materials are to be transported thither forthwith.

REVIEWS.

Penny Cyclopædia. Part 92. Article "Portico."

Unless the style adopted prohibits the introduction of such feature, a portico is now considered almost a *sine qua non* in a design; ample proof of which being the case was afforded by those for the Royal Exchange, the Assize Courts at Liverpool, &c.; and yet, whether in designs or executed buildings, we very rarely find any attempt at originality, or any fresh combinations in regard to plan. On the contrary, nearly all our porticoes consist merely of a single range of columns in front, and it is fortunate when that disposition of them is attended with the negative merit of there being no disagreeable drawback on the effect aimed at by them, resulting from a mean background to the external elevation. In fact, notwithstanding that so very much depends upon them, and almost endless variety may be obtained from them, *plan* and *background—i.e.* the interior elevation of the portico—have scarcely any study or attention at all bestowed upon them. We trust, however, that the very excellent article which has just appeared in the Penny Cyclopædia—a work which has already more than once obtained our notice and approbation for the architectural information it contains—will not be thrown away upon the profession, but spirit them up to endeavour to get out of their old routine course, and give us something more than six or eight columns, put beneath a pediment.

When we inform our readers that the article in the Cyclopædia extends to several pages, we hardly need observe that it is altogether original, for we know of no other work of the kind which contains much more than a mere definition of the term itself, while here in addition to the information brought together, there is a very great deal of able comment and criticism. Even were there nothing else to recommend it, this article would deserve to be noticed by us on account of the novel and ingenious terms invented by the writer to express clearly at once, of what kind a portico is, as regards its flanks, and its projection from the building to which it is attached. For this purpose he makes use of the terms *Monoprostyle, Diprostyle, Hyper-diprostyle, Triprostyle*, &c., the first indicating the simplest form of prostyle, namely, that which projects only one intercolumn before the building; the second, that which projects two intercolumns, and so on. By this most convenient innovation in architectural terminology,—and therefore likely to be generally adopted at once,—the plan of the portico of St. Martin's Church, would be clearly described by terming it Hexastyle Diprostyle, that is, having six columns, or five intercolumns in front and two intercolumns at its flanks, consequently one column there besides that at the angle. A *Triprostyle* has of course three open intercolumns at its sides; but the meaning of *Hyper-diprostyle* requires some explanation,—after which it becomes obvious enough, this term being coined by the writer to express that besides having two open intercolumns, the portico is advanced from the building by an additional space, whether equal to a third intercolumn or not: thus the portico of the National Gallery is described as a Corinthian Octastyle, *Hyper-diprostyle*, and with regard to its interior as having a distyle in antis within it,—that is, a recess of three intercolumns, produced by two columns between antæ.

The article is illustrated with a great many plans, showing various arrangements, and is further accompanied with a table of some of the more remarkable examples, which we shall here give, referring our readers to the Cyclopædia itself for the rest of the article, not doubting that they will procure the number which contains it.

TABLE OF PORTICOES.

Class.	Order.	Building.	Architect.	Remarks.
Dodecastyle	Corinth.	Chamber of Deputies, Paris	Poyet	Monoprostyle. sculptured pediment.
Decastyle	..	University College, London	Wilkins	Hyper-diprostyle, recessed. Height of columns 30 feet.
Octastyle	..	Pantheon, Rome	......	Hyper-triprostyle. Polystyle and recessed.
..	..	National Gallery, London	Wilkins	Hyper-diprostyle, with distyle in antis, recess within.
..	..	Fitzwilliam Museum, Cambridge	Basevi	Monoprostyle, recessed, and with order continued laterally, forming three intercolumns on each side.
..	..	Victoria Rooms, Bristol	Dyer	Unequal diprostyle, recessed, five intercolumns.
..	..	Exchange, Glasgow	Hamilton	Diprostyle, with two inner columns corresponding with second and seventh of the octastyle.
..	..	Buckingham Palace	Nash	Columns fluted, their height 26 feet
Octastyle-Peripteral	..	Birmingham Town-hall	Hansom and Welsh	Columns 36 feet high. Side elevations of twelve intercolumns on flanks.
..	..	La Madeleine, Paris	Huvé	See Paris.
..	..	Girard College, Philadelphia	Walter	Columns 55 feet high; marble.
..	Doric	The Walhalla, Bavaria	Klenze	
Octastyle	Ionic	Glyptotheca, Munich	Klenze	Monoprostyle, polystyle, recessed, tetrastyle in antis.
..	..	Great Theatre, Petersburg	Thomond	Monoprostyle.
..	Doric	Church at Possagno	Canova	Diprostyle, polystyle, double octastyle.
..	..	Manège, Petersburg	Quarenghi	Monoprostyle, polystyle, recessed.
..	..	Royal Institution, Edinburgh		
Hexastyle	Corinth.	St. Martin's, Charing-cross	Gibbs	Diprostyle, height of columns 34 feet.
..	..	St. George's, Bloomsbury	Hawksmore	Diprostyle, five arched doors, and five arched windows above them.
..	..	St. George's, Hanover Sq.	J. James	Monoprostyle.
..	..	Law Courts, Dublin	Cooley and Gandon	Monoprostyle.
..	..	Kazan Church, Petersburg	Voronikhin	Diprostyle, polystyle, a triple hexastyle.
..	..	Pantheon, Paris	Soufflot	Reliefs within portico, height of columns 62 feet.
..	..	Madre di Iddio, Turin	Buonsignore	A diprostyle, attached to a rotunda. Two inner columns behind the penultimate ones in front.
..	..	Custom-house, New York	W. Ross	Monoprostyle. White marble; columns 32 feet high.
..	..	St. Nicholas's Potsdam	Schinkel	Hyper-monoprostyle.
..	Ionic	Bethlem Hospital, London	Lewis	Monoprostyle; height of columns 36 feet.
..	..	Post-office, London	Smirke	Diprostyle, recessed, columns 37 feet high.
..	..	Theatre, Berlin	Schinkel	Monoprostyle, flight of steps in front.
..	..	East India House, London	Jupp	Pseudo-prostyle; height of columns 30 feet.
..	..	St. Pancras' Church, London	Messrs. Inwood	Monoprostyle; florid Ionic; columns 36 feet high.
..	..	Royal Institution, Manchester	C. Barry	Monoprostyle. Order continued laterally, forming loggias of three intercolumns on each side of prostyle.
..	..	Post-Office, Dublin	F. Johnston	Monoprostyle, columns 36 feet high, fluted.
..	..	Raadhus, Copenhagen	Hansen	Monoprostyle; deep recess in centre with steps.
..	Doric	Colosseum, London	D. Burton	A monoprostyle attached to a polygon.
..	..	Hunterian Museum, Glasgow	......	Monoprostyle, recessed, with a distyle in antis.
..	..	County Hall, Chester	T. Harrison	Monoprostyle, polystyle, recessed. A double hexastyle.
..	..	Wacht-Gebaude, Berlin	Schinkel	Monoprostyle, recessed as a tetrastyle in antis.
Pseudo-hexastyle	Corinth.	Front of Roman Catholic Chapel, Finsbury Circus	......	Four pilasters and two columns beneath a pediment, or five intercolumns.

Papers on Iron and Steel, Practical and Experimental. By David Mushet. London: Weale, 1840.

Second Notice.

Iron possesses among metallic products the same pre-eminence which cotton has over those of vegetable origin, and has for many centuries been one of the great staples of our foreign trade, and a main supporter of our internal industry; to the progress of this manufacture in our own country we shall subsequently have occasion to refer, we shall now therefore call attention to its origin elsewhere. Mr. Mushet in his fourteenth paper combats the traditional account of the discovery of iron in Greece by the accidental burning of a forest, and gives a probable theory so well confirmed by experience here as to carry with it a high degree of authority. I have seen, says he, a mass of perfectly malleable iron produced by roasting a species of ironstone, united with a considerable quantity of bituminous matter. After a high temperature had been excited in the interior of the pile plates of malleable iron of a tough and flexible nature were found, and under circumstances where there was no fuel but that furnished by the ore itself. Mr. Mushet thence argues the possibility of the properties of the metal having been discovered during the process of making charcoal by a mass of ore accidentally dropping into the burning pile. Iron, it is most probable, was for a long time after its discovery applied solely to agricultural purposes, for the want of a regular method of converting it into steel long gave a preference to hardened copper and its alloys as the material for edged tools and instruments of war. So little indeed was the art of making steel advanced, that a present of 40 lbs. of steel from Porus to Alexander is quoted by biographers as a most acceptable and valuable gift.* Even in India itself where this branch of art is now carried on upon a very extensive scale, the progress seems to have been very slow, for the value of that gift of Porus would now be the produce of one man's labour in 240 days. It is to India however, that according to the best authorities we are to look for the origin of steel, and from which other countries were supplied; even the obelisks of Egypt being supposed to have been worked with Indian tools. Among ourselves the production of iron claims a very early date, for there is every probability of the Cornish mines having been worked at least 2300 years ago by the Phenicians, while we know by the testimony of Cæsar† that this branch of mining was still pursued by the nations inhabiting Britain. The current money was of brass or iron, valued according to weight, although Cæsar observes that the produce of this latter metal, which was worked in the maritime districts was small. As however the tin trade had long been a staple, and copper and brass were imported, it may be reasonably doubted whether among a mining population, the workings were, although rude, carried on upon a greater scale of magnitude than is implied from the terms used by the Romans. During the subsequent occupation by the Romans, remains now existing fully attest that the workings were kept up by them, and indeed during the whole period of history there seems to have been no intermission in the prosecution of this branch of the national wealth and strength. The Danes are particularly noted in this pursuit, and large heaps of scoria, named after them, are to this day to be met with in many parts of England, with so great an accumulation of soil upon them as to bear trees of large size. At the time of the Norman accession we find the king demanding of the inhabitants of Gloster 36 icres of iron, for making nails for his fleet, every icre to consist of 10 bars or rods of iron; which iron was very probably made in the neighbourhood in the Forest of Dean. The kings of England held in this forest iron works, consisting of three blast furnaces and two forges, which are supposed to have been given up by Charles 1st, somewhere about the year 1637. Cromwell and other princes are also said to have embarked capital in such pursuits, and indeed the iron trade seems always to have been the object of the highest solicitude.

One of the first events which led to an extension of the iron trade, particularly as regards castings, was the invention of cannon, the precise date of which is not however known. Cast iron is said by M. Verlit to have been known in Holland in the 13th century, and staves to have been cast from it at Elass in 1400, but how produced is not known. Cannon are mentioned in a record of the accounts of the Chamber of Paris in 1338, and were used by the English at Cressy in 1346, and by the Venetians in 1366 and 7, but we are by no means to conclude that such cannon were cast, as for two hundred years hooped cannon were made, formed of staves of wrought iron, bound together with strong hoops of the same metal. It was not until 1517 that the first iron guns were cast in London by a person named Owen. The precise date of the origin of the blast furnace is far from being ascertained. Mr. Mushet who has investigated the subject with his usual research, seems to be of opinion that it cannot be beyond the beginning of the seventeenth century. It is then that we perceive a fresh epoch in the progress of the manufacture, as a greater power of blast was required, the old situations would be abandoned, and the iron trade pass from the township in the neighbourhood of the mines to the banks of the adjacent streams; this is particularly evident from examining the sites of the oldest workings. The introduction, or invention of the blast furnace here, for we seem to have some claim to its first use, was productive of a great extension of the trade; a great exportation of iron artillery to the continent was the result, and without giving implicit belief to the statements of Dudley, in his Metallum Martis, we are still bound to believe that the trade was great. According to Dudley's computation in 1615, there were then no less than 300 blast furnaces for smelting iron ore with charcoal, and 500 forges and iron mills. The total quantity of iron produced from the works is said to have been 180,000 tons per year, an enormous amount considered in relation to the then population of the country, although not impossible so far as the question of fuel is concerned. Supposing Dudley's statement of the number of furnaces to be accurate, although some question may be raised upon that point, a deduction is still to be made for furnaces out of blast and building, for which, from modern experience we might easily assume the deduction of a third, leaving 200 as the actual number in work. A less number of weeks (perhaps 35), and a lower average (say 12), should also be taken, and the estimated produce would then not exceed 80,000 tons, a quantity by no means incredible. It may be mentioned here by the way that the extensive exportation of artillery is not only in favour of the origin of blast furnaces in this country, but also of our possessing a very large share of this trade, which might well give an impulse to it in this country.

We have now to contemplate the history of another great improvement, the use of pit coal, for which we find several patents granted by James I. In 1612 a patent was granted to Simeon Sturtevant, Esq. (seemingly a Dutch name) for 31 years for making iron with pitcoal, in return for which patent Sturtevant was bound to publish his discoveries, which appeared in a quarto form under the name of "Metallica." In the next year Sturtevant, having tried his plan upon a large scale and failed, was obliged to give up his monopoly. John Ravenson, Esq., was the next in the field, and was also enjoined by his patent to publish his discoveries, which he did under the title of his "Metallica." Several other candidates also failed, when, in 1619, a new competitor came into the field, who was destined to excite more attention. Dudley's father possessed iron works at Pinsent, in Worcestershire, and it was there that Dudley perfected the patent which he obtained in 1619. He declared that although he made only at the rate of three tons of pig iron weekly, that he made it with profit. His success was such as to excite the alarm of the charcoal iron manufacturers, who formed a powerful opposition, and obtained a limitation of his patent from 31 to 14 years, new adventurers also sprang up to encroach upon his rights, until at last their rivalship, and his attachment to the cause of Charles 1st, prevented his improvements from being followed up. In the meanwhile the deficiency of wood had begun to be felt, and Dudley had fully proved the efficacy of his plan for the manufacture of pig and bar iron, and for various castings, all of which he sold much lower than the charcoal-manufacturers. In the article of castings alone, Mr. Mushet says, he must have had greatly the start of the charcoal foundries, as the quality of carbonated coke pig iron is far superior to that of the charcoal iron of this country for the general purposes of casting. Such success greatly provoked the hostility of his rivals, particularly of those who still possessed a good supply of fuel, who at last in the true spirit of combination led on an attack upon his devoted works, and led to the evil results to which we have alluded. His improved bellows, forge, &c. all fell a prey to the lawless banditti. While he was thus openly plundered, his rivals were not less active in endeavouring to undermine him, or at least profit by his success by evasions of his patent. Among these attempts that of Captain Buck, Major Wildman and others is a singular instance of failure. Attacked on all sides Dudley was also foiled in 1663, in his last attempt to obtain a patent from Charles the Second, and deserted by all, he was compelled to give up the pursuit.—Dudley was the author among other works of the "Metallum Martis," in which we possess many curious details of the early state of the trade. We may here pause and view the present state of the charcoal iron manufacture, which from 310 furnaces has dwindled down to insignificance, so as to be almost extinct, the whole annual quantity manufactured not exceeding 1000 tons. In Lancashire, two or three furnaces are occasionally in blast, and one in Argyleshire. The purposes to which iron made from this fuel is now applied are limited indeed. In Lancashire a small quantity of steel iron for the Sheffield market has of late years been made from it; but the principal consumption is for casting knives, forks, razors, snuffers, bridle bits,

* Quintus Curtius, B. 9. ch. 25. Ferri candidi talenta centum.

† De Bello Gallico, L. 5, c. 10.

stirrup irons, &c. These articles, after having been cast, undergo a process of deoxidation, which gives them a surprising degree of tenacity, with great flexibility and a capacity of polish resembling steel: those castings, not intended to receive a polish, present surfaces capable of receiving and retaining tin for a considerable length of time.

To return to the date where we left off, we may observe that the improvements which had been made had increased the power of the furnaces, from which as well probably as from their concentration a diminution had taken place in their number. In a prospectus drawn up about the year 1720, near the time of the South Sea Bubble, we find the number of furnaces rated at only 59, but as this list is manifestly imperfect, we are perhaps bound to consider the number as larger. Sussex, Kent, and Hampshire were then the seat of 15 furnaces, now of not one. Resuming the history of pitcoal iron we find that after the time of Dudley, nothing of importance was done until 1740, when a new auxiliary, the steam engine, had come into the field. The application of this machine gave the manufacturer greater liberty in selecting the site of his works, and enabled him to erect larger furnaces with a proportionate quantity of blast. From this date the use of pitcoal every year became more prevalent, and has ended by superseding charcoal in this country. In aid of this two other circumstances operated with advantage, the introduction of Mr. Watt's double blast engine, and the invention of puddling and rolling bar iron by Mr. Cort.

In our own days improvements not less important have been effected, and since the commencement of the literary career of the author, whose work is now before us, the quantity of pig iron necessary to produce a ton of bar iron has been reduced from 40 cwt. to 26 or 27 cwt., with almost as great an economy of fuel. This has principally been accomplished by means of the hot blast, the use of which however can be only considered as recently established, so strong was the prejudice against its application. One great property it possesses is that it diminishes the quantity of vitreous matter formerly required in the furnaces, so as to diminish the consumption of both fuel and limestone. An equalization of the blast is another result, so as to diminish the effect of the atmospheric influence, which it is well known interferes with the operations of the furnace. In this, as in other countries, a larger produce of cast iron is obtained in the winter months than during the summer or autumn, while the quality of the metal is improved by being much more carbonated and less fuel is consumed. During the months of June, July and August, more especially in hot seasons, the quality of the iron in this country will be depreciated 30 per cent., and the quantity very considerably reduced, and in many parts of Sweden, says Mr. Mushet, when the summer heats are intense, the manufacturer is obliged to blow out or stop his furnace for two or three months; not only is he unable to make carbonated metal, but is frequently incapable of keeping the furnace in such trim as to make a produce of any quality whatever.

An improvement scarcely inferior in importance, although only local was the discovery by the author in 1801, of the Mushetstone or Black Band ironstone, a new class of carboniferous ironstone, principally found near the river Calder, near Glasgow, but also in South Staffordshire, North Wales, and North Staffordshire, in which latter district it is called Red Mine. Although used by Mr. Mushet in the Calder iron works, so strong was the prejudice against it that it was not until 1825 that its application was at all extensive. It is now used in about 50 furnaces in Scotland, and the quantity of iron produced is above 100,000 tons; on one estate alone £12,000 is received as royalty in consequence of this discovery. A powerful auxiliary in the hands of the Scotch masters has been the use of raw pit coal, and coking under dust, which have been found to be particularly suited to the Scotch coal and iron. A dawning discovery and one which promises to be not less important than that of the Mushetstone, is Mr. Crane's process for smelting iron with anthracite, thus making available a large supply of mineral wealth, and extending our national resources.

A Practical Inquiry into the Laws of Excavation and Embankment upon Railways, being an attempt to develop the natural causes which affect the progress of such works, &c. By a a Resident Assistant Engineer. London: Saunders and Otley, 1840.

It may be laid down as a general axiom that in every inquiry of this nature, the degree of dependance which shall be placed upon the laws established, should be proportionate to the extent and generality of the experiments on which such laws are founded.

If we take as our groundwork the gross performances of a long series of months during which the attendant circumstances as to weather, state of the earth, as it may be wet or dry, adhesive, loose, or crumbling, and so troublesome or otherwise in filling and teaming, with all the other circumstances by which earth-works are affected, we shall be able to deduce from these in connection with detailed experiments upon the requisite particulars of getting, filling, teaming, and times of travelling, a tolerably perfect set of expressions by which calculations may be made with reference to earth works in general.

It must be borne in mind, however, that all results derived from such expressions, however accurately determined, and however comprehensive the data from which they have been derived, are still liable to be affected by circumstances which no human foresight can predict. All that can ever be with safety relied upon is, that supposing all attendant circumstances to be identical as to effects with those which had place during the period of former observations, then that the calculations applied to other works varying in form and magnitude, shall give results agreeing with such former observations.

But if we attempt without reference to the gross performance during some long period, to derive from the observation of a few days, fixed laws for the actual time of executing large works, it is obvious how impossible it must be to derive correct results in any such way. The days during which the observations have been made, may have been remarkably fine or remarkably unfavourable, or in some intermediate stage between these. But whatever this stage may have been, there is no alternative but to adopt them as our standard for the whole year, and thus it will be seen on what an unstable foundation such a structure must be raised.

We do not mean to say that any experimentalist would so far stultify himself as to proceed blindly on the isolated experiments of certain days on which the performances would notoriously be either much less or much more than on the average of the year, but we can readily imagine that the imputation of improper selection can scarcely fail to apply more or less to the experiments of any 10 or 12 single days at any period of the year. Let us suppose on the one hand one of the dull gloomy days of our winter months, the ground slowly parting with the frost which had hardened it for some weeks before—the falls of earth possessing more than usual tenacity, the workmens' tools clogged with the soft retentive clay adhering to every thing like bird lime; the rails clammy and dirty from the same cause, the wagons when teamed retaining a third of their contents plastered to the sides and bottom, and so requiring double the time for teaming, and then let us with this contrast a fine dry day of spring or autumn, the rails almost free from dirt, the shovels all clean and bright, and parting instantly with the contents filled into the wagons. These latter again when tipped immediately discharging their contents, and leaving none to be shovelled out by the teamers. And let us ask any man, practical or not practical, on which day the performance will be greatest. We shall not hesitate to say that the performance on the one day shall be 50 per cent. more than on the other, and shall be independent of the number of hands employed, because assuming that on the favourable day each department of the labour is occupied by the proper proportion of men and horses, then on the unfavourable day an increased number will rather serve to impede than to hasten, as they will be in each others way, and the hands will at intervals have to wait for their turn to exert themselves, it being impossible that more than a certain number at a time can be fully employed.

We repeat we have no intention of charging the experiments before us, or any other of the same kind with such glaring absurdity as would attach to them, did they exhibit the extraordinary results of one or other of the extremes we have pointed out as a foundation for estimating the work of the year, but we contend the chances are, that as isolated experiments they bear more or less to one or other of the extremes. It is barely possible that the days selected shall represent a fair average of what may be done throughout the year.

It is for such reasons that we would hesitate before adopting as the basis of important calculations, the results of a few days observation.

We would much rather rely on well authenticated records of the performance during many months, under different systems of working, and we would suggest to the author of the present treatise, and to all others who may in future undertake experimental inquiries of this nature, that the really practical and experienced, whether engineers or contractors, will invariably, as their test upon the accuracy of any particular theory, however derived, proceed at once to compare the results which such a theory will give them with their own actual knowledge of what has been done on the great scale in other works. They will therefore pronounce the theory correct or otherwise, according as it coincides or disagrees with their own experience. We are thus over and over again impressed with the importance of founding all theories upon the actual performance of as long a period as possible.

Let it not be understood that we are here objecting to experiments in detail. These are exceedingly useful, because placing as they do before our eyes the precise amount of time occupied in all the various tages through which the soil passes from its original position in the cutting till it is finally placed in the embankment, we are better able justly to apportion the quantity of labour necessary in each several department, and so to economize both time and money.

Our author professes to have selected the experiments he has given from a much more extensive series, and this may possibly be held as an answer to our objections, as to the limited space over which the experiments extend, but it must be understood we are not objecting to the insufficiency of these experiments, for the purpose of showing the distinct periods of time occupied in the several processes of filling, tipping, and travelling; the real meagreness of the experiments, we conceive, arises from the absence of all information as to the gross performance of some long periods. It is obvious that with such information, even should the results not agree with those which might be derived from calculation by the author's formulæ, these latter might still be of service, as expressing the ratio of the times occupied by the various details of earthwork operations, and this, we apprehend, is almost the extent of what can be expected from the experiments we are considering.

Thus should we find that the calculations on being applied to any particular work already executed, shall afford a less result in point of performance than we actually know to have been accomplished, we may still perhaps rely upon the numercial relation to each other of the several times determined in the experiments, which form the basis of such calculations. We may conclude that the separate times assumed for filling, teaming and travelling are all too great, but that they may all safely be reduced in a certain ratio: and when so reduced we may be satisfied with the conclusions they establish. Thus for purposes of comparison as to the amounts of labour which can most advantageously be employed in the several departments of earthworks, we hold the experiments in this book to be extremely useful, and we think with the restriction we have laid down against applying them to establish gross results, that they may be safely depended upon.

We will now briefly describe the mode of investigation pursued in this work.

From the observations of sixteen days the author proceeds to establish first the rate of speed at which the wagons travel, and then the time occupied in tipping each wagon, or each set of wagons, supposing a sufficient number of men at the teaming place to prevent unnecessary delay. His method of deriving the rate of speed is neat and ingenious, and liable to less objection than actual observation on the time of passing between fixed points. For instance, the time occupied in "filling, removing, and tipping the wagons," as the average of several experiments, on a lead of half a mile, was 55 minutes. Also the time occupied in filling, removing, and tipping the wagons on a lead of three-quarters of a mile, amounted to 69·47 minutes. Hence we have $69{\cdot}47 - 55 = 14{\cdot}47$ minutes for the difference between the time required for filling, removing, tipping and bringing back a set of wagons upon a lead of three-quarters of a mile long; and the time required for filling, removing, tipping and bringing back a set of wagons upon a lead of half a mile long. This difference, namely, 14·47 minutes is evidently the time which elapsed while the horses were drawing the loaded and empty wagons backwards and forwards over a quarter of a mile, or in fact the difference in the lengths of the leads.

"This shows that the average speed of transit rates at 2·40 miles per hour."

We regret to be under the necessity of pointing out that the author has here made an error in calculation, as may at once be verified by ascertaining the rate of speed corresponding to half a mile in 14·47 minutes. This rate will be found equal to 2·07, instead of 2·40 miles per hour; a material difference, and one which must affect any subsequent calculations founded upon it. We believe that the rate made use of by the author, namely, 2·40, is more correct in practice than the other, but this tends rather to weaken our faith in the experiments, since they undoubtedly, by the author's own showing, establish 2·07 miles per hour as the rate of horses' speed in transporting earth. To proceed, the time of tipping is then found $= 7{\cdot}06$ minutes, and that of filling $= 19$ minutes, both these being derived, independently of the rate of speed, and so not affected by the error we have pointed out above.

From the data thus established, our author derives in a simple manner, the necessary expressions for finding the number of wagon loads which may be removed from cutting to embankment in a given time, with a given number of wagons, both for constant and varying loads.

The next section is devoted to the investigation of the causes which limit the rate of progress in forming an embankment. The author shows that this rate of progress is limited by the number of teaming, or as he terms them shunt roads, which can be fixed at the end of the embankment, and this number will of course depend upon the height, top breadth, and rate of slopes of the embankment, as affording a greater or less breadth to team over. The breadth occupied by each road, he assumes at 8 feet, so that the whole breadth available for teaming over being divided by 8, will give the number of roads which can be laid down.

It will now be necessary to notice the author's hypothesis as to the available breadth of the teaming or battery head. He assumes that most soils will stand at a slope of $1\frac{1}{2}$ to 1, when first tipped, and as most embankments are to be finally dressed off to flatter slopes than this, the difference between the base for a slope of $1\frac{1}{2}$ to 1, and that for the slope to which the embankment is to be finally dressed off will be so much additional breadth, which being added to the top breadth will give the whole available breadth for teaming. Thus for an embankment 40 feet high, slopes 2 to 1, and top breadth 30 feet, we shal have $\overline{40\times2\times2+30} - \overline{40\times1\frac{1}{2}\times2} = 190 - 120 = 70$ feet, the available breadth for teaming over in this case.

This brief analysis contains, we believe, the elements of the author's theory, as to the limits of progress in an embankment, for taking 7·07 minutes as the time of tipping a set of wagons, it is evident that 84·8 can be tipped from each shunt road in a day of 10 hours.

The number of wagons that can be tipped per day from each shunt road, being multiplied by the number of these roads, gives the total number of wagon loads that can be tipped per day from all the roads, and this number being multiplied again by 250, the working days in a year, gives the whole performance in wagon loads per annum.

The quantity in cube yards depends of course on the capacity of the wagons, which varies from two to three cube yards, according as they are heaped or not, and according to their build.

Our opinion of this part of the author's work is principally influenced by comparing the gross results which his calculations establish as to the rate of progress, with what we know to have been the actual performance in cases where every effort was made to get through as large a quantity of work as possible. Taking the case of an embankment 50 feet high, slopes 2 to 1, and top breadth 30 feet, it would appear by the formulæ that we have been considering, that 848 wagon loads, or say (at the most moderate allowance for each wagon) 1696 cube yards per day of 10 hours, can be tipped at each end of the embankment. We think our author would be somewhat puzzled to point out an instance where even two-thirds of this amount has ever been performed, under the circumstances we have supposed, even for a single day, much less during any long continued period.

There is some difficulty in comparing the formulæ in detail with actual performance, for the want of knowing the breadth of tip in the latter cases. There is however one well authenticated example which may be found in the evidence of Mr. Provis, on the London and Brighton Railways.

We allude to his description of the great Skelmere embankment on the Birmingham and Liverpool Canal, where he states, that over a breadth of 60 feet, 105,000 yards were teamed in 16 weeks during fine summer weather, being at the rate of 1094 cube yards per day.

"During one month," however, says Mr. Provis, "we worked double gangs, beginning at three in the morning, and ending at ten at night." So that this quantity reduced to days of ten hours in length, becomes 105,000 in 120 days, equal to 875 yards per day. It must be remembered that Mr. Provis was here certainly not *understating* the performance on this work. It was his interest to show the greatest possible quantity which had ever before been accomplished, and the fact he relates was considered at the time, as indeed it is entitled to be considered now, a wonderful and almost unexampled performance, exhibiting no small share of contrivance and energy on the part of those directing the operations.

We shall only further remark that up to April 1837, no instance could be found where even 200,000 yards had been teamed into embankment from one face in a year; whereas our author's formulæ for an embankment of the dimensions last described, would lead us to calculate taking 250 working days in a year, as a performance of 424,000 yards per annum, and this too without nightwork, but simply during 250 days of 10 hours each.

The difference between actual experience and the results of our author's experiments arises here, we conceive, principally from the use of the constant 7·07 minutes as the time of tipping. This time may be perfectly correct as applicable to small embankments, and a few sets of wagons where there is no danger that either men, horses, or wagons will ever be in each others way, but we conceive it is quite inapplicable to large works, where interruptions to the regularity of proceeding would inevitably be very frequent, if the wagons were worked with the proper complement of laboar to ensure the condition that no instant of time shall be lost at the teaming place. Thus it will ever be found that the theory here laid down furnishes results as to gross performance, which must not be expected in practice.

The second part of the work commence with an inquiry into the effects of the lead, principally as determining the number of wagons to be employed for different lengths of lead. Without accompanying the author through his investigation of this subject, it may be sufficient to say that while his theoretical deductions from certain assumed data cannot be objected to, yet these deductions are certainly at variance with what any practical man would think of adopting. For instance, he ascestains by means of this investigation, that for working a 20 feet embankment at one end only, and for a lead of 150 chains, there should be employed no fewer than 109 horses and 235 wagons, a proposal sufficiently monstrous to startle any one at all acquainted with the nature of earthworks.

The next section is devoted to an examination "of the amount of friction incident upon contractor's rails." The author here establishes that the gross load for a horse on contractors' rails may vary (on a level?) from 5·28 to 7·17 tons, so that knowing the weight of the wagons employed, and deducting this from the gross load mentioned above, we may readily ascertain the number of wagons to be assigned to each horse, provided the quantity of stuff which each wagon is to hold be known, or *vice versa*, the quantity of stuff which each wagon is to carry, according as 1, 2, or 3 wagons are to be drawn by each horse.

The following extract from this section exhibits the author's results derived from an examination of the friction.

"Let P represent the power of a horse, F the friction per ton, upon the load which he draws, and W the weight of a loaded wagon in tons; then it follows, that

$$\frac{P}{F \cdot W} = X$$

is the load proper for each horse, expressed in wagons; and this value of X has been given in the following table:—

TABLE, GIVING THE LOAD PROPER FOR A SINGE HORSE, EXPRESSED IN WAGONS, ACCORDING TO THE STATE OF THE WEATHER.

Value of F in lb.	Value of W in tons.	Value of P in lb.	Value of $\frac{P}{F \times W}$	Value of X.	State of the weather.	Remarks.
25·45	3·43	188·27	$\frac{188·27}{25·45 \times 3·43}$	2·09	Fine.	Rails in good order.
31·22	3·43	188·27	$\frac{188·27}{31·22 \times 3·43}$	1·75	Fine.	Road wet, and rails greasy.
26·86	3·43	188·27	$\frac{188·27}{26·06 \times 3·43}$	2·04	Fine.	Rails and road in tolerable order.
35·54	3·43	188·27	$\frac{188·27}{35·54 \times 3·43}$	1·54	Wet.	Road and rails in very bad order.

We observe that in several pages of this section the erroneous velocity of 2·40 miles per hour is made use of.

The eighth section contains a summary of those preceding, but as we have already considered these so minutely, it may be unnecessary to remark particularly on the summary.

The remainder of the work is occupied by an investigation into the barrowing system, our notice of which we must defer till next month, and in the mean time we may safely recommend the work to the younger branches of the profession, as exhibiting a very neat, clear, and simple application of algebraical calculation to subjects of practical inquiry.

For the reasons already so fully stated, we cannot advise dependance on the gross results to be derived from the author's mode of calculation, but whenever the student shall either from his own, or the experience of others, have acquired sufficient *data* to found his calculations upon, then the method of handling the subject generally, and particularly of adapting calculations to the practical facts on which they are established, will be found exceedingly useful.

A great deal of useful information may also be gleaned from the observations detailed in the work, and the young engineer in particular, can scarcely fail to have his knowledge of the subject improved by a perusal.

Report of a Proposed Line of Railway from Plymouth to Exeter, over the Forest of Dartmoor. By JAMES M. RENDEL, C.E. Plymouth: Stevens, 1840.

This is a well drawn up report, but we can do no more than call attention to the mode proposed of working the inclines, respecting which we may also mention that a similar plan is described in the First Volume of the Journal.

"From the point of divergence of the Tavistock branch, the main line ascends to Dartmoor; the prevailing gradient being 1 in 38, and the plane 5 miles 860 yards. This part would be worked as one continuous plane, by two water wheels, each equal to 160 horse power, constructed at the head of the plane, and supplied with water as hereafter to be described. The rope to be used for drawing the trains up this plane would be what is technically called an end rope, of the whole length of the plane; being very little longer than the rope similarly used on the London and Blackwall Railway, upon which there is an enormous passenger traffic."

"To insure a supply of water for working the water-wheels before described, by which the trains are to be drawn up the two great inclined planes, at a velocity of not less than from 15 to 20 miles an hour, I propose to throw dams across the gorges of the following valleys on Dartmoor, viz.—across the Blackabrook valley east of the prisons of war, the Cowsick valley above Two Bridges, and the East Dart valley, about three miles north of Post Bridge. These reservoirs would have an area of 255 acres, with an average depth of 20 feet, and contain a sufficient quantity of water, during a continued drought, to pass eight trains per day up the planes, for three months; their height above the wheels is from 50 to 300 feet. The great depth of these reservoirs will cause their supply of water to be independent of the severest known frost; whilst from their height above the Railway, the leats by which the water is conveyed to the wheels, will have so quick a descent as to prevent all chance of the passage of the water being interrupted by either frost or snow. The wheels will work under ground, or rather, in chambers under the Railway, and would not therefore be affected by weather."

The Process of Blasting by Galvanism, addressed to the Highland and Agricultural Association of Scotland. By MARTIN J. ROBERTS, F.R.S.E.

In mentioning that Mr. Roberts has been as successful in Scotland with blasting by Galvanism, as Col. Pasley has been in England, we say enough for the merits of Mr. Roberts. We may farther observe that this small pamphlet contains in addition to a good description of the process, several illustrative plates.

Scott's Practical Cotton Spinner and Manufacturer. By ROBERT SCOTT and WILLIAM SCOTT. Preston: Livesey, 1840.

We are glad to perceive that a useful class of works by practical men are springing up in the manufacturing districts, and likely to prove of great benefit. The book now before us is a collection of calculations applied to the several parts of cotton spinning machinery, adapted equally to the use of the engineer and the manufacturer. It seems indeed to be a most useful work.

A Glossary of Civil Engineering. By S. C. BREES, C. E., &c. London: Tilt, and Weale, 1840.

Mr. Brees seems to have been so successful with his previous works, and rendered so confident by his good reception by the public, that after a very short interval he is again before us. The present work is one of less pretensions than those usual emanating from his pen, being a glossary of the terms used in civil engineering, adapted for popular use, and that of the younger members of the profession, and very useful as a handbook of reference. It is copiously illustrated with woodcuts, some of them of considerable artistic pretension. We should have wished that Mr. Brees had given a little more room for mining terms, of which a manual is much wanted.

The Martyr's Memorial, Oxford. By S. S. SCOTT, and W. B. MOFFATT Architects.

This fine monument is an elevated cross in the pointed style, of majestic proportions, having in the second story statues of the three bishops. The cross is raised upon a series of steps, and we are glad to observe without an iron railing round it. The irregular pinnacles of the church in the back ground are made by the cross to look rather awkward, and should be made more symmetrical—we should suggest, by the gentlemen who have so well fulfilled their previous task.

Ricauti's Rustic Architecture, No. 5. London: Grattan and Gilbert, 1840.

Mr. Ricauti goes on with success in his undertaking, he has shown completely how much beauty may be combined with economy by the simplest means. Even the woodman's axe is an efficient instrument in Mr. Ricauti's hands for giving a picturesque appearance to unbarked trees and small branches. It appears to us that in several of the plans Mr. Ricauti might have greatly promoted the convenience of the arrangements by a few slight alterations.

The Dominican Convent and Chapel at Atherstone, Warwickshire. By JOSEPH HANSOM, Architect.

These buildings were finished in August 1839, and consist of a pile of mixed character in the pointed style. The turret or spire attached to the chapel is a new arrangement of the details of the pointed style, but it appears to us to be rather out of character with the remaining portions.

A Brief Survey of Physical and Fossil Geology. By Frederick John Francis. London: Hatchard, 1839.

This small work is a republication of two lectures delivered at Literary Institutions, and therefore well adapted for popular circulation. The object of such a performance almost places it out of the range of criticism, particularly, whereas in this instance, the work seems carefully compiled.

LITERARY NOTICES.

Mr. Standish Motte, the Parliamentary Barrister, has published at the request of the Aborigines Protection Society, a system of registration for the Aborigines of our Colonies, which, although it recommends engineers to be sent out to the colonies, hardly comes within our province; we can say, however, that it contains many profound and original views.

Mr. Wyld, the Geographer, in addition to his national work on the Campaigns of the English Armies in the Peninsula, has recently published several authentic Maps and Plans of the Seat of War in the East.

Mr. Tyas is about to publish a cheap Map of England in shilling sheets, from the graver of Mr. Jobbins, and on the scale of a third of an inch to a mile. From the specimen it seems likely to prove a useful work.

The new Catalogue of Mr. Weale contains the most copious list yet published of works on engineering and architecture.

NOTES OF THE MONTH.

With the rage for promenade concerts, it is scarcely surprising that architecture should have been a little affected with the mania. The Princess's Theatre in Oxford Street, has been opened at present for concerts; it is a gorgeous building in the style of the revival; finished by Mr. Thomas Marsh Nelson; the original design, we believe, being by Mr. Duncan. The ground in Leicester Square, next to the Zoological Society, is being cleared preparatory to a building for promenade concerts.—The Adelphi Theatre has had a new front put on, we believe from the designs of Mr. Beasley. It is a novelty admissible in such a style of decoration, but the pilasters of the lower arch have been unfortunately contracted, from the interference of a neighbour who possesses a right of way.—Oxford Street is being improved by the erection of several new shops on a large scale.—The Architectural Society commenced its proceedings on Tuesday the 3rd.—Mr. Baily has just finished two statues, one of Sir Thomas Brisbane, for New South Wales, and a statue of a distinguished Irish judge for Dublin.—The foundation has been laid of the new Collegiate School at Liverpool.—The British Museum has received several accessions to its Egyptian collections; a fine colossal head has been erected over the doorway, which produces a fine effect.—Considerable stir is being made as to the formation of new railways, but we fear that the Standing Orders will prevent their making much way this Session. Among others we mention, the London and Manchester, the Cambridge and Norwich, through Thetford, the Lincoln and Nottingham, the Devon and Cornwall lines, the Edinburgh lines, one from Mr. Marshall's Slate Quarries to Ulverston.

ON TIDE GAUGES.

Sir,—In your October number you have, somewhat incautiously, given insertion to a letter most injurious to my character, signed "James Inglis, London," on the subject of my new Tide Gauge, a description of which was communicated to the Royal Society by the Rev. Professor Whewell, of Cambridge, and printed in their Transactions for 1838.

Divested of those portions of it which, being merely ornamental, may be safely passed over without remark, Mr. Inglis's letter contains an assertion and an implication, to each of which I must give a separate reply. It is *asserted*, that in answer to various letters which I had addressed to Mr. Mitchell, I received from him a description and drawings of his machine, by the aid of which my own was constructed. In reply to this assertion, I beg to state, distinctly and simply, that I never had the slightest correspondence or communication with Mr. Mitchell in my life, either directly or indirectly, and challenge either him or his friend, Mr. Inglis, to produce one scrap or syllable of any letter of mine in evidence of such correspondence. I may also add that I never saw any drawing or description of Mr. Mitchell's tide gauge, and that I have not, at this moment, the least idea of its principle.

The *implication* contained in the letter of Mr. Inglis is, that as my tide gauge was merely a copy taken from that of Mr. Mitchell, with little or no claim either to originality or improvement, it was not only superfluous but unjust that any description of that machine should have been permitted to appear, with my name attached to it, in the Transactions of the Royal Society. On this latter point I cannot do better than transcribe the document itself which was the immediate occasion of my communicating that description to the public. This document was a letter addressed by Major J. B. Jervis, to the Hydrographer to the Admiralty, Captain Beaufort, R.N., and by him enclosed to me, with the following note:—

"*Admiralty, Feb.* 23, 1838.

"My dear Sir—The enclosed note is from the Engineer Officer who has been appointed to succeed the present Surveyor General of India.—Do me the favour to read it, and tell me how far you can assist us, and when.

"Yours very truly,

"F. Beaufort."

(Note enclosed.)

"To Capt. F. Beaufort.—My dear Sir—I rejoice to say that I have found the Court of Directors disposed to give the fullest effect to our wishes in respect of the registry of the Tides, throughout the whole line of coast of India, and wherever their authority extends. I stated my own views to the Chairman, Sir James Carnac, to Mr. Melville, and other influential persons, and fully explained to them that unless the thing were well done, it were far better let alone; whereupon they directed the dispatch and instructions which they had already prepared for the Governor General and Bombay Government to be withheld, and empowered me to arrange with Mr. Whewell, Mr. Lubbock, and yourself, to propose any course of proceeding and measures we thought advisable, and point out the requisite apparatus. With such a magnificent carte blanche, with such superior co-adjutors, it would indeed be a reproach to be either supine or unsuccessful. Mr. Whewell heartily concurred with us on the importance of having the Tides registered with a far greater degree of precision, and at shorter intervals, at several additional points on the shores of India, Arabia, Persia, the Eastern Islands, and China; and was of opinion that at such stations exact meteorological observations should also be made contemporaneously, and these punctually and promptly transmitted home in duplicate every month, to the Admiralty, to the India House, and to the Royal Society. Although Mr. Mitchell's Tide Guage, erected at Sheerness appears to Mr. Whewell to answer sufficiently well for the subordinate stations, he laid great stress on the necessity of something far superior to this, for those stations where it was intended to have more precise and frequent measurements. He spoke to me in terms of high praise, as did also Captain Washington, of Mr. Bunt's apparatus, but said that he much regretted that it had not been published, although he had been in treaty with the inventor to give it to the public with a complete description." ...... "It is the chief object of this epistle to move you to write to Mr. B. to publish his descriptions and drawings. Do let me urge you to use all your influence with him in so good a cause,—and if he would permit a working model to be made under his own eye, it would greatly assist the native artificers of India and expedite the construction of the several tide gauges. The Directors would readily defray the expense of such model.

"Yours, sincerely,

"J. B. Jervis."

In compliance with this earnest solicitation, I immediately prepared and forwarded to Professor Whewell drawings and a description of my tide-gauge, which were soon afterwards inserted in the Transactions of the Royal Society. In doing so, I acted in opposition to the advice of some of my scientific friends, who thought that I was entitled to secure to myself the fruits of so much labour and study. A few months afterwards I was requested to superintend the construction of two machines, similar to my own, for the East India Directors, agreeably to the tenor of Major Jervis's letter, already quoted; with which request I also complied without hesitation. These machines were completed and intrusted to the care of two scientific officers in the Company's service, Lieuts. Elliott and Ludlow; who, after visiting Bristol for the purpose of inspecting my original tide-gauge, sailed with the two new machines for India in February last. From one of these gentlemen (Lieut. Elliott, who had, I think, seen Mr. Mitchell's tide-gauge,) I have received several letters, in all of which he speaks of my machine in terms of the highest commendation.

Immediately on the appearance of Mr. Inglis's letter, I inserted a reply to it in several of the Bristol newspapers, and sent a copy of my reply to Professor Whewell, from whom I received the following note:

"*Trinity College, Cambridge, Oct.* 9, 1840.

"My dear Sir—I have received your slip of the Bristol Standard, and am full of astonishment at the malignant absurdity of Mr. Inglis. Even on his own letter his conduct has this character; for no amount of correspondence with Mr. Mitchell could have deprived your machine of its vast superiority."...... "I am glad you have replied to him so calmly. Captain Beaufort's and Major Jervis's letters must satisfy every body, and do you justice."

I now beg leave to request of you, Mr. Editor, that you will write immediately to Mr. Mitchell, and inquire of him what letters of mine he is able to produce in confirmation of Mr. Inglis's statements; whether he acknowledges any friendship or acquaintance with that gentleman; and whether he will favour you with his precise address: and when you have received Mr. Mitchell's reply, that you will be pleased to communicate it to the public.

I am, Sir, your obedient servant,

Small Street Court, THOS. G. BUNT.
Bristol, October 15, 1840.

[In addition to Mr. Bunt's letter, we may ourselves mention that we have written to Mr. Mitchell, and received from him a complete denial that he was ever in correspondence with Mr. Bunt, or that he authorized Mr. Inglis to circulate such statements. In closing this correspondence, therefore, which must be most satisfactory to the claims of Mr. Bunt, we have to express our regret that we should, by the insertion of Mr. Inglis's unfounded charges, have been the means for a moment of raising a doubt as to the originality of Mr. Bunt's invention. We must say that we have never seen a case of grosser or more wicked representation than this by Mr. Inglis, to call it by no other name, and we cannot forbear expressing our severe reprobation of such unwarrantable conduct. We hope that, if he has any feeling of shame about him, he will see the propriety of apologizing as publicly to Mr. Bunt as he has been the means of annoying him.—EDITOR.]

STATE CAPITOL AT RALEIGH, U.S.

SIR—Under the head of AMERICA, at page 52 of the volume of 1837-'8 of your learned work, entitled "*The Civil Engineer and Architect's Journal,*" the *State Capitol* in this city is introduced to the attention of your readers, in an extract of a letter from Ithal Town, Esq., Architect, dated New York, Nov. 3, 1837.

As a Senator, myself, of the State Legislature which ordered its erection, and residing on the spot, I have watched its progress with pride and pleasure, and beg leave to tender to you my thanks and those of my State for even that brief notice of this noble edifice, confessedly unrivalled by any State Capitol in this country. But as I am very sure your readers, and especially artists, would be pleased to see in your Journal a more full and satisfactory description of the building than Mr. Town's letter furnishes, I here copy such a description from the "*Star,*" a weekly newspaper published in this city, and dated 25th March last. It was furnished for publication, at the request of the editor of that periodical, and is known to be from the pen of David Paton, Esq., some years since of Edinburgh, Scotland, the ripe scholar and scientific architect, under whose daily and untiring supervision and direction, for 5¼ years past, this great public work has been executed, and is now nearly completed—a work which entitles him to rank among the first architects, theoretical and practical, of this or any other country, and his private virtues and retiring worth, claim for him universal esteem.

I would not, if I could, detract aught from Mr. Town; his professional fame is the property of my country; but then, "let justice be done, though the hearers should fall." I can not, I will not, conceal the fact, that Mr. Town is mistaken when he supposes that the architectural honour of this fine building belongs to him. It is an honour, indeed, of which any artist might be proud, because it is so perfect and durable a monument of his fine taste and great ability. But this honour belongs to David Paton, Esq., and to none else—and it will wear well, because he has earned it well, and left to others and the work itself, to inscribe his name upon the scroll of fame. Mr. Town did, indeed, furnish a draft for the building, and, likewise, most fortunately for the people of this State, engaged the services of Mr. Paton, 10th Sept., 1834, to execute it; but he is probably unaware that his draught was laid aside, and the whole of the details, alterations, and working drawings, made and executed by Mr. Paton himself. But to the description:—

"The length of the State Capitol in this city, (Raleigh) from north to south, is 160 feet, and from east to west 140 feet; the whole height is 97½ feet. The columns of the east and west porticoes are eight in number, and are 5 ft. 2½ in. in diameter, and 30 feet high, and standing on a stylobate 18 feet high, which, as well as the entablature, which is 12 feet high, are continued round the building; and the details are of the Temple of Minerva, commonly called the Parthenon, which was erected in the Acropolis of Athens, under the government of Pericles, about 500 years before the Christian era. The Rotunda, in the centre of the Capitol, is formed into an octagon at top, which is built of polished granite and surmounts the building, ornamented with Grecian cornice, and its dome is crowned at top with a decoration similar to that of the Lanthern of Demosthenes at Athens.

"The interior of the Capitol is divided into three stories. The basement consists of ten rooms, eight of which will be soon occupied by the Governor, the Secretary of State, the Comptroller, and the Public Treasurer; each having two rooms of the same size and finish, which, as well as the corridors, are of the Roman Doric, and are completely fire-proof, by arches springing from pillars and pilasters of polished granite. The east and west vestibules are richly decorated with granite columns, antæ and staircases; all of polished granite, copied from the Ionic Temple of Ilissus, near Athens; also two committee-rooms.

"The second or principal story consists also of ten rooms, two of which are appropriated, one for the Senate Chamber, and the other for the Hall of the House of Representatives, which are 38 ft. 6 in. in height, having galleries, and their walls are contained in areas of the same size, 59 ft. by 55½ ft., having retiring rooms taken off the corners, four in the former, and two in the latter. They, as well as the rotunda and vestibules, are respectively of the octagon Tower of Andronicus Cyrrhestes, of the Temples of Erechtheus, Minerva, Polias and Pandrosus, in the Acropolis of Athens, near the Parthenon. The other rooms on this floor are appropriated for committee rooms.

"The third, or attic story, contains a room for the Supreme Court of the State, and one for the State Library, which are situated in the east and west wings; which, as well as the galleries and other apartments, will be approached by granite steps, and the lobbies and Rotunda are lit with cupolas; the whole of which is now in progress, so as to be ready for the next meeting of the Legislature.

"Before concluding, it may be well to remark that the stone with which this edifice is constructed is of the toughest and hardest description, containing less iron than any stone I have ever seen; hence it presents a beautiful cream colour, of a much warmer tint than marble. It is also variegated with beautiful veins of quartz, the conformation of which deserves notice, having every appearance of having been separated and again knit, by some trembling or concussion in its formation; and from the circumstance of no petrifaction being as yet discovered, whether of the animal, vegetable, or mineral kingdoms, geologists would term it a primitive, if not a transition, formation.

With regard to the cost of the Capitol; the Legislature have appropriated 500,300 dollars; it may cost a little more by the time it is finished. The President's house at Washington cost, without furniture, 665,527 dollars; and the Federal Capitol cost 2,596,500 dollars, both of which have to be repeatedly painted, at a cost of upwards of 12,000: and this has to be done to prevent the disintegration of the stone, they being built of soft, loose, friable and porous sandstone.

ARCHITECTUS."

City of Raleigh, North Carolina,
United States of America,
22nd November 1839. J. B. HINTON.

RECOVERY OF THE CHAIN CABLE OF HER MAJESTY'S SHIP HOWE, AT SPITHEAD.

THE chain cable of the Howe having by an unfortunate accident run entirely out of the hause-hole on Friday morning last, after the anchor was cast, and fallen to the bottom, a creeper was employed to discover it, which grappled it near the buoy over the anchor. On Saturday afternoon, in compliance with a request communicated by one of the lieutenants of the Howe, Colonel Pasley sent a boat to the spot with Mr. George Hall, one of his most expert divers, and a party of men employed about the wreck of the Royal George, to attend him, who threw out a small anchor near the Howe, and then moored their boat in the supposed direction of the chain cable, by making fast a line from the stern of the boat to that cable's buoy. Mr. Hall then descended by the rope attached to the creeper, by which he found the chain, and from that point walked along the whole extent of the chain until he reached the extreme end of it, to the last link of which he made fast one of the bull ropes that had been used for weighing the fragments of the Royal George, by means of which Mr. Purdo, master-attendant of Portsmouth dockyard, and Mr. Taylor, master of the Howe, with a strong party of seamen and marines, got up the end of the chain cable first into a mooring lighter, and in the course of about two hours afterwards it was passed thsough one of the hause-holes of the Howe and properly secured. Mr. Hall went down to the bottom about half-past 2, and finished his task about 4 o'clock, and only came up twice in the mean time, to communicate with the men in the boat. It is supposed that he walked at least 200 yards along the bottom, and during this period the boat with the pump, which was constantly at work to supply him with air, being warped along in the same direction, according to signals made by him from below. This is the second time that this excellent diver has been of use to the navy at Portsmouth, having on a former occasion examined the bottom of the Vanguard after she took the ground on being towed out of harbour by the Echo steamer. As this difficult operation required him repeatedly to pass head foremost under the keel of the Vanguard, he performed it in Mr. Siebe's improved tight diving dress, but in recovering the cable of the Howe, which was comparatively an easy task, he used the common diving dress, in which he has generally worked on the wreck of the Royal George, leaving Siebe's dress to the divers of the Royal Sappers and Miners, who have been employed on the same wreck for the last three months, and whom it was desirable to send down in a tight dress, as being the safest, they not having had any previous experience like the professional divers with whom they have been co-operating.

NEW INVENTIONS AND IMPROVEMENTS.

Improvements in Steam-engines and Steam-boilers; patented by Thomas Craddock, of Broadheath, near Presteign, in the county of Radnor, Sept. 16. —The improvements in steam-engines consist, first, in an improved mode of obtaining a rotary motion from the rectilinear and reciprocating motion of the piston rod; and, second, in an improved method of condensing steam.

The improvements in boilers consist in an improved construction of boiler, and in an improved method of regulating the generation of steam.

First claim is to the mechanical arrangement of the apparatus delineated and described, whether employed for converting the rectilinear into the rotary motion, or the rotary motion into the rectilinear. In this improvement the piston rod carries two toothed racks, one being behind, on one side of the other; one of these toothed racks works into a pinion, which pinion takes into the teeth of a drum, which is firmly keyed on the main shaft, which drum has teeth over half its circumference on one side, and over the remaining half of its circumference on the other side. The mode of working is as follows: by the up-stroke of the piston-rod, the pinion, taking into the teeth on one side of the drum, brings it half round, and is released; then by the returning stroke of the piston-rod, the other rack takes into the teeth on the other side of the drum, and finishes the stroke in the same direction.

Second claim is to the exclusive right of condensing the steam or vapour of water, or other liquids, by causing it to pass into metallic tubes of small diameter, or into metallic vessels of any other suitable figure, which tubes or vessels are put in motion, either rotative or otherwise, either in air or water, independently of any motion of the carriage, boat, or vessel, to which the condenser may be attached, whereby the condensation of the steam or vapour is greatly accelerated. This condenser is composed of two chambers, connected by a bar, and supported by hollow axes revolving in bearings, which axes are connected, the one with the eduction pipe of the engine, the other with a hot well or reservoir. From each chamber a number of hollow arms diverge, which are connected together by small tubes, reaching across several times.

The condensing is performed as follows: the steam, after operating on the piston, is introduced through the chamber into the tubes; the condenser is then caused, by bearings from the engines, to revolve with great rapidity, by which means the caloric is abstracted and the steam condensed; the water resulting from which is conveyed from the other chamber, into which it flows, through a pipe into the hot well; from whence it is drawn by the feed pump into the boiler.

Third claim.—The construction and arrangement of the parts constituting the boiler.

Fourth.—The use of a separate cylinder to supply both air and fuel to the furnaces, and regulating the supply of steam to the cylinder by the pressure of steam in the boiler, in such a manner that as the pressure increases, the supply of steam to the cylinder is diminished, thereby diminishing the supply of air and fuel to the furnace. The boiler is composed of two furnaces, the sides of which are formed of ranges of hollow tubes, which are full of water, communicating at the top and bottom with rectangular reservoirs; the bottom is formed of smaller tubes, extending horizontally from one reservoir to the other, and acting as fire-bars; the top is likewise composed of tubes extending from one reservoir to the other; the ash-pit is a tank filled with water, which, by the heat from the fire-bars, evaporates, and passing up a tube into the condenser, is there condensed; thereby supplying any loss from leakage. The fuel is conveyed into the furnaces by shoots from two hoppers; upon being thrown into the hopper, it falls upon two fluted rollers, which are worked by the pinion that drives the fan; it then falls through or between these rollers, and down the shoot upon a swinging plate, which scatters it over the surface of the fire. The wind passes from the fan through a pipe to the bottom of the fire-bars. When the steam gets beyond the regular working pressure, it shuts the valve which supplies the fan cylinder with steam, and escapes through another opening into the atmosphere, whereby the pinion that works the fan is either stopped, or works very slowly, by which means the supply of air and fuel to the furnaces is very much decreased or cut off altogether; when the steam has returned to the regular working pressure, it is again admitted to the fan cylinder, which works as before. There is a suitable opening, provided with a cover, for the admission of the fire, and likewise a tube with an eye-piece of talc for viewing the fire when required. There is likewise a contrivance for burning the smoke arising from the coals when newly thrown on the fire; it operates in this manner—there is a tube which communicates with the two shoots, and at the bottom of each furnace there is a valve for shutting off the supply of air; when one or both of the furnaces have burnt bright, and fresh fuel is required, the supply of fuel and air is shut off from the other one; the smoke arising from the fresh fuel is driven, by the force of the air from the fan, through the flue into the other furnace, where it passes through the fire and is consumed.—*Inventor's Advocate.*

Improvements in the manufacture of iron and other metals; patented by Sir Josiah John Guest, of the Dowlais Iron Works, Glamorgan, Baronet, and Thomas Evans, of the same place. Sept. 28. These consist principally in the introduction of jets of steam into the puddling furnace while the iron is in the state usually called "fermentation." The success of the operation depends very much on bringing the steam in close contact with the melted iron, to effect which, wrought iron telescope tubes, sliding one on the other, are employed, the jet pipe being ¾ of an inch in diameter, and the steam pressure 15lb. upon the inch. These tubes are raised or lowered according to the quantity of fluid metal in the furnace, by means of a suitable lever. In the second place, jets of damp steam are introduced into the refining furnace, after the pig iron is melted, through the same apertures as the blast, the quantity and pressure of the steam being regulated by the quality of the metal acted upon. During this process, in order to keep the sides, bridge, and bottom of the furnace from burning, a quantity of steam is introduced upon the fluid cinders as soon as the heat is drawn, until the cinders become of the consistence of paste; this paste is then raked up against the back, sides, and bridge of the furnace, so as to fill up any cavity that may have been burned during the previous heat of iron. The use of cinders in this state keeps the iron quite clean and free from the dirt which always attends the use of clay and limestone. In this instance four jet pipes are used, ½ an inch in diameter, and steam of 20lb. on the inch. The steam may be generated in a tube or cylinder in the furnace chimney, or may be supplied from a regular steam boiler. The employment of steam in a similar manner in melting the alloys of copper and iron, and iron and tin, is also claimed, but the particular application is stated to be to the manufacture of iron, whereby a better material is obtained with greater economy. The claim set forth is for the use or application of steam forced upon or into, or in contact with the melted iron in the refining or puddling furnaces for the manufacturing of the same; also for the similar use of steam in the process of melting or manufacturing alloys of copper and iron, and of tin and iron, in such furnaces: and lastly, the application of steam to fluid cinders as described, to produce the paste aforesaid; and the use and application of the said paste.—*Mech. Mag.*

Improvements in preparing surfaces of paper; patented by Henry Martin, o Morton-terrace, Camden Town. Sept. 30. The processes constituting these improvements, are fourfold, viz.: 1. The mode of preparing surfaces of paper by combining thereon a coating of oil paint, with subsequent embossing as afterwards described. 2. The mode of preparing surfaces of paper in the manufacture of paper-hangings, by combining thereon a coating of oil paint, and afterwards printing or producing thereon the required pattern. 3. The mode of preparing surfaces of paper by combining thereon a coating of oil paint, and subsequently glazing or planishing the same. 4. The mode of producing a coating of oil paint on paper, by means of rollers. The paint used for this purpose is the same as ordinarily employed in house painting; a piece of paper of 12 yards, or other required length, is to be laid upon a table of similar dimensions, sized with one or two coats of common or superior size, and then painted with an ordinary brush; while yet wet, the surface is to be smoothed over with a dry brush, to take out the marks left by the first, and subsequently finished with a badger softener, which produces a smooth and level surface, so essential to the success of this process. In the other process, oil colour is laid on the surface of paper by passing it between two rollers, together with an endless felt; this felt in its revolution is supplied with oil colour by passing into a trough, and under a roller partly immersed in the colour; a scraper removes the superfluous colour as it rises, and levels and equalizes the colour; the paper is passed through the rollers two or three times, according to the thickness of colour required. Paper thus prepared on the surface, may be embossed with engraved dies or rollers in the usual manner, or printed with blocks, &c., for paper hangings, which may be washed with soap and water when soiled. If marbled paper is to be produced, the colours are thrown upon water in the usual manner, the effect being increased by softening off before they are dry. If the surface is to be glazed or enamelled, the oil colour is thinned wholly with turpentine, as a flatting colour; when set, it is to be mounted on a woollen cloth, cotton velvet, or other firm soft bed, and smoothed over with a pallette knife, or trowel having a very smooth surface; when dry and hard, the polish may be heightened by any of the usual methods, which will produce a beautiful surface for copper-plate printing, paper hangings, and various other purposes.—*Mech. Mag.*

Valves for Canal Locks; patented in America by William Lake, Richmond, Virginia, June 7, 1839. The patentee remarks, that "the valves of canal locks are subject to a pressure, the intensity of which is measured by the height of the head and the area of the valves; and this pressure on the common sliding-valves for locks of ordinary lifts is of such magnitude, and requires the application of so great a force to open them, as greatly to detract from the superiority which they otherwise possess."

"My improvement consists in giving such form to the valves and apertures that, by the momentary application of a very small force in opening a small orifice, I apply the hydrostatic pressure in such a manner as to open the valves. Upon the back of the valves closing the aperture through which the water flows in filling and discharging the lock, I attach a flanch of the same length as that of the aperture, and of such a width as to have the same proportion to the width of the valves as the friction of the valve on the seat has to the pressure. At the lower edge of the valve, below the flanch, I make an orifice of about one inch in width and about half the length of the valve; this orifice I open and shut by means of a lever and connecting rod."

We were about to make further extracts from the specification, but find that in so doing we must occupy more space than is convenient to allow to the subject; and after all, should probably fail to give a clear idea of the construction without the aid of the drawing; we, therefore, skip over to the concluding paragraph.

"I have represented the valve as fixed in a lock-gate, but I by no means intend to restrict myself in my said improvement to valves placed in this particular situation; neither do I claim as my invent on the manner of applying the lever and screw as exhibited in the drawing. What I do claim as my invention, and desire to secure by letters patent, is the application of the hydrostatic pressure, to open sliding valves for canal and river locks, and making such improvements in the construction of the said valves, and in the form of the apertures to which they are applied, as will adapt them to the application of this pressure, as herein described."—*Franklin Journal.*

RAILWAY CAUTION.

Sir—Being a frequent traveller on railways, and generally choosing the slow trains, I beg leave to trespass on your valuable columns by suggesting an expedient by which, in my humble opinion, travellers situated like myself may avoid the disagreeable necessity of being run over by quicker trains. The plan to which I allude is this:—that at each station on the line of railway be placed a large dial, similar to a clock face, with minutes marked upon it from 1 to 60. It should have one moveable hand of sufficient size to be distinctly visible to the guard and engineer as they fly past; the officer in attendance to fix the hand at that particular number on the dial that may denote the number of minutes which have elapsed since the preceding train passed. This signal might be illuminated at night. Or a perfect clock face might be adopted to denote the hours in addition to the minutes.

I am, Sir,
Your obedient servant,
T. W.

Kennington,
Oct. 24*th*, 1840.

ROTARY ENGINE.

An engine, upon this principle, was latelytried in Leeds, in the presence of several engineers. Its enormous power, in so small a compass, (the whole machinery, with the exception of the fly-wheel, being contained in a box 2¾ inches in depth and 10 inches diameter) surprised every one present; the speed was tremendous, making from 600 to 700 revolutions per minute. Its power was tested by placing breaks upon the fly-wheel, which was done to the extent that the shaft was actually twisted in two pieces, but no accident occurred. It is the intention of the inventor to apply the machine to propel carriages on common roads, for which purpose it appears admirably adapted; likewise for the purposes of marine navigation, where the small quantity of room it requires is a material consideration; in short, it will answer all the purposes wherein steam is required; and the expense will be considerably abridged. The inventor is Josh. Briggs, watchmaker, of this town.—*Leeds Intelligencer.*

STEAM NAVIGATION.

INCRUSTATION STEAM ENGINE BOILERS.

We are informed by *L'Echo du Monde Savant*, of the 25th of July, that M. Edouard Richard had presented to the Geological Society of France a calcareous incrustation, which must be considered of great value, as it was not formed in the boiler, but in the cylinder of the engine, and beneath the piston. The incrustation formed a disc 12½ centimetres in thickness; and in consequence of the pressure of the piston, it is so hard that it is capable of receiving as high a polish as the densest marble. It is evident, therefore, that explosions may be produced as well by calcareous concretions of the cylinders as of the boilers of steam engines. The engine from which this specimen was procured, has been used for the purpose of pumping water from the mine of Auzin, and has been built after Newcomen's plan.—In *L'Echo du Monde Savant* of August the 5th, we find a communication upon the subject of steam-boiler explosions by M. Flesselle, a retired officer of the French Marine, resident at Graville, near Havre. M. Flesselle suggests, that, in order to prevent the formation of calcareous incrustations, (which have long been considered the principal causes of accident,) some common salt or muriate of potash, should be put into the boiler with each fresh supply of water. M. Flesselle recommends this measure, because the incrustations are formed of the carbonate, the sulphate, and perhaps the phosphate of lime—(salts, insoluble, or sparingly soluble); and these salts, boiled with the muriate of soda (common salt), or muriate of potash, will undergo double decomposition with these muriates; the products being the carbonate, sulphate, and phosphate of soda, and the muriate of lime—salts all of which are soluble.

M. Flesselle says that M. Chaix, of Maurice, has invented a method of preventing explosions, which appears to have been adopted with success in the French government steam vessels; but M. F. considers that auxiliary means also are requisite—and we think he is right; for the fact we have related regarding the engine at Anzin, proves that we should avail ourselves of every cheap and simple aid to prevent the fearful accidents to which incrustations may give rise, seeing that the sulphate, carbonate, and phosphate of lime may be held in suspension by the steam—be carried by it in a state of minute molecular division even into the cylinders—and there also be deposited in the form of hard concretions.—The method of M. Flesselle, seeming founded on correct chemical principles, will, we hope, be put to the test of experience, by some of the numerous engineers of our neighbourhood. We shall feel great pleasure in recording the result.

In England the precaution taken against incrustations is an index of the density of the fluid in the boiler; but this is evidently inadequate—for the calcareous particles are conveyed by the steam into the pipes and cylinder. Perhaps some of our scientific readers will have the goodness to inform us whether the English method of preventing incrustations is identical with that of M. Chaix.—*Gateshead Observer.*

THE PROPELLER STEAM-BOAT.

This vessel was built in the yard of Mr. Dichburn, at Blackwall The engine by which her paddles, or propellers, as they are termed, are worked, was made by Mr. Beale, the engineer, at his premises at Greenwich. She is a small vessel, but very elegant in her proportions, and formed to cut through the water with great rapidity. The engine is of 24 horse power. The propellers differ from the paddle-wheels used by other steamers, in being single blades of iron, only one blade on each side of the vessel, and not a series of blades brought into the water by the revolution of wheels. Each blade is very broad and large, and dips almost perpendicularly into the water, so that the concussion formed by the blades of paddle-wheels dipping into the water at angles is avoided, and the consequent unpleasant vibration of the vessel. Directly the blade dips into the water it is forced back by an arm or limb of iron, performing a motion similar to the leg and web-foot of an aquatic bird, and by means of this motion the vessel is propelled forward. She can perform from 10 to 11 knots or miles an hour. The appearance of the propellers is like that of the legs of a grasshopper, and when in motion their action in some degree resembles the legs of that insect in its walk. One great advantage is, that the propellers occasion no swell in the water, no wake or trough in the river, and no backwater, so that no danger is occasioned to small boats by the rapidity of her progress. This vessel now runs hourly between Blackwall and Greenwich, and appears to be a great favourite, from the number of passengers she is continually conveying backwards and forwards between those places.—*Times.*

Iron Steamers.—Another iron steam vessel was launched from the yard of Messrs. William Fairbairn and Co., at Millwall, on Tuesday the 27th ult., being the second of three vessels for New South Wales, intended for the trade from Sydney to the Hunter's River. She glided gracefully into the water amid the cheers of a number of spectators, and of nearly 600 men who are employed on the premises, and was named *The Thistle.* She is 145 feet long, 20 feet 6 inches beam, and 11 feet 6 inches depth of hold, about 305 tons burthen, and drew when launched only 3 feet 6 inches of water upon an even keel.—*The Rose*, the first of the trio, has sailed for her destination, and she proved herself before leaving the river to have a speed of 13½ miles per hour, and to be one of the strongest and best sea going vessels afloat. The frames of these vessels were much admired on account of their great strength, as well as the manner in which the whole was put together. The engines, which are of 50 horse power each, were also manufactured, and the whole of the fittings executed by Messrs. Fairbairn and Co., within the same premises. The extent of work which was in progress in the yard, and in the engine manufactory, &c., seemed to surprize many of the gentlemen present, who remembered the place in which these operations are now carried on as a piece of marsh land overflowed by the tide little more than four years ago. Within this period the whole of the extensive workshops and iron foundry have been built. Thirty-one iron vessels, to the amount of 6100 tons have been constructed, and steam engines to the extent of 1260 horse power have been manufactured.—An iron schooner intended for the coasting trade from London, and various steam boats, are now in course of preparation, so that it seems this material is making rapid strides in the public estimation for the purposes of ship building.

War Steamer.—It will be recollected that the steamer of war *Polyphemus*, of 800 tons burthen, was launched at Chatham, on Monday the 28th of September, the same day that the *London* of 92 guns was launched, the former vessel proceeded up on the following Thursday, the 1st of October, to the engineering establishment of the Messrs. Seawards and Capel, of London, and they have completely equipped this fine vessel with engines of 200 horses power, with all her fittings, spare gear, implements and stores, and coal boxes of wrought iron to contain 220 tons of coals, in the short space of 22 working days; being the shortest time upon record that a vessel of this magnitude has been fitted. She proceeded down by steam to Chatham on Wednesday the 28th instant, to take in her masts, being quite completed in her machinery; it is considered that it would require a period of six months in any port of

Great Britain to fit a vessel of war of the same magnitude. There were about 220 men employed by the Messrs. Seawards on the vessel; her engines are upon the same system as those of the "Gorgon, Cyclops, Alecto and Prometheus." The "Polyphemus" will be immediately armed with two 10 inch guns, and will proceed directly to the Mediterranean.

Navigation of the Trent.—An attempt is about to be made to revive the steam navigation of the river Trent. There were packets on the river about twenty years ago, but the extreme shallowness of the water in dry seasons between Nottingham and Newark, frequently interrupted the navigation.—*Hull Advertiser.*

Great Western Steam Ship Company.—We understand that some of the experimentalizing Directors of this Company, have resolved on adopting the Archimedean screw for the great iron ship, and are now reconstructing her at an enormous expense, for that purpose. We need hardly observe, that this course has been adopted without the sanction of the Proprietors.—*Bristol Mirror.*—[How many more changes and whims ?]—Ed. C. E. & A. Journal.

Steamers in the Pacific.—Extract of a letter from Captain Peacock, dated on board the Pacific Steam Navigation Company's steam vessel *Peru*, lat. 9 15 N., long. 25 50 W., out 14 days from Plymouth:—"The *Peru* has hitherto had a most prosperous voyage, answering in every respect my most sanguine expectations."

Calcutta.—A Company has been formed at Calcutta for establishing two steam ferry boats upon the river Hooghly with chains, upon the principle of Mr. Rendel's floating bridges at Plymouth, Portsmouth, and Southampton; and orders have been sent to this country for their purchase. We have great pleasure in stating, that the contractors are Messrs. Acraman, Morgan & Co., of the Bristol iron works; their competitors having been Messrs. Fairbairn, of London, and Messrs. Jawcett and Co., of Liverpool.—*Bristol Mirror.*

Sicily.—On Thursday, the 15th ult., was launched at Mr. Pitcher's yard, at Northfleet, the *Mongibelle*, a vessel of 500 tons burden, for the service of the Steam Navigation Company, for the kingdom of the two Sicilies. It is intended to fit the *Mongibelle* with a pair of Messrs. Maudslay, Sons, and Field's patent double cylinder engines, of the collective power of 200 horses.

America.—Two large steam-ships are building at New York for the Spanish government, and one for the Russian. Mr. Norris, the engine manufacturer of Philadelphia, has received an order from Frankfort-on-the-Oder for 15 of his best locomotives. Thus American ingenuity in steam machinery is prospering.—*Times.*

Canal Steam Navigation.—The experimental steamer, at present on the Forth and Clyde Canal, was lately docked for the purpose of making certain alterations on the propeller. On the former occasion the floats were fixed at an angle of 45 deg. to the shaft of the propeller, which gave, of course, a progressive motion from six feet in each revolution, the diameter of the propeller being two feet. On the present occasion, the floats were placed on the shaft at a more obtuse angle, so as to reduce the progressive motion six to four feet. On Friday week, the boat was got under way from Lock 16. To conduct to a satisfactory conclusion, of course, the pressure of steam in the boiler was made the same as on the first experiments, viz., 54 lb. on the square inch; and the result of this change in the angle of the floats to the shaft, was found to be an acceleration of speed of 20 per cent., or rather more, as compared with the first experiments. That is, when the floats are placed at an angle of 45 deg. upon the shaft, the speed was found to be five miles an hour; now, when the angle was rendered more obtuse so as to produce four feet progressive motion, it was found that the speed was at the rate of six miles an hour. The result was extremely satisfactory to all the gentlemen present, confirming, as it did, their former anticipations; and the boat has again been laid up preparatory to other alterations which are contemplated, in order, experimentally, to demonstrate the most efficient angle at which the floats should be placed upon the propelling shaft.—*Paisley Advertiser.*

Improvement in Ship-building.—The *Roseanna*, a new ship, lately built by Mr. Jackson, at the South Shore, is the first vessel ever entirely fitted with iron lower-deck beams. They are remarkable for their strength and neatness, and above all, give additional room for stowage, equivalent to 12 inches depth of hold. It is by such practical combinations of wood and iron that we may expect to compete with other nations more highly favoured with shipbuilding; and we advise every man who takes an interest in the "wooden walls" to go and judge for himself. The *Roseanna* lies at the south-west corner of the Brunswick Dock.—*Liverpool Albion.*

ENGINEERING WORKS.

New Aqueduct at Dijon.—It is stated in a letter from Dijon, that the experiment made there of the aqueduct which is to conduct the water from the fountain of Rosoir to Dijon, a distance of 12,610 metres (about 13,700 yards) completely succeeded. Crowds of people assembled on the day the aqueduct was to be opened, to wait for the coming of the water, which was three hours and a half in flowing through that distance.—*Inventors' Advocate.*

The Fleet Sewer, Blackfriars Bridge.—A meeting of the City Commissioners of Sewers took place at Guildhall on Tuesday the 13th ult., for the purpose of taking into consideration Mr. Walker's plan of a culvert at the mouth of Fleetditch, adjacent to Blackfriars Bridge, as a remedy for the very great nuisance occasioned by the want of some scientific application. After some discussion in the committee, the Commissioners of Sewers agreed to the adoption of Mr. Walker's plan of the culvert by a majority of about 15 to 3. The apprehensions so generally entertained of the opposition of the Commissioners of Sewers to the enlightened project of the President of the Civil Engineers, are thus very agreeably and permanently removed.

Herefordshire and Gloucestershire Canal.—A general meeting of the proprietors of this canal was lately held at Ledbury. The report on the state of the works was very satisfactory, the committee expressing their conviction after a careful survey, that the main part of the line between Ledbury Wharf and Ashberton, upon which the heaviest portion of the works occurred, would be completed within the estimated cost, notwithstanding that the payments for land had been much larger than was expected. The three locks, communicating with the summit level, would be completed before November next, when the trade of the canal would be brought up to the town of Ledbury, from which an immediate increase of traffic was anticipated, and by the end of August, next year, the canal would be opened for the conveyance of goods to the distance of 7½ miles beyond Ledbury, by which extension the trade would, in all probability, be doubled, if not trebled. When it was recollected that the present annual average receipts of the canal, subject as it was to suspension and loss of trade for many months of the year from want of water, was £1,800, the committee anticipated a profitable traffic on the completion of the whole of the works. The estimated expense of the line to Hereford was £76,000, of which sum £45,000 was to be raised by preference shares, and they recommended that the remainder should be obtained by mortgage at five per cent. upon the tolls of the canal. The report concluded by a reference to the completion of the Birmingham and Gloucester Railway, which would open a direct communication with all the large manufacturing towns of the north, and thus operate most beneficially upon the interests of the canal. By the statement of accounts presented to the meeting, it appeared that the receipts amounted to £21,477 5*s.* 5*d.*, and the expenditure to £21,296 3*s.* 4*d.*, leaving a balance in hand of £181 2*s.* 1*d.* Mr. Ballard, the Company's engineer, read a satisfactory report on the state of the works, the leading features of which are embraced in the statement of the committee. The report was unanimously adopted, and a resolution passed for raising the sum of £35,000, in the manner suggested by the committee. Votes of thanks were then passed to the committee (who were re-appointed for the current year) and to the Chairman, after which the meeting separated.—*Midland Counties Herald.*

PROGRESS OF RAILWAYS.

Dublin and Drogheda Railway.—We are happy to announce that the Dublin and Drogheda Railway Company made their first contract on Friday last. The Messrs. Jeff of Lanarkshire were declared the contractors for the part of the line between the Royal Canal and Raheny, on very favourable terms for the Company, and for an amount less than the estimate of Mr. Macneill, the engineer-in-chief. The competition was a very brisk one, there being no fewer than seventeen tenders for the work, and from some of the principal contractors on the great lines in England and Scotland, as well as from some very respectable Irish Companies.—The parties selected have been engaged extensively on the Ballochine Railway, the Monkland and Kirkintilloch Railway, and have just completed a large work to the amount of thirty or forty thousand pounds, on the Wishaw and Coltness Railway in Scotland. Mr. Hart, a contractor on the Great Western Railway at Box, near Bath, made so satisfactory a tender, and so close in amount to that by the Messrs. Jeff, (we hear it was within five pounds,) that the Directors thought it right, with a view of encouraging such competition, to hand him a gratuity of £50, with an assurance that they will be happy to deal with him on a future occasion.—*Dublin Evening Mail.*

Norfolk, Suffolk, and Cambridgeshire Railway.—Considerable exertions are being made in these counties for getting up subscriptions to form a railway to Norwich and Yarmouth, in continuation of the Northern and Eastern Railway from Cambridge. The latter line it is expected will be opened to Bishop Stortford in June next.

West London Railway.—An adjourned general meeting of the proprietors in the West London (late Birmingham, Bristol, and Thames Junction) Railway Company was held in London on the 12th ult., to receive the report of Mr. R. Stephenson, the recently appointed engineer, on the state of the works. The chairman explained that the report of Mr. Stephenson was not yet prepared, but that the secretary would read to the meeting the report of the directors. It stated that it was proposed to make two extensions of the line, one to the Thames, (the original line stopping short of the river by about a mile and a half,) and the other to Knightsbridge; the extensions to be undertaken by a separate company. The directors calculated that £140,000 would be sufficient to accomplish the object. Both companies to be amalgamated when the whole of the works were completed, or as soon after the extension company had obtained an act of incorporation as the proprietors of the two bodies might consider fit. The report was unanimously adopted, as was also a series of resolutions in respect to the mode of issuing the new shares for the raising of the additional capital. It was explained that the amount of arrears due upon calls was £14,437. The meeting adjourned to the 14th November, to receive Mr. Stephenson's report.

Opening of the Taff Vale Railway.—The public opening of the completed portion of this interesting and important line, between Cardiff and Navigation House, nine miles from Merthyr, took place on Thursday the 8th ult. The manner in which the works on the line are executed, drew forth frequent expressions of admiration from the party. The tunnel and viaduct at Quaker's Yard are, indeed, noble specimens of engineering skill; the viaduct across the Taff rises to the height of 120 feet, and is built on six massive arches, the masonry of which is in admirable keeping with the character of the surrounding landscape. The tunnel which passes under Godre-y-coed is 500 yards in length; it was brilliantly illuminated for the occasion, and as the company passed through it, preceded by the band, the effect produced by the echoes of its walls and roof, and the glare of upwards of 2,500 lights, was striking and novel in the extreme. The line is differently constructed from the Great Western, the company having, on account of the number of curves which the face of the country rendered necessary, adopted the narrow gauge, and the rails being laid on chairs affixed to transverse sleepers. The travelling is easy, and will safely admit of a speed of from forty to fifty miles per hour. The carriages, which are admirably constructed, were built by our respected fellow-citizen, Mr. Walter Williams, and the two engines at present on the line, the *Taff* and the *Rhondda*, by Messrs. Sharp, Roberts, and Co., of Manchester.—*Bristol Mercury.*

Further Opening of the Manchester and Leeds Railway.—The first portion of this line, which was opened in July, 1839, was a length of about fourteen miles, from Manchester to Littleborough; and on Monday 5th ult., another portion was opened, to the extent of 27½ miles. This portion of the line commences at Hebden Bridge, about nine miles from Littleborough, and terminates at Mormanton, where it joins the North Midland Railway, about fifty miles from Manchester.—*Manchester Guardian.* The *Leeds Mercury*, in noticing the further opening of this line of railway, says,—"We speak on the highest authority when we say, that this railway is the greatest triumph of engineering science over the obstacles interposed by nature, presented by any railway in the kingdom. The high chain of hills which separates the counties of York and Lancaster is only intersected by one valley, namely, the valley of the Calder, and that so narrow and winding, so lined with towns and villages, and so preoccupied by the turnpike road, the river, and the canal, as to make it exceedingly difficult to carry a railway through it. Yet, by embankments and cuttings, by removing rocks and building up arches, by occasionally diverting the river and the road, and often crossing both, by piercing the hills with short tunnels, and taking first one side of the valley and then the other, a line has been constructed not only capable of being worked by locomotive engines, but of being easily and advantageously worked. There are no objectionable curves, and there is not one gradient having half the inclination of those on the Liverpool and Manchester Railway. The line is somewhat circuitous, and this is its only disadvantage; a disadvantage which the speed of locomotive travelling reduces to insignificance. The engineer by whom the line was planned, and under whose superintendence it has been executed, is the celebrated George Stephenson, whose genius and unparalleled works we have so often had occasion to notice with high admiration. Under him Mr. Gooch, one of his pupils, has been employed as resident engi-engineer, and has displayed abilities equal to the execution of the greatest undertakings. The managing director, who has given up his whole time to the superintendence of the work, is Robert Gill, Esq., to whose remarkable energy, zeal, and talent, the company are very greatly indebted for the completion of the work within so short a period."

Birmingham and Gloucester Railway.—The railway from Cheltenham to Gloucester is now completed, or at least one line of rails is permanently laid down through the entire distance, and along these several experimental trips have been made during the past week, wsth the most complete success. The first of these took place on the 17th ult., and the further opening of the line for the public will certainly take place on the day already announced, viz., the 2nd of November.—*Cheltenham Looker-on.*

PUBLIC BUILDINGS, AND IMPROVEMENTS.

ROYAL EXCHANGE.

This building appears at length likely to be commenced; the following tenders for the foundation were received, and that of Mr. Webb accepted.

Webb	8124		
Grimsdale	8738	6	
Cubitt	8984	14	
Little & Son	9423	1	8
Warde	9586	17	
Piper	9979	16	4
Grissell & Peto	10165	5	4
Lee	10387		
Bridger	10627	6	8
Baker & Son	10932	3	4
Bennett	11181	9	6
Winsland	11302	6	8

The New Riding-house and Stabling in Windsor Park.—This extensive building, the expense of which is to be defrayed by the Parliamentary grant of seventy thousand pounds, is now fast approaching towards completion. Some delay has been occasioned in consequence of extensive alterations in the roof of the stabling on the southern side of the riding-house having been suggested by Prince Albert a short time since. The woodwork of the roof of this portion of the building, which was then nearly completed, was observed by his Royal Highness to be discernible (from the interior) through the windows along the top of the south side of the riding-house; and as this was considered to be an "eye-sore," and highly disapproved of the Prince, the building was unroofed and its height reduced upwards of three feet. The riding-house is one of the most extensive in the kingdom; its dimensions being as follows:—height, 38 feet; width, 52 feet; and its length upwards of 170 feet. The frontage of the whole pile facing the Home Park is nearly 300 feet. Numerous bed-rooms for the grooms and stable boys in the service of Her Majesty have been erected over the riding-house. These are of very small dimensions, many of them not being more than ten feet by nine. Their long line of windows extending the whole length of the roof, and discernible from any point a view is obtained of the building, tends considerably to detract from the beauty and general harmony of the structure. Her Majesty and Prince Albert, who have occasionally visited the riding-house and stables during the progress of the works, have expressed themselves much pleased with the economy of the whole of the arrangements.—*Times.*

Improvements on the Exterior of the Mansion-house.—Scaffolding has been erected in front of the Mansion-house by direction of the General Purposes Committee, for the purpose of repairing the dilapidated masonry which has exhibited itself in several parts of the building, which has been vastly improved in appearance by the frequent application of the Bank water engines. The alteration is so great that the walls actually look in some parts as if they were whitewashed. The figures above the pillars, which had been for many years completely hidden under a mass of soot and filth, are now objects of striking interest. As they are in a measure new to the visitors and even the residents in the immediate neighbourhood, we shall briefly describe them. The centre is occupied by a female figure supposed to represent the presiding patroness or genius of the city of London. She holds in her right hand a spear. Her left hand is resting on a shield sculptured with the city arms. She supports a small sculptured castellated tower on head, and is trampling on a recumbent figure, representing her vanquished enemies. On her right hand stands the Roman Lictor and a boy holding the cap of liberty. The extreme right hand angle of the tympanum is occupied by a representation of the superiority of the British empire on the seas by a large reclining figure of Neptune, with his insignia as God of the ocean; and the spaces are filled up with an anchor and cable, &c. On the left of the centre is another female figure, attended by two boys, bearing the olive branch in her right hand, and pouring out abundance from cornucopiæ with her left; the emblems of commerce occupy the extreme angle on the left side, with casks and bales of goods. It has been considered the more necessary to make all practical improvements in the exterior of the Mansion-house, as the new Royal Exchange will much sooner than it is generally expected begin to show itself.—*Times.*

NEW CHURCHES, &c

Boston Wesleyan Centenary Chapel, erected from the design of Mr. Stephen Lewin, architect of Boston, is one hundred feet long, and seventy feet wide between the walls, and is calculated to seat two thousand five hundred persons. The design of the front is Græco Italian: a flight of steps forty-eight feet long, and a colonnade of Ionic columns in antis, and towers at each end, in which are constructed the grand staircases that communicate with the gallery, having steps five feet long, and landings at each angle five feet square; above the staircase are rooms appropriated to the Wesleyan service. There are two main entrances to the body of the chapel through spacious lobbies, with jib doors communicating with the aisles. The ground floor of the chapel contains three divisions of pews, and the sides are provided with free sittings, on each side of the communion is occupied by the schools; the pulpit is approached by two flights of stairs, at the back of the pulpit are vestries with private entrances to the same. The ceiling is forty feet high from the ground floor, it is panneled with ornamented ventilators at the angles, and a block cornice with panneled pilasters round the gallery, uniform with pannels of ceiling; the divisions and doors of the pews, &c., next the aisles are made of wainscot, framed and moulded: the orchestra is formed at the back of the gallery with private stairs and room for the singers.—The building and ground will cost upwards of eight thousand pounds.

St. Michael's Church, Basingstoke.—Extensive alterations are being made in this edifice, which is a fine specimen of the style of Parochial Church of the reign of Henry 6th. It is being entirely repaired and provided with new galleries, &c. to accommodate fifteen hundred persons. The fittings throughout will be of wainscot. The estimated expense is upwards of two thousand pounds, which has been raised by a liberal subscription in the town and neighbourhood, with the Societies for church extension. Mr. J. B. Clacy, of Reading, is the architect. The church is also undergoing extensive repairs, estimated at fourteen hundred pounds, to effect which a vestry last week empowered the churchwardens to borrow one thousand pounds, in addition to a previous rate of about five hundred pounds. This is an example worthy of imitation by other parishes, where, from a fal e economy, memorials of ancient ecclesiastical architecture are fast mouldering to decay.

Birmingham.—The ceremony of consecrating the church of St. Mathew, at Ashted, the first of the proposed ten new churches to be erected in the town, took place on the 20th ult., it is a spacious and commodious building of early decorated Gothic architecture, built of brick, with dressings to the windows, doors, &c. of Wedley Castle red stone, and also a spire of the same stone. It contains about one thousand and fifty sittings, including four hundred free seats, without side galleries. It was designed by Mr. Thomas, the architect of Leamington, who very handsomely presented a window of stained glass.

Wolverhampton.—The ceremony of laying the first stone of St. Mary's Church, wh ch, with the parsonage house and school attached, will be erected at the sole expense of Miss Hinckes, of Tettenhall, took place in the presence of a very numerous concourse of spectators, on Thursday last. The endowment, which it is understood will ultimately amount to three hundred pounds, and the site, are also the gift of the same benevolent lady; the total cost of the building is estimated at ten thousand pounds.—*Midland Counties Herald.*

Great Haywood.—The consecration of St. Stephen's Chapel, recently erected on a beautiful site given for the purpose by the Earl of Lichfield, in the parish of Colwich, took place last month. It is of very beautiful construction, and reflects great credit on the taste and ability of Mr. T. Trubshaw, by whom it was designed.—*Staffordshire Gazette.*

MISCELLANEA.

New mode of hanging Pictures.—A very clever and useful invention for the above purpose has been lately patented by Mr. W. Potts, of King William Street, Strand, which we think, as it becomes known, cannot fail of being patronised by all collectors of pictures. The methods of hanging pictures commonly in use are by driving nails into the walls, or running iron or brass rods round the room. Both are objectionable, the former as it damages the decorations, and the latter not only destroying the architectural effect of a well-proportioned apartment, but also that the brackets which support the rod prevent the hooks or cords from sliding to any part wanted. In the patent plan, the means of fixing being above the hooks, they can be moved all round the room with the greatest facility, and necessarily saves much time in hanging or arranging a collection, particularly when any addition is made to it. Attached to the invention are moveable pendant chains and rods, with cross bars and shifting buttons or studs, which can be used or not at the pleasure of the party. Another and very great advantage connected with the plan is, that the rail combines a cornice moulding with the means of supporting pictures, and can be made to form the bottom member of the entablature, as the line in front is not touched either by the hooks, chains, or cord. We cannot but recommend the plan to the notice of architects, as well as to the artist and amateur, as an invention deserving their attention and adoption.

Mr. Junius Smith.—The American papers mention that the degree of LL.D. has been conferred by the University authorities on Mr. Junius Smith, of London, the gentleman whose enterprise, science, and perseverance, have so eminently contributed to the establishment of steam navigation between the old and the new worlds.—*Morning Post.*

Experiment of Large Guns.—On Friday, 11th ult., a party of the Royal Artillery, commanded by Major Chalmers, proceeded to the proof butt in the Royal Arsenal, Woolwich, at 1 o'clock p.m., for the purpose of trying a plan which has been some time in operation in France, for discharging large pieces of ordnance by a hammer and detonating powder, the present system in the British army being with a portfire, ignited and kept burning until the word of command is given. Sir John May, Colonel Dundas, and Colonel Dancey attended to witness the experiment. The gun selected was a 32-pounder, and the charge each time was 10 lb. of powder in a flannel cartridge, with a 32lb. ball fitted in a wooden cup made flat at the end next the powder. Forty rounds were fired, and the simplicity and certainty with which they were discharged gave great satisfaction. The invention is so simple, and might be so easily applied, that there is every reason to believe it will be universally adopted in the Ordnance department. It consists of a small hammer, with a handle about six inches in length, the whole made of brass, acting in holes made in two small pieces of steel fixed by screws to the right side of the gun. The action is given by pulling a piece of cord six feet long, when the hammer falls on the vent charged with detonating powder with such force as to cause instant and certain ignition. There is a small piece of steel to cover the detonating powder, that it may not become wet in rainy weather, and this is so contrived that it falls back the moment the hammer begins to descend.

The New Town of Fleetwood-on-Wyre.—Three years ago there were only two houses at Fleetwood, and the site of the town was a barren waste overrun with rabbits; now there are 103 houses inhabited to overflowing, and 54 in course of erection. It is said that a considerable quantity of land is purchased for building upon, but there is considerable difficulty in procuring a sufficient supply of brick, stone, and lime, consequently building operations are considerably retarded. We may mention, however, that a small but neat church, capable of accommodating about 400 persons is reared, and that the two shore lighthouses, which will be lighted with gas, are in a forward state, one being about 60 feet high, and the other about 12. As the designs are chaste and beautiful, they will be highly attractive objects to strangers visiting the district. A portion of the iron pier head is completed, and the remainder is in a forward state. There will be a shade erected on the pier for the purpose of keeping the goods, as they are landed, dry, and a line of railway will be laid along the pier, with suitable cranes for the landing of heavy goods; and it is probable that these works will, in the course of a month or six weeks, be so far complete as to enable the Company to commence the carrying trade on a great scale, when a considerable increase of trade to the port may reasonably be expected.

French Steam Engine Factory.—The *Armoricain* of Brest, in giving an account of the Government steam-engine manufactory of Indret, says in its present condition it can only turn out three engines of 160 to 220 horse power per annum, but that Government wishes to increase it, so as to enable it to make annually 12 engines of 450 horse power each. The sum allotted to this establishment last year by Government was 700,000f., but it has now been carried up to 2,000,000f. Six slips for building steamers are attached to the establishment; and a war-steamer, the *Gassendi*, of 220 horse power, is at present building here.—*Galignani's Messenger.*

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 1ST OCTOBER TO 22ND OCTOBER, 1840.

FREDERICK PAYNE MACKELCAN, of Birmingham, for *"certain improved thrashing machinery, a portion of which may be used as a means of transmitting power to other machinery."*—Sealed October 1; six months for enrolment.

THOMAS JOYCE, of Manchester, Ironmonger, for *"a certain article which forms or may be used as a handsome nob for parlour and other doors, bell pulls, and curtain pins, and is also capable of being used for a variety of useful and ornamental purposes in the interior of dwelling houses and other places."*—October 1; six months.

WILLIAM HENRY FOX TALBOT, of Lacock Abbey, Esquire, for *"improvements in producing or obtaining motive power."*—October 1; six months.

WILLIAM HORSFALL, of Manchester, Card Maker, for *"an improvement or improvements in cards for carding cotton, wool, silk, flax, and other fibrous substances."*—October 1; six months.

JAMES STIRLING, of Dundee, Engineer, and ROBERT STIRLING, of Galsten, Ayrshire, Doctor of Divinity, for *"certain improvements in air-engines."*—October 1; six months.

GEORGE RICHIE, of Gracechurch Street, and EDWARD BOWRA, of the same place, Manufacturers, for *"improvements in the manufacture of boas, muffs, cuffs, flounces, and tippets."*—October 1; six months.

JAMES FITT, Senior, of Wilmer Gardens, Hoxton Old Town, Manufacturer, for *"a novel construction of machinery for communicating mechanical power."* October 7; six months.

JOHN DAVIES, of Manchester, Civil Engineer, for *"certain improvements in machinery or apparatus for weaving."* Communicated by a foreigner residing abroad.—October 7 six months.

THOMAS SPENCER, of Liverpool, Carver and Gilder, and JOHN WILSON, of the same place, Lecturer on Chemistry, for *"certain improvements in the process of engraving on metals by means of voltaic electricity."*—October 7; six months.

THOMAS WOOD, the younger, of Wandsworth Road, Clapham, Gentleman, for *"improvements in paving streets, roads, bridges, squares, paths, and such like ways."*—October 7; six months.

CHARLES PAYNE, of South Lambeth, Gentleman, for *"improvements in salting animal matters."*—October 13; six months.

ROBERT PETTIT, of Woodhouse Place, Stepney Green, Gentleman, for *"improvements in railroads, and in the carriages and wheels employed thereon."*—October 15; six months.

HENRY GEORGE FRANCIS EARL, of Ducie, Woodchester Park, Gloucester, RICHARD CLYBURN, of Uley, Engineer, and EDWIN BUDDING, of Dursley, Engineer, for *"certain improvements in machinery for cutting vegetable and other substances."*—October 15; six months.

WILLIAM NEWTON, of Chancery Lane, Civil Engineer, for *"certain improvements in engines, to be worked by air or other gases."*—October 15; six months.

JAMES HANCOCK, of Sidney Square, Mile End, Civil Engineer, for *"an improved method of raising water and other fluids."*—October 15; six months.

HENRY PINKUS, of Panton Square, Middlesex, Esquire, for *"an improved method of combining and applying materials applicable to formation or construction of roads or ways."*—October 15; six months.

CHARLES PARKER, of Darlington, Durham, Flax Spinner, for *"improvements in looms for weaving linen and other fabrics, to be worked by hand, steam, water, or any other motive power."*—October 22; six months.

RICHARD EDMUNDS, of Banbury, Oxford, Gentleman, for *"certain improvements in machines or apparatus for preparing and drilling land, and for depositing seeds or manure therein."*—October 22; six months.

THOMAS CLARK, of Wolverhampton, Ironfounder, for *"certain improvements in the construction of locks, latches, and such like fastenings, applicable for securing doors, gates, window shutters, and such like purposes."* Communicated from a foreigner residing abroad.—October 22; six months.

GABRIEL RIDDLE, of Paternoster Row, Stationer, and THOMAS PIPER, of Bishopsgate Street, Builder, for *"a certain improvement or improvements on wheels for carriages,"* for the term of seven years, being an extension of former letters patent granted to THEODORE JONES, of Coleman Street, and by him assigned to the said GABRIEL RIDDLE and THOMAS PIPER.—October 22.

TO CORRESPONDENTS.

R. *We have some suspicion that the Propeller is not new; we will inquire respecting its originality.*

Robertus. *We have not space for the communication he has favoured us with, containing a list of the "Queen's subjects" whose trades are connected with British shipping.*

Ω. *We will take advantage of his communication at some future opportunity.*

S. L. *Designs of a Wesleyan Centenary Chapel were received last month.*

Mr. Kingsford's *plan for a Harbour of Refuge at Dover, we are compelled to omit for the present.*

A Constant Reader. *We cannot inform him.*

Architectus *His communication from America will appear in the next Journal.*

Book received:—Science of Vision.

We have been obliged to defer until next month the Plan and Section of the Reform Club, *in consequence of the artist not being able to complete them in time.*

The next number for December will complete the Third Volume, and will contain the Title, Preface, and Index. Subscribers are requested to complete their sets of the Journal.

Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal," *No. 11, Parliament Street, Westminster.*

Books for review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.

DIRCKS' PATENT IMPROVED METALLIC RAILWAY WHEEL WITH WOOD-FACED TYRE.

Fig. 1.

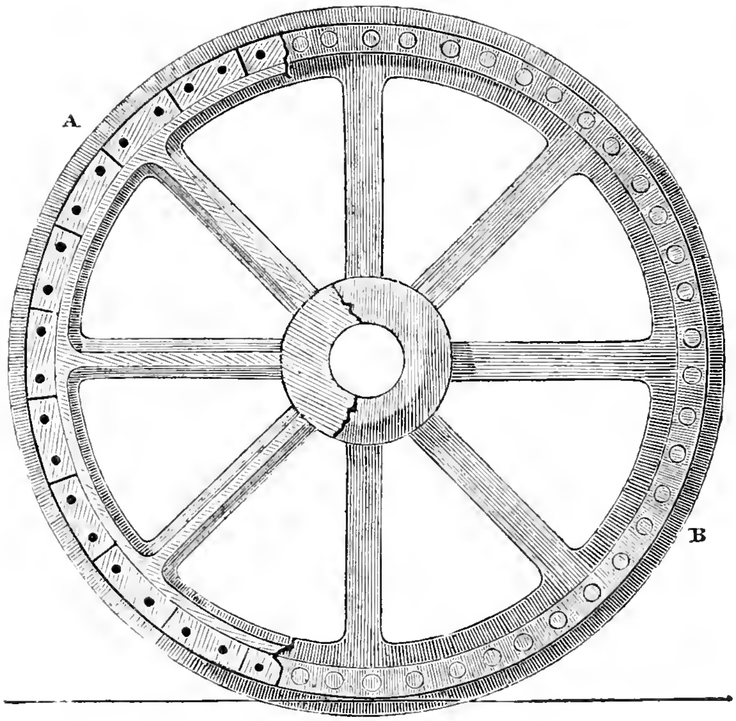

Fig. 2.

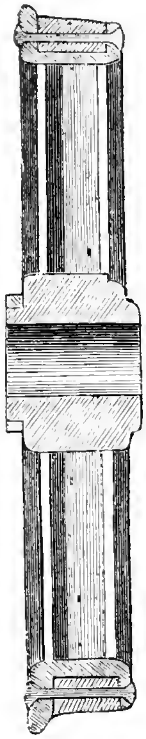

Fig. 3.

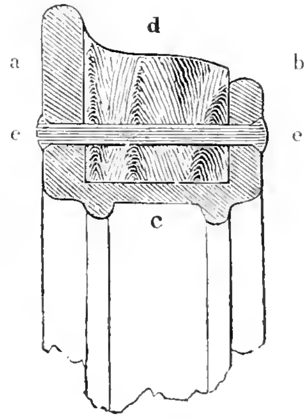

Fig. 4.

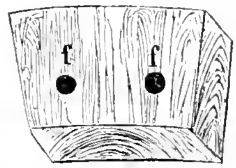

Fig. 5.

Description.

Fig. 1, represents the wheel, half in section, as at A, and half complete, as at B; the view being a front elevation.
Fig. 2, edge elevation, in section.
Fig. 3, showing the channelled tyre *abc*, with the wood inserted at *d*, fastened by the pin or rivet *ee*.
Fig. 4, represents one of the wooden blocks in perspective, perforated with two holes, *ff*, for receiving the pins or rivets.
Fig. 5, cross section of arm of wheel.

Read by Mr. Henry Dircks, before the Mechanical Section of the British Association, at Glasgow, Sept. 19, 1840. And also before the Polytechnic Society at Liverpool, Oct. 8, 1840.

As an introduction to the observations immediately relating to the improved wheel which is the subject of the present communication, a few preliminary observations may serve to make its nature and advantages more generally understood.

Wooden wheels were originally in common use on railways; these were afterwards superseded by the extensive use of cast-iron wheels; and both of these descriptions of wheels were much improved by manufacturing them with wrought iron tyres. Modifications of these wheels are still in use on the Liverpool and Manchester Railway, the wooden wheels having the nave of cast iron, and the spokes and rim of wood, the tyre being of wrought iron. On the London and Birmingham Railway, cast iron wheels are extensively used. On the continent of Europe, and in America, cast iron wheels are seemingly employed by preference; and are no doubt quite as safe for travelling, where great speed is not practised.

In England, a decided preference is given to wrought iron wheels, in which this metal is used throughout, with the exception of the boss being *cast* around the ends of the spokes. The latest improvement on these has been the making of the entire wheel, including the boss, of wrought iron.

The wheels now in general use derive their chief novelty from the construction and placement of the spokes, with a view to obtain elasticity, strength, and durability. One variety which does not come under this denomination, is the plate wheel, supposed on its introduction to possess some peculiar advantage in overcoming a supposed resistance of the atmosphere. Except, however, in relation to variations in size, the present wheels are little more than varieties in pattern. The common diameter of carriage and waggon wheels is three feet, and the largest driving-wheels for locomotives are those employed on the Great Western Railway, being six to seven feet in diameter,—though at one time they were made as laıge as ten feet.

The action of an iron wheel on an iron rail, though derived from a rolling motion, can only be compared to a series of blows, and the rebound occasioned by iron striking iron is well known to be considerably greater than is produced by striking wood on iron. To this simple fact we may trace the tremulous motion occasioned by iron wheels on an iron railroad; and when, by any trifling accident, as an inequality from the rising of one end of a rail, or sometimes even from small flinty pebbles getting on the rail, the rebound is not more fearful than dangerous. The tremulous motion of the rail just adverted to renders it necessary in most cases to lay the rails on wooden sleepers. As an illustration of what is meant, it may be mentioned that on the Dublin and Kingstown Railway the rails were originally laid on granite sleepers, but the tremor was so great as to loosen the rails, and occasion serious fears from the consequent damage sustained by engines and carriages passing along the line. It was, therefore, ultimately agreed to take up the granite and lay down longitudinal wooden sleepers, a work of considerable labour and expense. In some cases the nature of the soil or sub-soil may allow the use of stone blocks; and where they can be applied with safety, they are preferred, for the reason that a road laid on *stone* blocks can be kept up at a lower rate than one laid on *wooden* sleepers; and, as has been endeavoured to be clearly shown, the only reason for laying the stone aside, arises from the tremor imparted to the rail by iron wheels as at present used. Brees, in his Railway Practice (1839), gives, in a copy of an estimate for work on the "North Union Railway," the following particulars, at page 142:—

Maintaining railway crossings and sidings, when laid on stone blocks of five cubic feet, for the first year, per mile			£150 0 0
Ditto ditto second year			80 0 0
			£230 0 0
Ditto, on larch sleepers, for the first year, per mile	£200 0 0		
Ditto ditto second year	120 0 0		
			£320 0 0

We shall now proceed to a description of the improved metallic wheel with wood-faced tyre, showing its advantages in connexion with the preceding observations. The construction of the wheel may be understood by imagining a spoked wheel with a deep channelled tyre. The wheel may be made either of cast or wrought iron, it having been ascertained that tyre bars can be rolled to the required pattern. In this channelled tyre are inserted blocks of African oak, measuring about four inches by three and a half inches, solidified by filling the pores with unctuous preparations; thereby counteracting the effects of wet by capillary attraction,—to which, by this means, it becomes impervious, and at the same time is not liable to unequal contraction and expansion. The blocks of wood are cut to the requisite form to fit very exactly in the external circular channel of the wheel, with the grain placed vertically throughout, forming a complete facing of wood, as shown in the engraving. There are about from twenty-eight to thirty of these blocks round each wheel, where they are retained in their place by one or two bolts passing through each, the two sides of the channel having corresponding holes drilled through them for this purpose: the bolts are then well rivetted. After being so fitted, the wheel is turned in the usual manner. The wheel when finished has all the appearance of a common railway wheel, but with a rather deeper rim, the tyre faced with wood, and the flange of iron. Woods of various qualities may be used, whether hard or soft, requiring different chemical preparations according to their porosity, and in some instances requiring to be compressed.

The several advantages which this wheel possesses, are—

1. That the wood facing will wear a considerable time without requiring any repair.

2. That the wood can be refaced, by turning it up again in the lathe, as practised with worn iron tyres.

3. That the tyre can be re-faced with wood at little expense, and at a far less loss of time than usual. In the operations of re-facing these wheels, or putting in new wood, the work can be performed without the labour and cost of removing the wheels from the axles, which in the keying and unkeying is known to be very troublesome.*

4. That, in regard to their working, it is the opinion of practical engineers, confirmed by actual experiment, that they will work smoother, easier, and, as some have expressed it, more "sweetly" than iron-tyred wheels; with the advantage of going well in wet weather, even upon inclines,—having sufficient adhesion to the rail, without dropping sand to assist them in this respect, as practised when iron wheels are used.

5. That another and very important result will be, that the rails themselves will suffer less wear by using this kind of wheel, and that the fastenings, sleepers, and blocks will receive considerably less injury, and thereby favour the laying of railroads on stone blocks, wherever they are considered to be most desirable.†

A metallic wheel with a wood-faced tyre, which is the principle of this construction, obviates most, if not all, the difficulties which have been experienced, whether in the use of wooden, cast iron, or even wrought iron wheels. Cast iron wheels may, indeed, now be considered not far short of being equal to wrought iron wheels, for safety and durability, with all the superiority of which the application is susceptible. They are also neither clumsy nor inelegant in form, and are capable of being made to any pattern, even for carriage wheels for common roads. It may, therefore, very possibly occur that they will have the effect to bring cast iron wheels into as general use, and as much reputation here as on the continent. This new construction and simple adoption of wood makes excellent driving wheels for locomotives; it may be readily stopped by using a cast iron break, and does not undergo that wear which might be expected from the friction it then has on the rail. The wood, by use, becomes exceedingly close and firm, acquiring a surface not easily distinguishable from metal in appearance.

These wheels are manufactured by Messrs. Brocklehurst, Dircks, and Nelson, millwrights, engineers, and iron-founders, at their works, No. 12, Oil Street, Liverpool; where they may at any time be seen.

* As in every thing affecting railways, it is a desideratum to decrease the expense as much as possible, it may here be mentioned that three feet cast iron wheels, with wood-faced tyres and wrought iron axles complete, can be made much cheaper than the generality of wheels.

† On lines situated like the Greenwich Railway and the Blackwall Railway, wood faced wheels would diminish much of the noise which at present is a source of general complaint.

CANDIDUS'S NOTE-BOOK.

FASCICULUS XX.

> "I must have liberty
> Withal, as large a charter as the winds,
> To blow on whom I please."

I. After "*But*," the most provoking word in the language is your "Only"; which is employed extenuatingly to apologize away, as it were, the very sum of complaint, as being a mere trifle, too insignificant to be taken into the general account. This or that building may have *only* such or such defect, and of course you run the risk of being set down for a very ill-natured, or an exceedingly fastidious hyper-critical sort of person, if you object to it on such account, even though it should be of such nature as absolutely to cancel all other merits and recommendations. There are cases in which a single defect may be a fatal one; I might instance this directly and architecturally by referring to buildings which furnish cases in point; but it may be illustrated by the anecdote related somewhere, if I mistake not, by Theodore Hook, of the Adonis who had only a single blemish. In every other respect his person and countenance were unexceptionable. His mouth, teeth, hair, eyes, hands, were all allowed to be perfect, and were expatiated upon by a friend so eloquently that a lady fell in love with his description, and desired that the original might be introduced to her; on which the other thought fit to hint that he had omitted one slight imperfection in the portrait he had drawn, but it was "only a single blemish," a mere trifle, absolutely, in comparison with the loss of an arm or a leg. "Oh! some scar, I suppose—perhaps a wart?" inquired the lady; "an unlucky wart, perhaps, on the tip of his nose." "A wart on tip of his nose! Bless your heart, no! for the truth is, he has—*no nose at all!* which little defect is the one I alluded to."

II. It is precisely such "little defects" and slight blemishes that mar so many buildings and works of architecture. They have—in description at least—a host of merits; columns *comme il faut*, Doric or Corinthian, unexceptionable proportions, amplitude of dimensions, solidity of materials, &c., are expatiated upon till you raise your expectations almost to the highest pitch. At length you discover that the "slight defect"—the "only fault"—should any have been hinted at, renders the anticipated piece of perfection very much in the same plight as the Adonis with the single blemish—the Adonis without a nose.

III. When people begin to be sick of the everlasting boring and twaddling about styles, they will then, perhaps, begin to find out that quite as much or more depends upon the application of a style, as upon its merits as such. For what are the different styles of architecture, but so many different languages of the art—some of them more perfect, more expressive than others; but the excellence of a language, and the excellence of a composition in it, are quite distinct matters. The same language may be the vehicle of wit or of stupidity; and so also may the same style of architecture be employed tastefully or uncouthly; by one so as to charm and delight, by another so as to excite only ridicule and disgust. Which being the case, of what practical value are all those superficial, vague, and wearisome discussions from time to time on the subject of styles, in which not a single idea is brought forward that has not been repeated times innumerable before? On no other subject would such mere school-boy stuff be endured, much less pass for any show of learning, as is *parroted* in regard to architecture. Many prate most glibly about the age of Pericles; yet ask one of those erudite, sagacious gentlemen, what he thinks of that age in its chryseo-elephantine works, and architectural polychromy, and ten to one but he will be struck all of a heap; he wonders what *elephants* have to do with the matter, nor did he know before that Pericles had a daughter named *Polly*.

IV. The fact is, we are apt to judge of styles as we do of national or of professional character—in the lump; which, though a most expeditious and convenient, save-trouble mode, not unfrequently leads into dreadful blunders. The French are a lively people, yet shall you find Frenchmen of most excessive dulness and stupidity. You may stumble upon honesty in the shape of a lawyer, on temperance in that of an alderman, and on perfect good-nature in the person of a sarcastic satirist.

V. In an article in the Gardener's Magazine for November occurs the following bit of architectural comment: "in returning we observed two frightful chapels; the Hanover Chapel at Peckham, in the form of a pentagon, with small mean windows without facings, and red brick walls without cornices or any decoration whatever: and another chapel nearer Camberwell, of larger size, with similar walls. and *three or four stories* of naked windows like those of a third-rate dwelling-house! Chapels in general, throughout the country, are at present *a disgrace* to it, in an architectural point of view; but it is to be hoped that the spread of knowledge and taste will raise them to a par with other religious buildings." Yes, our chapels—and *churches*, too—generally are a disgrace to the country, as well on account of the beggarly, shabby, sordid meanness, as for the execrably bad taste they display. But as for the good taste that is to lead to a better system of things, where is it to come from? Certainly not from the fountain head—not from the Church Commissioners. However, I will not be quite sure that even brick boxes, with three or four stories of sash windows, are not a degree more endurable than those most trumpery *Gothicisings* or *Grecianizings*, as the case may be, which spring up like mushrooms in the purlieus of Islington, &c., and whose scanty pauper finery forms a contrast no less ludicrous than woful, with the bareness of their posterior parts. Economy is excellent, but the economy which treats itself with a smart shirt front, while it denies itself a pair of breeches, cannot possibly be extolled for its nice attention to decency.

VI. If I am rightly informed, more than one of the Islingtonian buildings alluded to is the joint production of two architects, in which case, to judge from the littleness of their united taste, the taste of each singly must be exceedingly little indeed. Or, would not the rather stale anecdote of the two helpmates come in here most pat? "What are you doing, Jack?" "Nothing, sir." "And Tom, what are you doing there?" "Please, sir, I'm just helping Jack." It was undoubtedly after some such fashion that the Messrs. Tom and Jack there employed *assisted* each other in providing taste for the Islingtonians. Certain it is that taste fares no better among Church Commissioners than among their worships the Churchwardens.

ON THE ORIGIN OF ALPHABETIC WRITING ON MONUMENTS, TOMBS, &c., IN ANCIENT GREECE.

Amongst the many pleasures connected with historic research, may be recorded that which the antiquary feels, as the evidences of some lost truth unfold themselves to his eye. To find how link after link completes the chain, or how the past is restored to observation after a lapse of centuries, is no less interesting, however, to the architect, the painter, and the sculptor, whenever the purposes of art are assisted by such a discovery. With this preface of apology for discussing the present subject, I humbly offer my opinions, with the unpretending wish only, that it may lead to a deeper attention from others. My idea of handling the theme arose from a remark of Canina's upon some ancient tombs found at Cœre, (now Cervetri, or Ceveteri). His remark is embodied in a paper, read at the Institute on the 30th March, 1840. He concludes from the peculiar form of the Greek characters of the inscriptions, that the tomb must have been erected before the Trojan war. Now the Trojan war is an event—an epoch in history. It encompasses within it a variety of interesting facts, customs, manners and rites. To determine the existence of alphabetic writing, as existing on monuments and tombs, before or after that period, is no less interesting: especially as in the investigation we trample on the memory of the honoured dead; for whom art has done and expected so much, and for whose deeds and memorable acts, genius has prepared such monuments of beauty and of skill.

Canina evidently presumes alphabetic writing as common to the tombs of the great before the Trojan war. With submission then to his opinion, as well as to others, who I know agree with him, I will assume the contrary, and endeavour to prove it of a later period.

First, I rely greatly on the authority of Homer, on the minuteness, care, and correctness of that poet, on his punctilious observance of customs, and on the extreme finish of his descriptions. Assuming this, I turn to the tale of Βελλεροφον (Iliad 6th, 168), not to disprove the non-existence of letters, &c., but to reveal Wolfius a German commentator upon Homer, guilty of the same idea as myself, since upon that tale, he presumes alphabetic writing unknown in the heroic ages. Secondly, our introduction to Patroclus's tomb, has no mention of any inscription, or written memorial. Thirdly, that the word γραφειν of such frequent occurrence, according to Guoquet, "ne signifie jamais chez Homer que representer oû decrire un objet." Fourthly, that wherever commands are given, or messages sent, they are done verbally; and whenever a treaty is ratified, it is done by sacrifice, or oath. Then again, Virgil's careful picture of Misenus's death and burial, and of the tomb erected, &c., mentions no inscription, which strengthens the argument, when we consider that Eneas is trying to pacify the spirit of that hero in the infernal regions, with a minute detail of all the honours and tributes paid to his memory. To omit one observance, would display a carelessness totally at variance with an otherwise ingenious recital.

Besides no nation was ever more jealous than the Greeks of funeral honours. The advantages of an illustrious victory were often neglected to perform this duty. Victorious generals were sacrificed for want of zeal in burying the soldiers slain in battle; whilst the auguries they derived from, and the vows they made over tombs, evince with what earnestness, the depositaries of the precepts of religion, had ever recommended the duties of the sepulchre. But perhaps it may be said that Guoquet in his work "sur les origines des lois, des sciences et des arts," admits the existence of alphabetic writing in Greece before the Trojan war. If so, let it be remembered, he adds, "that it was less practised." Besides if Guoquet were correct in his supposition, the knowledge of letters as a medium of conveying thoughts through the body of the people, must necessarily prove tardy and progressive. And although we believe it in existence at the time of Cadmus, still a natural inference would be, that the priests, as in ancient Egypt, were for a long time alone familiar with the written or descriptive language. The fact, too, that the Mexicans and Peruvians had attained to a great degree of civilization, without the use of letters, may assist such an idea.

The question then naturally arises, how, if inscriptions be to memoralize worth, or to record virtue, and how, if the knowledge of letters be assumed as slight, partial and confined, could the object be effected; or why would the artist chisel out in letters, the deeds of the departed, when most of the passers by were unable to interpret. Upon these grounds I humbly dispute the remark of Canina's: and I do so, not for the bare love of agitating subjects, which but for the curious and ingenious, would be contentedly dismissed, as unworthy and trivial; but from an anxiety to arouse the slumbering energies of the artist, and to invite a cool and rational enquiry into the antiquities, literature and minutive of his art.

November, 1840.

DESCRIPTION OF THE HYPSOMETER.

An Instrument invented by John Sang, *Esq., Land Surveyor, for taking the Heights of Trees, Buildings, and other objects. Communicated by* Mr. Sang, *Land Surveyor, Kirkcaldy.*

(From the Gardeners' Magazine.)

I have taken the first leisure hour to make you the instrument for measuring the height of trees and buildings which I mentioned to you when having the pleasure of visiting you at Bayswater. It is sent by post at the same time as this letter.

The instrument was tried on some houses and trees here, and it gave their height (especially the houses) with great accuracy. It is rather difficult to manage at first, but after a few trials it becomes quite easy. The method is as follows:—

By means of a small hook (if a knot of white cloth be attached to it, so much the better), fix the end of a tape line to the bole of the tree, at exactly the height of the observer's eye from the ground. Retire from the tree, letting the tape line unwind until, by using the instrument, the top of the tree and the end of the tape line are seen quite close together. Add the height of the observer's eye to the length of the tape line, and the sum is the height of the tree. Now, the difficulty is, to catch the image of the top of the tree in the instrument, and it is this which requires a few trials, although any person who has been accustomed to use a sextant will do it at the very first. Hold the instrument at one of the milled ends, taking care that the fingers do not project over any of the holes, and that the brim of the hat is out of the way. Apply the eye to the round hole marked a in fig. 1, and look through in the direction of the small square hole b, the instrument being held so that the line joining $a\,b$ is about level, while the large square hole c is turned towards the sky. You will then see some object directly through the small hole, and at the same time the image of some other object, the light from which enters the large aperture, and, after being reflected by the two mirrors inside, passes into the eye. Whatever two objects are thus seen in contact, subtend at the eye an angle of 45°, as in fig. 2; so that, if one of them be the end of the tape line on a level, or nearly so, with the observer's eye, while the other is the top of a tree, supposed to be growing straight up, the distance from the eye to the bole of the tree will be exactly equal to the distance from the end of the tape line to the top of the tree.

Fig. 1.

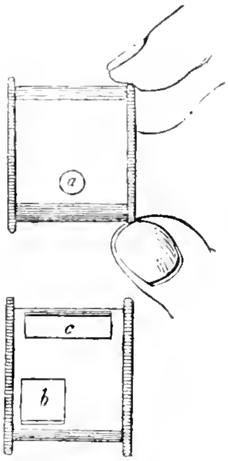

Fig. 2.

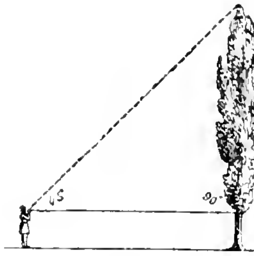

Fig. 3.

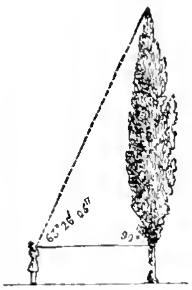

Fig. 4.

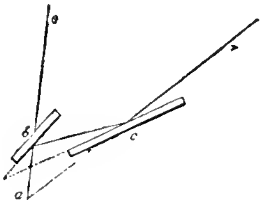


You will thus observe that the accuracy of the measurement depends on the tree being erect from the ground. On sloping ground the measurer would require to go out from the tree in such a direction that the tape line was perpendicular to the stem, but this could be judged sufficiently well by the eye to give the height, of even a very high tree, nearly correctly. The heights of those houses I tried were given within an inch, which was no doubt owing to their being perfectly upright on a level court yard.

The principle of the instrument is quite simple, being exactly the same as that of the sextant or quadrant, only that the mirrors are fixed at a certain angle instead of being movable. Thus, in fig. 3, *a* is the eye, *b* a mirror partly silvered, and c a larger mirror wholly silvered. A ray of light *r*, falling on the mirror *c*, is reflected from it in the direction *c b*, and again reflected from the mirror *b* in the direction *b a* to the eye; at the same time another ray of light comes from an object *o* direct to the eye at *a*, without being reflected. From the nature of reflected light, the angle *r a o* is equal to twice the inclination of the mirrors, and is constant, however much the whole instrument may be moved in the plane of the objects, as you will easily perceive by catching the reflection of the candle in the instrument, and moving it in the plane of the milled ends.

I am sure this very portable instrument will be useful for measuring single trees, or buildings, which are as far asunder as they are high, but I am afraid it will not work well in a close wood, on account of the operator not having room to retire as far from the trees as their height. If this is found to be the case, the remedy is to construct another instrument in which the mirrors are placed so as to give an angle of 63° 26′ 05″. In this case the height of the trees will be equal to twice the length of the tape, added to the height of the observer's eye. (See fig. 4.) Of course a small deviation from squareness in the trees and tape line will make a greater error than with the instrument sent, but still it will give a result near enough for all practical purposes.

I have only to add, that the mirrors are made of common window glass selected as the most even from among a great many pieces, but still they are not quite flat. I had some glass from London perfectly true and flat, but so dim and badly polished as to be unfit for use.

Kirkcaldy, Jan. 31, 1840.

Postscript in Answer to some Questions asked of Mr. Sang by the Conductor.

The instrument for measuring the height of trees is not a pocket sextant, like that of Mr. Blackadder, mentioned in vol. xiv. p. 257, although nearly allied to it. The sextant, quadrant, reflecting circle, improved Wollaston's goniometer, as well as the optical square and tree-measurer, are all varieties or improvements on Hadley's first invention. The two latter differ from the rest in the mirrors being permanently fixed at angles suitable for the purposes for which they were intended. The pocket sextant would measure the height of trees quite as well, but, being expensive, and requiring some skill to use it, it is not likely to be much employed for such purposes. There is no sort of merit in designing the instrument; and is so exceedingly simple, that I have no doubt the idea of modifying the sextant, so as to make it readily measure the height of trees, has occurred to many a one. I, however, never heard of such an instrument, and believe that the one you have is the second of its kind in existence. The other is one which was made for yourself. My father was so much pleased with it that he asked me to make one for him, which turned out neater than the first, and accordingly I sent it to you, as being the better of the two. As there is nothing like a Greek name for giving identity to it, you might call it a dendrometer, or, better still, a hypsometer (measure of height).

Of course any instrument maker could supply these articles; the price, I should think, would be about 20*s.* each. If there were any prospect of selling a dozen or two, I could easily employ a workman here to make them, and they might be sent from the seedshop to any place by post.

Kirkcaldy, Feb. 18, 1840.

BRITISH MUSEUM.

SIR—That the British Museum is a *monument*—as the French term it, which does honour to this age and country, is what, for peace sake, I will take for granted, notwithstanding that I myself perceive nothing particularly monumental or dignified in the sulky and barrack-like aspect of the exterior of the new buildings. No one, indeed, can deny that the most frugal economy has been observed there—of course a very plain proof with what rigorous conscientiousness the cash is uniformly doled out of John Bull's public purse. Still there are illnatured grumblers who opine there are occasions when liberality bespeaks more prudence than cheese-paring economy, and is the more becoming virtue of the two; and that such an edifice as the one I am speaking of, ought to be in every respect a finished piece of architecture. Possibly, the façade—whenever that comes to be executed—may make some amends; yet it surely would have been better that the whole should be of a piece, and not like Dick Wilson's fine embroidered waistcoat, with its 'back-front' made out of one of his own picture-canvasses. It may be very true that the rest of the building is not intended to be seen, but still as it is not screened from view, it is rather hard to tax the imagination of matter-of-fact folks like myself, so far as to tell us we are to imagine we do not see what is staring us in the face, nor to give credit to our own eyesight. Upon such notable principle of economy, the backs—I mean the East end of St. Paul's, might have been left a plain brick wall; but it seems Sir Christopher's notions of economy were very different indeed from those of Sir Robert.

I find I have rather committed myself, for what I have been saying is likely to call the sincerity of my first sentence, terribly into question. No matter; it can't now be helped; and only proves that liars and critics ought to have good memories. Accordingly my willingness to 'take for granted' and so forth, must now either be set down as a palpable *hum*, or be imputed to my considerate forbearance in not discussing the architectural merits and demerits of Sir R. Smirke's edifice. I will not inquire whether the taste he has shown in the interior of the building is such as to indemnify us for its excessive homeliness without; nor whether he has been prodigal or economical in drawing upon his fancy and imagination. But I will say that however much he may have consulted convenience rather than splendour, or may have succeeded in combining both, in other parts of the plan, he has attended to neither the one nor the other in the Reading Rooms, which are about as inconvenient for the purpose as could well have been devised,—to such a degree that without taxing our fancy very much, we might fancy no instructions respecting them had been given to the architect, and that when it was afterwards discovered that the Book-makers and Novel-readers who frequent the British Museum, must be put somewhere, they were *accommodated* where they are now crammed. "Remuneration means five farthings," and in the present case accommodation means being left to shift as well as you can for yourself, and perhaps be forced to sit in dim-twilight—where if you cannot see to read, you may at least sit and muse,—which of course looks solemn and meditative, and is highly becoming in a *Muse*-um.

This is no exaggeration of mine, since it is hardly possible—except, indeed, for literary *owls*—to see to read at any of the tables on the window-side of the West room, in dull weather; those windows being at a considerable height from the floor, and there being no others at either end. Consequently one-half of it is so imperfectly lighted, that were it a church people would grumble at it as a dismal dark hole, where they could not see either to hear the sermon, or to study the newest fashions of the congregation. There may indeed be some who can see to read by their own inward light; but the generality of people will perhaps agree with me that apartments not intended merely as libraries, but as *public* reading-rooms, where instead of seating themselves just where they can see best, people must be content with the best vacant places they can find,—that such apartments should be sufficiently and uniformly lighted, so that every part should be equally commodious in that respect.

It would have been infinitely better to have had for the purpose, rooms less lofty, and lighted entirely from above, with a clerestory lantern along the centre, and skylight compartments along the sides, so as to diffuse the light as equally as possible every where. But, it will be said, it was quite out of the architect's power to do this, there being an upper floor: yet it was surely then matter for consideration whether it would not be more eligible to convert the present rooms to some other purpose, and make use of one of the upper galleries (lighted from above) as Reading-rooms. The extra trouble of having to ascend higher in order to reach them, would be amply compensated by their greater comfort and commodiousness,—for their present length might then have been considerably extended. Perhaps it will be objected—for *buts* and objections are always plentiful enough—that this would have been attended with one serious inconvenience,—namely, the distance from which books would have to be fetched were the Reading-rooms not upon the same floor as the Libraries. Yet that difficulty would be at once obviated by having a *lift* or shaft (as many as might be requisite), close by the bar where the books are delivered; and by means of which a whole cargo—if requisite, might be raised equally expeditiously and easily.

There are, however, other inconveniences in the present rooms that ought to be remedied. One is that the space is by much too confined, for either the tables ought to be nearly double their present width, or there ought to be seats only on one side, for when a person has—which is frequently the case—very large folios before him, they occasion inconvenience both to his opposite neighbour and himself: besides which sufficient space is not allowed between one sitter and another, should they both happen to have many books or very large ones by them.

Were it not that it might be deemed a piece of shameful extravagance, I would hint that it would not be omiss if a few yards of drugget or matting were purchased to lay down along the centre avenue of the Reading-rooms, in order to deaden the noise of persons perpetually passing to and fro on the stone pavement there. By way of providing the ways and means for raising the sum required for buying the said drugget, I would recommend that the open wire-work doors now enclosing the bookcases in those rooms should be taken off their hinges and sold; because so far from being of any use, they are merely a very great nuisance. Being unglazed they do not protect the books from dust, neither are they any protection whatever against plundering—if such be their intended purpose, because those cases—which contain books of reference, journals, dictionaries, &c., are accessible to any one, as he may have as many as he pleases opened in turn, if he summons the turnkey attendant, and as when once opened the cases are left unlocked, there are always several from which persons can take down books. There are, besides, always piles of books on the tables, from which a person frequenting the Museum for such a purpose, might filch away any pocketable volume, though even then he could not pawn it without first mutilating it, by tearing out the Museum stamp-mark. Therefore in the way of precaution against filching books, the doors to the cases in the Reading-rooms are quite nugatory—a mere idle show of carefulness and security. In themselves, however, they are a nuisance, not only as imposing needless trouble and bustling about, to both attendants and visitors; but because they are actually in the way when opened, while persons are referring to the books, there being then no room for other people to pass between them and the tables. If, therefore, there must be doors to those bookcases, the tables ought to be shortened two feet, so as to allow greater space between the ends of the tables and the walls. I will not now speak of the Catalogues except to say that I believe they are blessed undevoutly backwards, every day and all day long. Neither will I now touch upon the literary wealth of the Museum in those departments which are most likely to interest your own readers, it being utterly impossible to do justice to either topic at the fag end of my present letter; I must, therefore, reserve them for another. That some improvements have taken place of late years I do not deny, but still the Museum requires a good deal of poking up, before it will be placed upon the footing which it ought to be.

I remain, &c., &c., &c.,

JOHN [but not John Wilson] CROKER.

P.S. I forgot to remark that had the Reading-rooms been on the floor above that where they now are, namely, on the first floor from the sky, they would have been much more in character, for the votaries of literature have always greatly affected the upper regions of buildings—vulgarly termed garrets—for their abodes.

SURVEYING.

REMARKS ON THE NEW SCALING INSTUMENT.

SIR—The last number of your Journal contained a letter from "An Old Surveyor," in which, speaking of the New Scaling Instrument recently introduced at the Tithe Office, and extracted from my *Treatise on Engineering Field Work*, into your Journal for October, he remarks "that I must have been misinformed when I stated that the principle of the plan had long been known to some few surveyors, &c., and also believing that I did not wish to deprive the inventor of his due share of credit, to state who were the parties acquainted with the principle of the plan, prior to its introduction at the Tithe Office." From the courteous—not to say complimentary tone of your correspondent's letter, I feel much pleasure in affording him the requisite information. By referring to page 353 of your Journal, he will perceive what I mean by the *principle of the plan*, which was communicated to me about three years since by an esteemed professional friend, but who at the time did not inform me that it was his own conception; and which I was not aware of until I applied to him, since reading "An Old Surveyor's" letter, to know in what manner he became acquainted with the process. Subjoined is the reply, but at his request his name is withheld; but for your correspondent's satisfaction, I send you the letter to take the requisite particulars from. In the autumn of 1837, he observes, "being engaged upon a survey of 12,000 acres, I looked with some degree of concern at the drudgery of computing the quantities. Mr. B. had previously explained to me his mode of ruling parallel lines across the several enclosures, but this method I thought would be troublesome, and be attended with the risk of injuring the maps. The idea then occurred to me of using a thin piece of horn ruled with lines one chain apart. In the interval that elapsed between my sending for, and receiving the horn, I made of tracing paper the machine I described to you, and find it to answer my purpose, used it to the end of my survey in the spring of 1838, since which time it has not seen the light, but is no doubt amongst my old papers."

I think the above particulars must be satisfactory to your correspondent, at least I hope so; and now perhaps I may be excused asking him, who the inventor of the modified instrument at present in use at the Tithe Office, is? for certainly there is great credit due to him, and which I indeed stated in my work, when I called it an "ingenious application of the above system." If an Old Surveyor will favour me with this particular, I shall have much pleasure in mentioning it in the second part of my work shortly to be published.

I remain, Sir, your's very obediently,

PETER BRUEF.

Charlotte Street, Bloomsbury, Nov. 16, 1840.

SIR—An "Old Surveyor" in your last number doubts the remark made by Mr. Bruff, that the *principle* of the New Scaling Instrument had long been in use by some few surveyors.—In reply I beg to observe that I have known many surveyors of the old school who worked on this principle, by means of a long scale and pricker, taking the amount of the chain widths and transferring them into acres, roods and perches by the decimal table; the new instrument has certainly much improved the system, and having the parallel lines on glass paper is a further improvement. The old system was a very defective one, and repudiated by all really practical men. As to the new instrument, after using it in my office for many months, and in various large surveys—I find it unsatisfactory, it is after all (notwithstanding its high recommendation) best adapted for the schoolboy and the tyro.

I am not surprised at its general adoption, for the former approved system of equalizing into trapeziums and triangles is very laborious work, if pursued for a length of time successively, but after giving both a fair trial, I must say I find the old system the most expeditious and certainly the most satisfactory. One feels no satisfaction with the instrument without repeating the operation, in repeating, the results will not always be the same, a third or even a fourth operation will frequently be required, each time requiring the whole to be done over again: whereas by allowing two young hands to figure for each scaler, they check one another, and repeating the operation from opposite points, prevents any serious errors by using proper precautions.

Perhaps I have a little feeling with yourselves against "ready reckoners," but I have experience on my side, and I have laid the *instrument* on the shelf.

It is a pity to see practical men recommending such games of marbles as your Dublin correspondent, if he would work with *eleven* arrows and make *frequent* use of his pen, he would bequeath his marbles to his children. Every *surveyor* should follow his own chain in long lines, and stopping to hook his changes, stations, crossings, &c., will find him plenty to do, without carrying a marble bag.

The number of mushroom surveyors whom the pressure of business have hatched into life, has detracted much from the respectability of the profession, the public however are beginning to find out, that old and tried hands are most to be depended on; an engineer too may be a good surveyor in theory, but he will never come up in the field to an old fashioned surveyor. I do not know any thing that would give me greater pleasure than to give a certain eminent gentleman in that line, (well known to our profession, for his upright, impartial, and gentlemanly demeanour), one week's *practical surveying*, he would find there was but little "Sham Abraham" in it.

I shall conclude these few remarks by again assuming a name under which I have before entered your columns,

As your very obedient servant,

"Surveyor."

Ashford, Nov. 14, 1840.

ON REMOVAL OF EARTH-WORK FOR EMBANKMENTS.

Sir—In your Number 38, for November 1840, at page 392, you state that "up to April 1837, not even 200,000 cube yards had been teamed to embankment on one face, in one year."

Between Nov. 2, 1839 and Oct. 17, 1840, there were tipped, according to my official returns, on the Birmingham and Gloucester Railway, on one face of embankment, across the valley of the river Rea, near Birmingham, 293,246 cube yards; the mean lead being 1¾ miles, and the extreme height of embankment 62 feet from the meadows. I believe that a ratio of progress fully equal to the above, was maintained not far from Gloucester on the same railway, for a few months in the Autumn of 1839; but as the work was then in the hands of the Cheltenham and Great Western Company, I cannot give you farther particulars. I am under the belief that other engineers could supply you with information as to larger quantities than the above being tipped in the same space of time.

I am, your's faithfully,

W. S. Moorsom, *Engineer.*

[Communications similar to the above are of great importance to the profession; we hope other engineers will follow Mr. Moorsom's example, and favour us with the result of their observations.—Ed.]

THE NAPOLEON MONUMENT.

Mr. Editor—Having in the September number of your highly interesting periodical, perused an article under this head, and feeling a deep interest in the subject, I take the liberty of sending you my own opinion; though, whether it is likely to effect any good, or is worthy of insertion in your Journal, your able judgment will best decide.—During a recent visit to Paris, I was particularly struck by the exhibition (mentioned in the above number) of a full size model of the intended testimonial to the Emperor in the Dôme des Invalides, as not being altogether consistent with that good taste so frequently displayed in the French capital. To every one who has seen the effect of the Baldachino in St. Peter's, at Rome, which is universally acknowledged a complete eye-sore, this striking similarity of arrangement must evidently tend to give the same result. The magnificent Dôme, being itself such a tastefully decorated room, can, according to my ideas, by no means suffer any erection, like this complicated, by an equestrian statue crowned monument, to dispute its grand simplicity. A colossal statue of the hero, say from 18 to 24 feet high, *cast in white metal and frosted*, erected on a circular pedestal of Egyptian porphyry, in the centre of the large Mosaic star, would methinks produce a different effect. The sublime grandeur of the Egyptian colossi, all rude and mutilated as they are, speak for themselves, and in behalf of my opinion. They likewise convince me that supernatural size would here especially answer the purpose. I suggested my idea on the spot to a friend present, and have since found no reason to make any alteration.

Your's most respectfully,

C. Tottie.

11, *University Street, Nov.* 9, 1840.

COMPETITION DESIGNS.

K. P. S. in reply to Mr. Sparke.

Sir—It gives me much pleasure to see in your number for the present month, that you have other correspondents who interest themselves in the subject of competition, and it is with especial satisfaction that I have read the answer of Mr. Sparke, to my letter on the subject of the Bury affair, since it leaves every essential fact in my statement unshaken, except one. Nobody can be imposed upon for one moment by the mist of words in which the Hon. Sec. flatters himself he has enveloped the truth.

It seems I have been misinformed as to the amount of the contract, which is £3,353 instead of £3,550. What then? Does the amount affect the moral principle?

There certainly are cases which differ from competitions, inasmuch as the law is apt to take cognizance of them, in which the proper name by which the transaction is called, varies according to the pecuniary amount involved in it, but as we cannot suppose the Hon. Sec. to the subscribers means to insinuate any analogy, we must conclude that he argues like the damsel who excused her peccadillo because it was "*a very little one.*"

As to the conundrum about the duties, it is too shallow to be respectable. The contract is £3,353,—there is £230 to be laid out in foundations, which it was evident must be laid out to all but those determined not to see, and then there is the painting and plastering. £350, supposing it to be so much, will not cover an excess of upwards of £600.

Though quite unnecessary for the argument, I will beg your readers to peruse the clause referred to by Mr. Sparke relative to the duties. Will any one undertake to say whether it is intended to mean that the duties are or are not to be considered in the estimate. It is most ingenious, and well calculated to maintain a quibble upon. Where the meaning is obscure, we must enlighten it by the context. "*If the subscribers shall be unable to find a respectable builder willing to execute the design of any architect for the sum of* £3,000, *such architect shall have no claim of any kind upon the subscribers,*" &c. This at least is plain English, and I shall take the liberty to believe it can have but one meaning, even though it should be explained away as satisfactorily as Lord Peter proved his shoulder-knot to mean neither more nor less than a broomstick,* or as Mr. Sparke has explained away all the rest of my statement.

But one word more—I will not dispute whether the contrivers of this business were *called* a committee, but it is notorious to all Bury that it was managed by a *clique* who, according to Mr. Sparke's showing, turn out to have been as irresponsible as they were officious. I could name an occasion on which one of the leading members expressed himself in no measured terms, upon some symptoms of dissent from his authority, shown by other parties concerned.

Enough of this, and more than enough for any good it is likely to produce. I have said before, and say again, that reform must come from the profession, and to them I would recommend a very simple plan, by which it may be effected, viz., that every one should reform himself. In the mean time, Sir, accept another contribution to the *facts*, which I hope to see accumulated, until architects shall be ashamed to rake in the filthy puddle of competition at the command of every body and any body. For reasons which will instantly be appreciated, I omit all names.

It is now nearly two years since the following advertisement appeared in the public papers:—

"To Architects.—Any architect desirous of competing for the proposed enlargement of W—— church, must send in his plans, specifications, and estimates, free of all charge or expence, to the Secretary, the Rev. Mr. T——, Vicarage W——, on or before the 19th January, 1839. For farther information apply to the Secretary."

Application having been made for farther particulars, the following were furnished in reply:—

* See the Tale of a Tub.

"That the committee would require a plan of the different floors of the church, showing the present arrangements and proposed alterations, an elevation of each front affected by the proposed alterations, a longitudinal and transverse section showing the timbers of the roof, &c., together with a detailed specification of the works, and estimate of rendering the church, both inside and out, fit in every respect for public worship. An additional estimate of what would be the expence of repewing the present church on a better plan, in conformity with the proposed new addition. An estimate of the expence for an additional gallery.

"That the limited amount of the funds would not allow of any premiums being given for the plans.

"That the committee considered it indispensable for the competitors to inspect the church.

"That a commission of five per cent. on the sum expended would be allowed to the architect for his plans, &c., including the superintendance of the works."

And now, gentlemen of the profession, what do you suppose was to be the amount of this commission for the *chance* of which all this was to be done, and a journey to be made to W—— at the candidate's expence?

"That the Secretary informs the several architects that the sum to be expended will *not exceed four hundred and fifty pounds!!!*" I write it at length that no one may suppose a figure has been dropped.

The following letter, part of the correspondence, is too curious not to be given entire. The *naive* impudence of the latter part will not easily be surpassed :—

"*W——, January* 5, 1839.

"Sir—In answer to your's of this morning, I beg to state that the committee desire me to say that they consider a personal inspection of the church necessary. Should you consider this worth your while, I shall be happy to give you any information in my power on the subject. I should state that the length of the church is 60 feet by 16 feet 10 inches, so that the work will be on a small scale. The amount to be expended will not exceed £450. *The Rector of the parish is an Architect, but has not informed me whether he intends to compete for the work.*

"I am, Sir, your obedient servant,

"H—— S——."

Begging every architect who values the respectability of his profession to lend his aid in exposing these scandalous practices.

I remain, Sir, your obedient servant,

K. P. S.

Nov. 13, 1840.

ATMOSPHERIC RAILWAY.

In our last monthly number we published a letter received from Mr. Pinkus, commenting on an article in our July number on the atmospheric railway, in which he complains that great injustice had been done him, by giving credit to Mr. Medhurst "for having originated the idea of employing the power of the atmosphere against a vacuum created in an extended pipe laid between the rails, and communicating the power thus obtained to propel carriages moving on a road," and to Messrs. Clegg & Samuda "for having rendered this idea practicable and useful, by their simple and ingenious invention of constructing and closing a continuous valve, by hermetically sealing it up with a composition each time the train passes."

In treating on scientific inventions of interest, this Journal pursues the undeviating course of giving the fullest and clearest information, preserving the strictest impartiality as to the inventors; conferring praise where it is justly due, and pointing out error where we consider it to exist. Mr. Pinkus, after denying *in toto* all we have said of Medhurst and of himself, describes himself as "an humble labourer in the field of science," who would "never be guilty of that meanness of mind that would detract from another the merit justly due to him for any mental production." This principle we admire, and cannot but regret that he should have lost sight of it in the very next paragraph of his letter, where he attempts to deprive Medhurst of the praise we awarded him, by describing Papin as the author "of employing the power of the atmosphere against a vacuum." We are aware that this is due to Papin, but if Mr. Pinkus had not stopped short, but quoted our whole sentence, Medhurst must have come in for the praise we justly awarded him, viz. "of using the power of the atmosphere against a vacuum created in a pipe laid between the rails, and communicating the power thus obtained to propel carriages on roads,"—a very different thing from simply "using the power of the atmosphere against a vacuum," which we were fully aware originated with Papin, had been followed by Lewis in 1817, and Vallence in 1824. Returning, then, to the original idea of employing atmospheric pressure against a vacuum inside a pipe, and communicating that power to carriages moving on a road outside it"; we see nothing to alter our assertion that it is the invention of Medhurst, who published a detailed account of the means he employed, in 1837.*

Indeed, however reluctant Mr. Pinkus may be to admit this fact, the following extracts from Medhurst's pamphlet, places the matter beyond all doubt.

In page 15, this passage occurs—

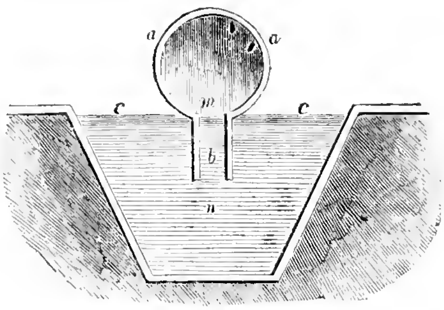
When the carriage is to go through the canal, from the engine, the air must be forced into the canal behind it; but, when it is to go the contrary way, the same engine is to draw the air out of the canal, and rarify the air before the carriage, that the atmospheric air may press into the canal behind the carriage, and drive it the contrary way.

In the following page 16, he says—

It is practicable, upon the same principle, to form a tube so as to leave a continual communication between the inside and the outside of it, without suffering any part of the impelling air to escape; and, by this means, to impel a carriage along upon an iron road, in the open air, with equal velocity, and, in a great degree, possessing the same advantages as in passing withinside of the tube, with the additional satisfaction to passengers of being unconfined, and in view of the country.

If a round iron tube, 24 inches in diameter, be made, with an opening of 2 inches wide in the circumference, and a flanch 6 or 8 inches deep on each side of the opening, it will leave a channel between the flanches, and an opening into the tube. If the flanches of this tube are immersed in water up to the circumference, as represented in fig. 1, where *a*, *a*, is a section of the tube; *b*, the channel; and *c*, *c*, the surface of the water.

Fig. 1.



If such a tube is laid all along upon the ground, with the iron channel immersed in a channel of water, up to *m*, and a piston or box made to fit it loosely, and pass through it upon wheels or rollers, this box, driven through the tube by the air forced into it, may give motion to a carriage without, by a communication through the channel and the water.

Again in page 20, he describes

A plan to combine the two modes together, that the goods may be conveyed within the canal, and a communication made from the inside to the outside of it, so that a carriage may be impelled in the open air, to carry passengers, would be an improvement desirable and practicable. It must be effected without the aid of water, that it may rise and fall as the land lies; and it must give a continual impulse to the outside carriage, without suffering the impelling air to escape.

And aware that his only difficulty was in constructing a means of confining the power in the tube by using a valve in lieu of the water joint, he remarks, that

For this purpose, there must be some machinery which will diminish the simplicity, make it more expensive, and more liable to be disordered, unless executed in the most substantial and perfect manner; but, by skill, by experience, and sound workmanship, it may be accomplished in various ways, one of which I will describe, which, I presume, will evince the practicability of it.

In order to make this in the best manner, the top of the canal should be made of wrought iron (or copper) plates, rivetted together, and rivetted all along, on one side, to a cast iron rail securely laid upon the top of one of the side walls; and made to shut down close, and air-tight, upon a cast iron rail laid firmly down upon the other side wall.

In order to make the plate shut down air-tight upon the cast iron rail, without being rivetted to it, there should be a groove all along, upon the top and inner edge of the cast iron rail, and a thin edge of iron rivetted to the plates all along, to fall into the groove; then, if the groove is partially filled with some soft and yielding substance, as cork, wood, leather, hemp, &c., the thin iron edge will bed itself into it, and shut so close that the air will not escape, with so light a pressure as one pound per square inch.

The plate that is to form the top of the canal, being thus prepared, may be

* This work was entitled "A New System of Inland Conveyance."

lifted up out of the groove two or three inches high, in any particular place of the side that is not rivetted: and, when let down again, the edge will fall into the groove, by the spring and weight of the plate, and stop close as before.

Therefore, if there is a large and light iron wheel fixed in the front of the interior carriage, and close to the side wall on which the plate shuts into the groove; and if this wheel is planted to stand two inches higher than the under side of the covering plate, this wheel, as it passes along, will constantly lift up the plates, and make an opening of two inches wide, or more, and 8 or 10 feet long; and, when the wheel has passed, the plate will fall down into the groove, and close the joint, as before.

Through this opening, a bar of iron may pass, that is fixed to the interior carriage, may project over the side wall, and the outer end may be attached to the exterior carriage by a chain or strap, and pull it along upon its own wheels and wheel track, which should lie along by the side of the wall of the canal.

The iron bar will not touch any thing as it passes through the opening, for the iron covering may be lifted up two or three inches high; but the bar need not be more than one inch in thickness.

In page 24, he says—

The same principle, and the same form, may be advantageously applied to convey goods and passengers in the open air, upon a common road, at the same rate of a mile in a minute, or sixty miles per hour; and without any obstruction, except, at times, contrary winds, which may retard its progress, and heavy snow, which may obstruct it.

If a square iron tube be formed, 2 feet on each side, 4 feet in area, with three sides, and one-half of the top, of cast iron, the other half of the top made of plate iron or copper, to lift up and shut down in a groove in the cast iron semi-top plate, as before described; and if a strong and light box or frame be made to run upon wheels, within the tube, and an iron arm made to pass out, through the opening made by lifting up the plate, as before described, this arm may give motion to a carriage in the open air, and upon the common road, without any rail-way, if the pressure within the tube is made strong enough for the purpose.

The opening of the iron plate should be made in the middle of the top, so that the iron arm may pass out, and stand upright a few inches above the top, to which the strap should be attached, to communicate motion to the carriage.

The frame or box, within the tube, should be 10 or 12 feet long, and must be guided by wheels, on all sides, as large as can be admitted, and as truly formed and planted as possible; the number will be 14 or 16.

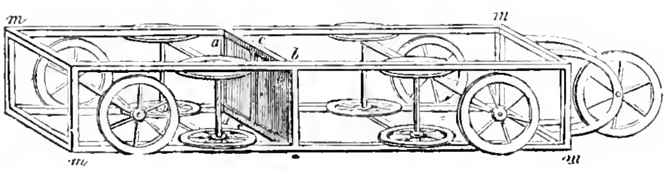
A piston, or vane, must be formed near the middle of the frame, to intercept the air, and must be leathered all round, so as lightly or barely to touch the sides of the tube.

The inside, or middle of this vane, should be open, and the opening filled up and closed by a valve, suspended by an axis across the middle of the opening, so that this valve, by turning on its axis, may open the vane, and suffer the air to pass through, and prevent its impulse upon the vane and carriage, or, by closing the valve, intercept the air, and give it motion.

By this means, the conductor of the carriage may restrain and limit the velocity, and stop the carriage, at any time and at any place, by a communication from the valve, through the opening, to the conductor on the outside; and this will be done without the least violence, shock, or chance of disordering any thing, either within or without.

Fig. 2 represents the vane within its frame *m, m, m, m*; the outside edge

Fig. 2.



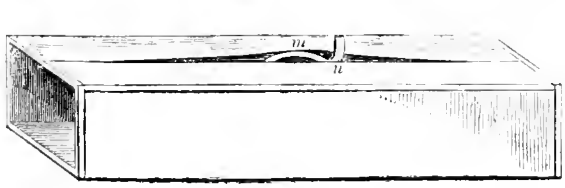


Fig. 4.

of the vane, *a, b, c, d*, is leathered all round, and the middle part, *o, p, q, r*, is open, and is to be closed by the double valve, that is to turn upon its vertical axis *e, e*. The valve will shut, half on one side of the vane *a, b, c, d*, and half on the other; when it is shut, the air will be intercepted, and the impulse of the air will be given to the carriage; but, when the valve is turned a quarter of a circle, it presents its edge to the air, and leaves the interior of the vane open for the air to pass by unobstructed, when the carriage will gradually be stopped, by the friction of the road and the resistance of the outward air. It may be put in motion again, as soon and as gradually, by closing the valve.

m, m, m, m, is the box, or open frame, that is to pass through the tube, on the wheels *n, n, n, n, n*, to support the vane, and the iron arm, and to be impelled by the air in the tube.

Fig. 3.

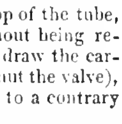

Fig. 3 is a section of the iron tube, with the wrought iron semi-top, *a, b*, rivetted to the flanch, and represented as lifted up by the projection of the wheel under it; and of the crooked iron arm *n*, as it is to come out through the opening, and stand up for the carriage to be attached to it.

The semi-top of cast-iron, *o, p*, is to be screwed upon the tube by the flanch *p*, and, at the edge *o*, is a small projection, which the edge of the wrought iron is to cover, to prevent the rain or dust from entering into the tube.

Fig. 4 represents a part of the tube, with the semi-top as lifted up at *m*, and the section of the crooked iron arm, *n*, as it is to pass out of the opening, besides the wheel that lifts it.

The iron tube should lie in the ground, with the top of it a few inches above the surface; and the carriage should run over it, with the wheels on each side; then the iron arm *n*, would draw the carriage in the fairest position.

The opening being, in this plan, made in the middle of the top of the tube, instead of the side, the lifting wheel will act either way, without being removed; but the iron arm that passes through the opening (to draw the carriage), as well as the arm that is to pass through (to open and shut the valve), must be changed to the other side, when the motion is changed to a contrary direction.

If the carriage is attached to the regulating arm that is to pass through the opening, and that arm is supported by the main bar, the effect will be, that, if by any accident the chain should let go its hold of the arm, the inside valve would instantly fly open; and the vane, being no longer impelled, would soon stop of itself, and the chain might be replaced.

In summing up this invention he remarks,

Although the perfection of this work is not to be obtained but by time, skill, experience, and the wealth of a nation, yet, upon a smaller scale, and less rapidity, the expense will be moderate, and within reach; and the value of it, compared with the present mode of conveyance, would be abundantly advantageous and desirable.

Here then is a clear and full explanation of a mechanical arrangement for employing the power of the atmosphere against a vacuum inside a tube, and communicating the power so obtained to carriages moving on a road on the outside.

No impartial person, and not even Mr. Pinkus can read these passages without being convinced that this most ingenious, though unfortunate inventor Medhurst, had brought the atmospheric system to the point where it was taken up by Messrs. Clegg and Samuda, and that his great practical failure was, that he could not, and did not make the valve air-tight, upon doing which the entire success of the system depended.

And now that we have shown what Medhurst did, and what he failed in, viz., "in making a continuous communication from the inside of the pipe to the carriage tight enough to allow a useful degree of rarifaction to be produced;" we will examine what progress the invention has made since then.

On the 3rd January, 1839, Clegg and Samuda obtained a patent "for a new improvement in valves and the combination of them with machinery." This valve, says the inventor, "works in a hinge of leather, (or other flexible material which is practically air-tight), similar to the valves commonly used in air-pumps. The extremity or edge of these valves is caused to fall into a trough containing a composition of beeswax and tallow, or beeswax and oil, or any substance or composition of substances which is solid at the temperature of the atmosphere, and becomes fluid when heated a few degress above it; after the valve is closed, and its extremity is laying in the trough, the tallow is heated sufficiently to seal up or cement together, the fracture round the edge or edges of the valve which the previous opening of it had caused, and the heat being removed the tallow again becomes hard and forms an air-tight joint or cement between the extremity of the valve and the trough. When it is requisite to open the valve, it is done by lifting it out of the tallow with or without the application of heat, and the before named process of sealing it or rendering it air-tight is repeated every time it is closed.

The inventor then goes on to describe how, by means of this valve in combination with a line of partially exhausted tubes, it may be rendered useful to move weights on railways. The combination employed being described precisely similar to that invented and published by Medhurst. The only claim set up in the patent being "the method of constructing and using valves as above described." The success of this valve has been demonstrated by six months experience on the Thames Junction Railway, and as the whole combination there employed, *except the valve and mode of sealing it*, is precisely that invent-

ed and published by Medhurst,—it follows that to Clegg and Samuda is due the credit of perfecting what he began.

Now let us see what Mr. Pinkus has done. His first patent we find is dated 1st March, 1834, in this he sets forward a combination precisely similar to that published by Medhurst seven years previously, only proposing to use a rope for his continuous valve, which he terms a valvular cord, and which he describes thus: "A flexible cord E lies in the groove at the top of the cylinder, for the purpose of closing the longitudinal aperture; this cord is to be of the same length as the pneumatic railway, and to fit tightly into the groove or channel. The cord is passed under the wheel *c*, and over the wheel P; and its purpose being to close the opening in the cylinder, it is required to yield freely when acted upon by the apparatus, and it should be made heavy, and it may be pressed down into the groove by the wheel W, which passes over it."

Now if Mr. Pinkus can prove any better result to arise from this rope than from the valves suggested by Medhurst, he has a perfect right to it. We fear, however, that the success he says, attended his experiments made in 1835 on a model, could not have been very flattering, as we find he took out another patent in 1836, "For improvements in inland transit," in which he says, "the method of carrying it into practice consists in a method or in methods of constructing the pneumatic valve and the valvular cord, and in the manner of using the same, one of which methods hereinafter described, I design *to substitute for and in lieu of the valve and cord described in the specification of my said former patent.*" He then goes on to describe a valve formed of iron plates secured to felt to lay against pieces of wood, which he proposes to fix to the inner sides of the trough, as presenting a smoother surface than cast iron. He next describes a spring copper valve fastened at its foot to the pipe, and meeting at the top in the shape of an inverted V; and lastly, a combination of the two, viz., using half the spring copper valve against the upraised side of the trough, and pressing it against its surface with the valve with iron plates, as before described, which in this case acts as a wedge pressing against the side.

These valves, however, could not have pleased him much better, for on 3rd August, 1839, he obtained a third patent, in which he not only describes a valve similar in every respect to that of Messrs. Clegg and Samuda, but also proposes to seal it with a composition to be rendered fluid and solid, as described by them; with the sole exception of using a galvanic wire instead of a heater to melt the cement. As this patent was enrolled eight months *after* the publication of Clegg and Samuda's specification, we cannot but think that their invention was instrumental in leading Mr. Pinkus' ideas to this valve, as nothing of the sort is discoverable in either of his previous patents.

[Erratum.—For 1837 read 1827, p. 407, 2nd col., 4 lines from the top.]

REFORM CLUB-HOUSE.

(With 2 Engravings, Plates XVIII. & XIX.)

Fully to describe and explain the interior of the structure would require a plan of every floor—amounting altogether to six, besides as many sections, to say nothing of particular sections on a larger scale, of some of the rooms, perspective views, and drawings of ceilings and other details: in short it would demand a volume similar to that on the Travellers' Club House.* Of course we cannot devote so many engravings to a single edifice, though it be one so deserving of attentive study as this of Mr. Barry's; nevertheless a sufficiently clear idea of the general arrangement, of the sizes of the rooms, and of the height of the different stories, may be obtained from the ground floor plan and section through the building from East to West. Being confined to a single section, we have judged this last to be the best for our purpose, because although one through the centre from north to south, would have shown the ascent from the vestibule to the hall, and the coffee-room and drawing-room above it, it would have shown merely the end elevations of those apartments, not their longitudinal ones—which are their more important ones; whereas the line of section chosen makes no difference as regards the hall, while it explains the character of the staircase, and the room over it, and also shows the kitchen court, at the east end of the building. When, however, we say none, we mean that it makes no other difference in respect to the hall itself than what is evident from the ground plan, namely, that in this direction the three intercolumns are of equal width, whereas the east and west sides being somewhat shorter, the lateral intercolumns are narrower than the centre one, on which account those elevations are better than the others, where the columns are wider apart than is altogether consistent with the richness of character here observable in other respects. This excess of width in the intercolumns is not so apparent in our drawing, because that being both a geometrical and outline one, it is the plan which chiefly explains that the arches between the columns belong to a different plane, viz., that of the wall within the colonnades. Hence it is likely enough that from the first glance at the section it will be supposed that, instead of being insulated the columns are attached to the piers of the arches, in which case the intervals between them would not be too great. It becomes a question, therefore, whether it would not have been better, to enclose the lower part at least of this saloon by open arcades so decorated, whereby a character of solidity would have been there produced, that would have served to relieve and set off the upper colonnades. Still wherefore that idea—supposing it to have presented itself—was not adopted is sufficiently apparent from the plan being neither a perfect square, so as to allow three arches of equal width, on each of its sides; nor so much greater than a square as to afford five spaces—whether arches or intercolumns, on each of the longer sides. Perhaps as the deficiency in the breadth from north to south, could not be supplied without intrenching too much upon other parts, it might have been adviseable to have got rid of the excess in the other direction, curtailing—not the entire hall, but merely the cetral space within the columns, reducing that to a perfect square. By this means, indeed, the breadth of the east and west colonnades would have been somewhat increased, yet that objection might have been got over by apparently contracting the width, putting columns against the wall, corresponding with those in front, and so as to render the distance between them equal to the breadth within the north and south colonnades. This adjustment of the plan, reducing the centre to a square of 28 feet, instead of 34 × 28,—might have rendered some other modifications requisite, and among the rest, some abatement of the present height.

If we have thus far taken the liberty of objecting to what we regard as a rather offensive irregularity as regards the colonnades, we commend the mode of grouping of two columns and square pillar, here employed at the angles, which produces a very desirable fulness of effect, as well as appearance of solidity at those points, and at the same time avoids the confusion—and perhaps heaviness withal—that might have resulted from three columns similarly placed. Another pleasing and, we believe, original circumstance is, that in the upper and lower colonnade on the south side, a view is admitted into the coffee-room and drawing-room over it through the centre arcade, which is to be filled in with plate glass to within a few feet of the floor, that is, to the level of the chimney-piece. By this means, the saloon itself will always present a striking architectural scene as so viewed from either of the two principal apartments, especially of an evening when brilliantly lit up. The mode also of lighting the saloon entirely through the cove, appears to us both a novel and happy one, although we can at present merely guess at its effect, it being quite blocked up with scaffolding when we last went over the interior of the building, when very little progress had been made in the decorations, or rather, they were hardly commenced at all, nor was it began to be paved. The staircase was also then a mere shell, with brick walls, and without any steps. Consequently, until we can see the interior again, in a much more advanced, if not perfectly finished state, we can add very little to the information the plan and section supply as to the parts just mentioned. For which reason, we must be allowed to reserve further description for another opportunity, and request our readers to consider the present account merely a provisional one.

* The whole of the plates in that work have lately been pirated in the most barefaced manner by the editor of the Revue Generale d'Architecture, without the slightest acknowledgement, or mention of the source whence they have been taken, notwithstanding that a copy of the publication was actually given to the French editor in order that he might give a notice of the book! Yet instead of doing any thing of the kind, he does not even inform his readers that there is such a volume in existence, but makes it appear that both his article and the plates are entirely his own, and the information collected by himself while he was in London. It is true the drawings are not exactly facsimiles, for they are considerably reduced in scale from the originals, and in other respects far less satisfactory: still that circumstance does not cancel the act of piracy, or the injury done by it to the English publisher.

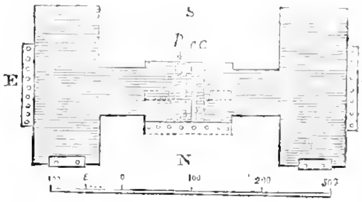
Ryde, Nov. 7.—The committee appointed to decide on the plans for our new church, have selected the designs of Mr. T. Hellyer, architect. It is a handsome structure, and the interior is composed after the model of the Temple church in London. The subscriptions for the building are progressing steadily, and the contributions for enclosing the new burial-ground already amount to more than 150*l*. Too much praise cannot be given to our vicar, the Rev. W. S. Phillips, for the energy and exertions he has put forth to accomplish these two important objects.—*Hampshire Advertiser.*

ARCHITECTURE OF LIVERPOOL.

SIR—When I first saw the remarks of your correspondent "Eder" in a Liverpool paper, I felt strongly disposed to make a few observations in reply to some of them, which seemed to me strangely at variance with his professions of careful and long continued architectural study. This inclination was confirmed when I found they had obtained a place in your journal, and would thus fall under the notice of so many interested in the matters they refer to. In putting this design in practice, I shall borrow his introductory paragraph, in so far as it relates to partiality and prejudice, both which feelings so inimical to all fair discussion, I can most candidly disavow.

The Custom House is the first building noticed by Eder—its size perhaps entitles it to such priority. He applies the terms "imposing and magnificent," to this structure. Now any very large mass of building may be allowed to be *imposing*, if of an adequate height, but magnificence implies something more than mere mass of material and extension of surface: it includes, I conceive, a symmetrical arrangement of parts, fine proportions, and a degree and character of ornament suited to the importance and purpose of the building. In these three points I hold the Liverpool Custom House to be most lamentably deficient. First, as to *arrangement* or *composition*. The building is on a plan much like the letter H, the cupola occupying the centre of the cross part of the letter, and a portico on one side of the cross, and on each of the upright parts. The consequences of this arrangement are destructive of all fine perspective effect, for when viewed on its north front, the cupola serves only to destroy the effect (such as it is) of the portico on that side, and seen from the east and west fronts that feature seems hardly to be part of the pile, so completely is its connection with those fronts hidden by the projection of the wings. This cupola (in his opinion, in which every body I imagine must agree with your correspondent), in fact never terminates the perspective from any point of view, nor combines with any of the intersections of the wings and central portion of the mass. With regard to the position of the porticoes, that to the north is buried between the wings, and can never be seen in profile, and its projection is so slight that were it not that the only light it ever receives from the sun falls very much aslant, and consequently gives a great prolongation of shadow, it would have no more relief than a row of attached columns with a pediment over them. The above remarks as to want of projection, apply with greater force to the other two porticoes, which however *can* be seen in profile, or obliquely, though for reasons I shall point out when I come to speak of the *proportions* of the parts, their effect is completely destroyed. The site of this building was well adapted to a cruciform plan, and had such an arrangement been adopted, the porticoes, however deficient in projection and depth, would at least have formed suitable terminations to the several portions of the cross; and the cupola, however foreign to this, so called, Grecian design, would have risen naturally, as I may say, at the intersection, and have terminated the converging perspective of the body and transepts with good results as regards its own effect and importance, and without interfering with the porticoes in those respects. Such a disposition of the plan would also have insured a better distribution of light, and greatly have benefitted the interior arrangements, which as your correspondent justly observes, are sadly wanting in this point. As regards the proportions of the several fronts, and the features which compose them, it seems to me that very little consideration, or consideration to very little purpose has been bestowed on them, more especially as respects those very important parts of the composition, the porticoes. Their projection (for they are all alike) is so slight as to appear nothing in comparison with their frontal extent, and to take away all idea of shelter or shade. I do not know whether Candidus will include expression as one of the banished or obsolete architectural terms, but this quality (for I for one believe in its existence) appears to me to be utterly wanting in three of the fronts. As I wish to advance nothing without endeavouring to give a reason, I shall explain myself as well as I can. I am of opinion, then, that there are two general proportions in which a portico may be combined with a front, of which it does not occupy the whole extent, without loosing its own effect, or interfering injuriously with that of the front of which it forms so material a feature. These proportions seem to me to be firstly, such as shall give to the portico the greater part of the façade, and make the remainder on either side appear as mere adjuncts or accessories thereto; or secondly, such as shall make the portico a subordinate feature in the design, leaving an extended surface on either hand. In the first case the impression on the mind will be (such at least is the effect with myself,) that the front being of a proscribed extent both as to length and height, and a portico a requisite part of the edifice, that portion had been kept within the extreme dimensions of the site for the purpose of preserving to it a fitting proportion as to elevation: and in the second, that the portico being as before supposed a necessary and ornamental feature in the proposed arrangement, had been so proportioned to the whole extent of front as not to destroy its unity and continuity of appearance. The expression of the first named portico, I conceive, will be found that of dignity and grandeur combined with use, and that of the second more allied to comfort and convenience judiciously united with a due regard to ornamental effect. Of the first mentioned proportion I consider the portico of the Fitzwilliam Museum at Cambridge, a good example. As a specimen of the second I may quote that of the India House, inharmonious as that front may be in some of its details. In spite of what I have said above, I still greatly prefer the truly Grecian application of the portico, where it includes the whole front of the building, and continues without interruption or break, save its own angle, the order or entablature, as the case may be, of the lateral portion. But to apply these remarks to the building under consideration.

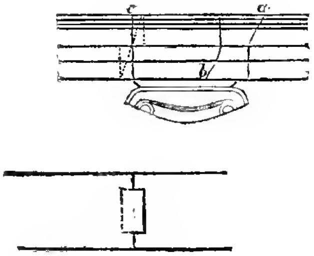
Fig. 1.



The east and west porticoes of the Liverpool Custom House occupy, to my eye, exactly the unhappy medium between the proportions I have attempted to describe; and instead of leaving the mind at rest to contemplate and enjoy their air of simple dignity, or of inviting and hospitable shelter, together with the varied effects of light and shade of which these beautiful architectural features are capable when happily conceived and applied, they distract the eye, both mental and physical, by a puzzling uncertainty as to the meaning of the architect, and by their bareness and lack of depth give no idea but that of useless show, and of an exposed, comfortless, and contracted entrance passage. With regard to the north or principal front, the portico has an advantage over those of the east and west fronts—having in rear a slight projection of its own width from the main building; this gives an appearance of greater projection from the general line, but is of no avail as regards the shallow and ineffective aspect arising from deficiency of depth. The proportion which this portico bears to the whole space between the wings is nearly the same as the two already described bear to their respective fronts, and it appears to me to labour under the same uncertainty as to whether it be a principal or accessory in the general design. The wings themselves are perhaps not too far in advance as respects their own proportion as *wings*, but they unquestionably do stand out to such a degree, as to drown completely the portico and its adjoining projection. The fronts of the wings which consist of openings of three intercolumniations divided by two columns in antis, and a flank of about two intercolumns pierced with windows, on each side, are certainly the most effective and least objectionable parts of the front under notice, but I am inclined to think that a greater height of blocking either over the whole front, or at least over the central portion, would tend to improve their aspect. I come now to speak of the rear or south elevation which Eder describes as "infamously miserable,"—terms which well apply to the whole of the wings on that side, but not, I maintain, to the main front which comprises, in my opinion, the only really redeeming feature in the whole building.

All pretension to Grecian character appears here to have been abandoned. The cornice of the columnar order is, to be sure, continued, but without the frieze and architrave, and being of good projection, with a massive dentil member in the bed-mould, it harmonizes well with the general character of this portion of the building, which is most decidedly Italian. Though I think the central projection of this front is, like those in the others, faulty in its indecision of proportion to the whole, still, in itself, I consider it in all respects much the best part of the structure. It consists of a plain well-proportioned elevation, divided into three parts by two slight breaks. The middle portion of the three is pierced below by three open segmental arches leading through the building to the opposite front; and above these, three semicircular-headed windows of good proportions, and pleasing though simple character. The lateral divisions have above each, one window corresponding with those of the centre; and below, a window recessed in an arch similar to those forming the three openings above mentioned. The front is divided horizontally by a bold string course, and surmounted by a massive but suitably proportioned plain attic wall, with its cornice and blocking. The impost moulding of the upper windows is also carried through, which lightens, without too much cutting up, the massive and substantial piers which divide them. There is a good height of plain wall between these windows and the cornice, which, in my opinion is a great assistance towards gaining dignity of aspect, giving me always the same kind of impression as a lofty forehead surmounting a human face. The solid and void are, I think, very happily apportioned in this front, and though I could wish for a better description of rustic work than the horizontal channels in the basement, still the effect of the whole is simple, substantial, and dignified. Here, and here only, does a cupola, supposing it to be something very different from that which really exists, not appear misplaced. The attic wall hides the roof completely, and conveys the idea of a solid support for the mass above it, and the breaks dividing the front are so proportioned as to carry the eye easily upwards to the plinth or stylobate of the cupola, which falls just enough within their line to give the appearance of a proper degree of stability. In the article of decoration, which I mentioned as the third requisite to fill up my idea of magnificence, the Liverpool Custom House offers but little for our consideration, and the quality of what exists can hardly, I imagine, excite a wish that there was more of it. It is difficult to conceive that Greek details could be applied with a more complete absence of all classical effect and feeling. Unfluted Ionic columns, with fluted tori in their bases, composed each of eleven stones; pilasters with capitals, whose mouldings are certainly copied from Greek examples, and enriched, according to established use, with water-leaf, &c., but which mouldings, alas, project more than three times as far beyond the faces of the pilasters, as the pilasters do from the wall, the projection of these latter being barely 3¼ inches to a diameter of 4 ft. 6 in. The projection of the entablature follows, of course, that of the pilasters, and shares in their meagre aspect. In the architraves of the porticoes it appears that stone could not be obtained in sufficient lengths to bear from column to column, and the architect has had recourse to the method of notching shown in Fig. 2.

Fig. 2.



Plan of joint at C.

The effect of this mode of jointing is, that in one portico the part marked *a* has broken through and the stone fallen considerably out of the horizontal, a defect which is only too clearly shown by the broken lines of the tenia moulding and the faces of the architrave; and in another a fracture has occurred as shown at *b*, but not to the same extent. Might not these evils have been avoided by showing a vertical joint in front, and backjointing the stones as shown by the dotted lines at *c*. This must be considered a digression as it belongs rather to the constructive part of the matter; but it was mentioned for the purpose of calling attention to the bad practical effect, of a mode of construction which is in itself an eyesore, and which is enhanced in the present case by the fact, that the stones resting on the columns are almost uniformly some degrees darker in colour, than the intermediate ones which are notched into them. Through some defect, as I imagine, in the foundation, a very serious fracture is visible in the N. W. wing over one of the windows within the recess. But to return to the details; the stylobate so much commended by Eder is a plain square plinth, projecting just sufficiently to receive the bases of the very slab-like pilasters I have described, whose moulding is also, as noticed by your correspondent, carried entirely round the building, with the exception of the south front and wings. This stylobate is certainly much too low to be in proportion to the order—as to the doors and windows, I marvel much what any one can find to admire in them. The windows, except those I have mentioned in the south front, and similar ones under the north portico, are either plain oblong holes, or have a meagre ghost-like architrave, without even the knees or projections at the upper angles to be found in the only genuine Grecian example of such features in the Erectheum. The doors *may* be copied from Greek examples; but who can say that the upright unenriched cyma, is not an ungraceful member? I imagine that the very vertical profile of these mouldings, was adopted in the originals for the better display of the ornamental surface, which decorated them; but as here applied, in their naked state, they are positively ugly. The trusses of the doorways are, to my eye, little less unpleasing, and the nature of the stone and quality of workmanship, give no great effect to what ornaments they can boast. I have as yet said nothing of the interior, or of the details of the cupola. The whole of the former is not yet opened to the public, the fittings of the long room being incomplete. Having had a view of this room, I can only say that it seems to me no great improvement on the exterior. The plan is confused and choked, and the effect of space destroyed by the numerous columns, which, in their disposition, evince a singular disregard to any regular arrangement. The internal cupola, which springs from pendentives rising upon the entablature of the Ionic order of this room, is spacious, and considerably enriched, but claims no notice on any other grounds. On its exterior companion I must decline making any remarks, as my disclaimer of prejudice might perhaps not avail me, were I to say all I think of it. I believe, however, the original design of the architect was not so utterly tasteless. That part of the interior already occupied is sufficiently and fairly described by Eder, being very dark and inconvenient. I have trespassed long on your valuable space; my excuses are that a great deal of unmeaning, and I think ignorant admiration has been bestowed on this structure, both by residents and visitors; that I have never heard a reason given for any thing which has been said in its favour; that all that is the least good in it seems to have been uniformly overlooked; and that it is one of the most extensive and costly buildings which have been erected in this country of late years, having occupied more than ten years in completion, and having cost, as I have been informed, a sum approaching £400,000. In conclusion, I hope I have said nothing to impugn my opening professions of impartiality. Let those who have seen this building judge for themselves, and if, in comparing these remarks with the original, they consider the objections urged beyond the bounds of just and fair criticism, I hope they will, as I have endeavoured to do, give the reasons which influence their opinions; should such meet my view or that of others who think like me, I hope they will be judged of in the spirit of candour, which I trust has guided my pen in the foregoing observations.

Your's, &c.,
H.

Liverpool, Nov. 9, 1840.

Since the above remarks were written, the Long Room has been completed and opened for business. I have only to add, as regards this room, that, although a vista is preserved through its entire length, the effect is destroyed before one third of that length is traversed, by the confused appearance presented by the columns. This arises from the strange indifference here manifested to regularity of intercolumniation, which is such that, looking on either side of the room, no two pairs (not couples, for there are no really coupled columns, however nearly they approach such an arrangement) of columns seem equally far apart. The coffers of the cupola appear much too shallow, and the mouldings as much too large for the depth of the coffers, though perhaps not so when viewed, with respect to their surface, rather than their depth.

VICTORIA ROOMS, BRISTOL.

Sir—The portico of the Victoria Rooms, Bristol, although correctly placed in the Octastyle Class in the table of porticoes given in the Civil Engineer and Architect's Journal for this month, is therein stated to have five intercolumniations, a contradiction which you may not perhaps think it necessary to explain; allow me, however, to add that there is an important omission in the description of it, as the pediment I am happy to say is sculptured, or more properly is being sculptured, from a working model by Mr. M. L. Watson, the principal relief from the face of the tympanum being 2 feet 3 inches. I shall feel obliged by your attention to this letter.

And remain, Sir, your most obedient servant,

Charles Dyer.

36, *Guilford Street, Nov.* 11, 1840.

ON THE DRAINAGE OF LOW LANDS.

By Mr. William Fairbairn.

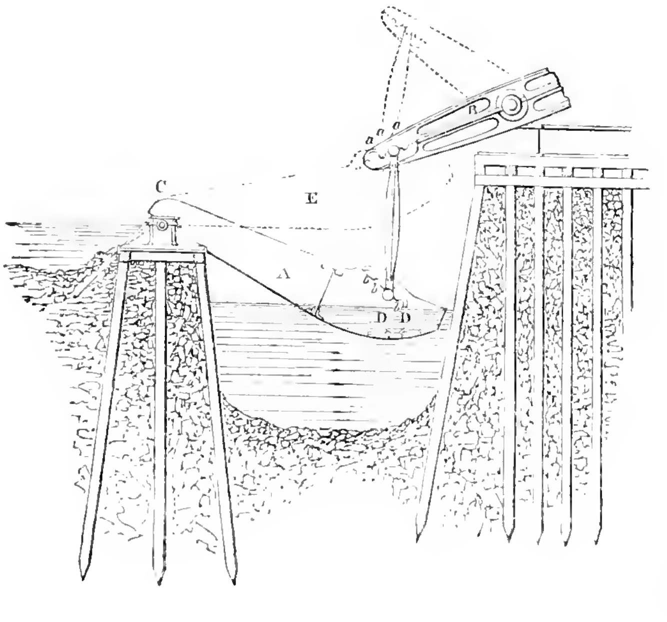
There are few subjects of more importance or more deserving of public attention than the drainage of lands. In cultivating land below the level of the sea, drainage is one of the first steps, for unless the superfluous waters of a low marshy district be freely removed and discharged at a level above its surface, it is in vain to look for productive crops, however rich the soil or the alluvial deposit may be.

Hydraulic machines of almost every description have been in requisition for this object, and in countries, such as Holland and the Fen districts of Lincolnshire, where the land is in many instances several feet below the sea, those machines have been extensively used, and many improvements have from time to time been introduced. Formerly windmills and animal power applied to scoop-wheels seem the only methods adopted, but since the introduction of the steam engine a material change has been effected. Engines of great power may now be seen giving motion to wheels of 25 to 30 feet diameter, discharging large quantities of water from the lower to the higher levels.

The scoop-wheel, although a simple and effective machine, is not (according to Mr. Fairbairn's opinion), the most economical for the drainage of low lands. In countries where fuel is expensive, it is an object of great importance to obtain power at a cheap rate, and by the application of the steam engine upon the Cornish principle, a saving of three times the fuel now consumed may be effected. The consumption of fuel by a well constructed condensing engine is from 10 to 12 lbs. of coal per horse power, per hour, or 10 lbs. of coal will raise 2,000,000 lbs. of water one foot high in a minute; whereas a single acting Cornish engine, according to the returns, will raise with the same quantity of fuel 8,000,000 lbs.—a duty four times greater than has yet been attained by the common condensing engine. Taking it, however, at only three times the duty, or 6,000,000 lbs. one foot high in a minute, the saving is even then so great, as to be entitled to the attention of proprietors whose lands are situated at a level requiring the aid of steam to clear them of water.

From these considerations it appeared to Mr. Fairbairn desirable to apply the Cornish engine, and having been requested by parties interested in the drainage of the Lake of Haarlem, to consider the best and cheapest means for the attainment of that object, he proposed a machine, of which the following is a description.

In raising water by the scoop-wheel, it is obvious that a uniform force is necessary to overcome the resistance upon the floats, as they successively discharge their contents from the lower to the higher level. This resistance being constant, the force applied, and the quantity of fuel consumed, will be equal to the load, or to that of a low pressure condensing engine, similarly constructed to those on board of steam boats. The effect produced on the bailing-scoop will be totally different, and instead of a continuous action as exhibited in the common wheel, a reciprocating motion will be produced, and the same economy insured as is now exemplified in the returns of the Cornish engines. In applying this description of engine it becomes necessary



to adopt the reciprocating principle, and by raising a weight suspended at the opposite end of the engine beam B, the large bailing-scoop A, revolving on a fulcrum at C, descends to the lower level, and is filled with water through the opening valves D, D. The weight having been elevated to the full height of the stroke, it descends by the force of gravitation, and raises the bailing-scoop to a horizontal position as at E, causing the water to flow over the pivot C, into the level above. The same process is repeated, each stroke by the admission of steam into the cylinders to raise the weight, and the bailing-scoop is again elevated by its descent.

The principal advantage peculiar to this machine, is its adaptation to the single-acting Cornish engine; first, by the introduction of a portion of high pressure steam to overcome the inertia of the weight; secondly, by its subsequent expansion to maintain the momentum; and lastly, by the gravitation of the weight to lift the load: on the same principle, in fact, as the engine at the East London Water Works, under the direction of Mr. Wicksteed, and as those in Cornwall.

The bailing-scoop is 25 feet long and 30 feet wide, composed of boiler-plates, with two partitions to strengthen the bottom and support the valves for the admission of water at D. The machine is calculated to raise about 17 tons of water each stroke, and with an engine of 60 horse power will effect a duty equal to 2½ or 3 lbs. of coal per horse power, per hour. It will be observed that the length of the stroke continues at all times the same in the cylinder, whilst at *a a*, *b b*, &c. it is varied by a series of stops fixed horizontal to the sides of the engine beams, and upon inclined planes on the bailing-scoop. This is done in order to lessen or increase the dip, and to accommodate the lift to a height commensurate with the difference of the levels which may exist between the surface of the lake and the height to which the water has to be raised.

ON THE COMBUSTION OF COAL.

Sir—Having lately submitted to the public an improved mode of introducing air to the gaseous matter of coal in a furnace, by which its complete combustion is effected, and the generation of smoke necessarily prevented; and finding that the principles on which this is produced have been misrepresented or misunderstood by the contributors to some of the public journals, I am desirous, through the medium of your columns, of being set right in the public view on this important subject. In some instances, indeed, the effect produced by my mode is attributed to causes which are the very reverse of the fact, and though evidently by a friendly hand, yet the result is so opposed to chemical truth, that I am unwilling to sanction such an explanation of the principles on which I have effected perfect combustion on the large scale of the furnace.

In the treatise published by me on the "combustion of coal, chemically considered," I have explained the source of those errors into which the patentees of "smoke burning" systems have fallen, by their search after a high temperature, and looking to that temperature as the means of consuming the gas or smoke, to the utter neglect of all that regards the quantity of air admitted to the furnace, or the conditions on which it combines with the combustible. In that treatise I have mainly relied on the fact that the question of effective combustion is a question as regards the *air*, and not the *temperature*. Modern patents have run on the erroneous idea that the gas evolved from coal in the furnace, and from which flame is exclusively derivable, is to be consumed by bringing it into contact with a mass of highly ignited carbonaceous, or coky matter. This I deny, and consider it to be not only a chemical fallacy, but a great practical error. On this ground, therefore, I am unwilling to be considered as regarding the question of a high temperature as the essential to the ignition or combustion of the gaseous matter of coal. My mode of effecting combustion, by introducing air to the gas in the way of numerous jets, depends for success on principles quite distinct from those which are attributed to the action of heated air. By one writer, the effect of my system is stated to be attributable to the circumstance of the air being heated in the passage through the diffusion tubes; now these tubes are used by me for the sole purpose of throwing the air into small jets, corresponding, in principle, to the jet from a blow pipe. This mode of explaining my principle goes neither to the right cause or effect.

So far from the tubes or pipes, which are made of fire clay or cast iron, heating the air in its passage through them, I have proved, practically, that the combustion goes on equally when the tubes are black and cold, and the air passing through them necessarily cold; this cold air, on issuing from the numerous small orifices, conveying the idea of jets of *flame* rather than *air*. It is important to state that I place no reliance on the question of the temperature of the admitted air.

It has been stated in explanation of the effect produced by my diffusion tubes, that as there is always plenty of air, or oxygen, in the furnace, and a deficiency of heat, the introducing the air at a high temperature, supplies this deficiency. This is directly the reverse of what I have stated to be the condition of the furnace, and the flues leading from it. The following extracts from my tract will put this in a clear point of view.

At page 124, I state, "The leading condition of the combustion of the inflammable gases being the *mixture* with the oxygen of the air in given quantities, and at a given temperature, those inventors have in too many instances, to the utter neglect of the former, exclusively directed their attention to the latter,—the obtaining the highest degree of heat, even to incandescence, for the gases. Now this is unquestionably the condition which demands the least attention on their parts, if *any at all*."

Again, page 129, "It is the palpable oversight of the distinction between increasing the *faculty* of combustion, and actually producing that combustion, which has led to that manifest chemical blunder,—the supposing that coal gas is to be *burned* by the act of bringing it into contact with bodies at a high temperature: or, in the words of the patentees, by 'causing it to pass through, over, or among, a body of hot glowing coals.' In our efforts then, towards effecting the combustion of the gaseous products of coals, it is essential that we steer clear of this hitherto unquestioned practice: attending solely to the question of *air*, and all that has reference to its introduction, distribution, and diffusion: for we may take it for granted, that the condition of *heat* is but a secondary condition; and that the required temperature will never be wanting in the furnace, from the moment we '*light the fire*,' if air be supplied in the proper quantity, at the proper place, and in the proper manner: but if these conditions be not satisfied, an accession of heat cannot remedy the evil, however it may aggravate it."

I assert then, that there can be no greater fallacy, than supposing that giving a high temperature to the air admitted, can be the means of effecting the combustion of the gases, or the prevention of smoke. An analogy has been drawn between the effectiveness of hot air in the manufacture of iron—this however bears no analogy with the introduction of hot air to the furnace, as the means of effecting combustion or preventing smoke. With your permission I propose considering this point on a future occasion—at present I confine myself to denying the assertion that my plan obtains any advantage from the circumstance of the air being heated in its passage into the flues through the small orifices of my diffusion or distribution tubes.

I am, Sir, your's, &c.

C. W. Williams.

Liverpool, Nov. 20, 1840.

THE NELSON MONUMENT.

Sir—Since I last addressed you, the first stone of the Nelson Column has been laid, the work is progressing rapidly, and will continue to do so until the public rise en masse to protest against so great an outrage upon the principles of beauty, or, peradventure, the subscriptions be, as at present, insufficient to complete the structure. We shall then have a piece of a column, to show succeeding generations the lofty standard of beauty amongst us, and to point out how *we* delight to honour the great, the virtuous, and the brave. Shall we, the British nation, permit this living libel to appear against our love of art; glorying in the matchless works of our ancestors, shall *we* allow posterity to point with derision to the evidence of their effect upon us. Enough has been said to show that the Nelson Committee are alone in their project, and it will be disgraceful, if the public submit to have this column thrust upon them, in opposition to their better judgment. Those journals in which we place most confidence in matters of taste, the Athenæum, the Literary Gazette, and the Art Union, have all protested against the proposed column; but despite this and the positive opinion of the Select Committee of the House of Commons, the projectors pursue their object *per fas aut nefas*, and the stone which Wellington would have been proud to lay, is laid, with no public announcement, and no popular enthusiasm, by the Secretary of the Committee. We do not hesitate to say, despite the expression of condemnation upon the whole building, that the *portico* of the National Gallery, exhibits many architectural beauties in its internal columns, and the depth of shadow caused by the projection of the antæ in front of the wall, and it is the portico which the pedestal of the column will completely hide. With all deference to one whose opinion as to the good effect in juxta-position of colossal, and ordinary proportions, demands from all, the highest respect, I would beg to notice that St. Peter's at Rome, has been objected to on account of the enormously disproportionate figures lessening the effect of the architecture, and St. Paul's itself, for the difference in size of its two internal orders. Sir F. Chantrey in his evidence as to the effect of the column as an ornamental object, says, "the Trajan, the Antonine, and the Napoleon columns are the only monumental objects of this class that I have ever looked upon with entire satisfaction; I read the history of the man on the shaft of the column, and the mind is thus reconciled to see the statue so elevated. I may be told we have not money enough for a work of this character, that naval exploits furnish bad materials for sculpture, or that the arts of this country are in too low a state to accomplish so noble a work; then I say, abandon the impossibility at once, and try something more in keeping with our means and our genius." The "general observations by T. L. Donaldson, Esq.," contain opinions as to the bad effect of a naked column. If, therefore, it can be shown, not that the funds do not suffice to enrich the shaft with bas-reliefs, and crown the column with a statue of bronze, but that the subscriptions are actually inadequate to complete the denuded shaft and the perishable statue, and if in addition to these sufficiently cogent reasons it can be proved, that a colossal column, when used without the structure of which it is as much a part as the leg is of the man, is an outrage against our most cherished principles of beauty,—it becomes the people to protest loudly and speedily against the infliction of so great a national indignity.

I am, Sir, your obedient humble servant,

A Lover of the Beautiful.

36, Tonbridge Place, New Road,
November 20, 1840.

ON COMPUTING EARTHWORK.

Sir—Observing an article in your October number, page 331, on the methods of computing Earthwork, by Mr. S. Hughes, in which the writer asserts, that the tables of Messrs. Macneil and Bidder, "are useful only for calculating sections where the scale is very small, and where the heights cannot be taken otherwise than in feet—and that where the scale is sufficiently large to show the heights in feet, and decimals of a foot, they are of no use." I take the liberty of transmitting to you the following for the purpose of proving that the tables of Messrs. Macneil and Bidder, are as useful for such calculations, where the heights are in feet and decimals, as in feet only.

I have at present the tables of Mr. Bidder only at hand, although I constantly make use of Mr. Macneil's for similar calculations, but an example based on the tables of the former gentleman will be equally illustrative of the use to be made of those of the latter.

For my purpose I have selected the same example as Mr. Hughes, in page 336.

Example.—Suppose a piece of cutting or embankment 39·8 feet deep at one end, and 24·6 at the other end, the base or top 30 feet and slopes 2 to 1, required the area, which being multiplied by the length, shall give the true content.

		Mid. part.	Slopes.
Intersection of columns	40 and 25, gives	79·5 and	2628.
Ditto ditto	39 and 24, gives	77 and	2471.
Difference		2·5 and	157.

$$\text{Then } \frac{\cdot 8 + \cdot 6}{2} = \cdot 7,\ \cdot 7 \times 2\cdot 5 = 1\cdot 75,\ 1\cdot 75 + 77 = 78\cdot 75 \text{ mid. part,}$$

$$\cdot 7 \times 157 = 109\cdot 9,\ 109\cdot 9 + 2471 = 2580\cdot 9 \text{ slopes.}$$

Mid. part $78\cdot 75 \times 30 = 2362\cdot 50$
Slopes $2580\cdot 9 \times 2 \text{ to } 1 = 5161\cdot 8$

Total contents in yards per chain 7524·3.

$$\text{Then } \frac{7524\cdot 3}{22} \times 9 = 3078\cdot 18 \text{ correct area.}$$

In practice the last operation forms no part of the calculation, as the lengths are taken out in chains and decimal parts.

I remain, Sir, your obedient servant,

Geo. B. W. Jackson.

Radcliffe Terrace, Goswell Road.
Nov. 24, 1840.

[The above is a very round about way for ascertaining quantities, to say the least of it.—Ed.]

RAILWAY MANAGEMENT.

Sir,—Before railways can ever be expected to be properly managed, several important alterations must be made in the present system. In the first place, the Directors must effectually suppress the propensity to *amateur engineering* on the part of the "clever practical men" of their body, of whom all boards have more or less. In the next place, they must make a common sacrifice of all patronage and personal consideration in the appointment of persons to situations, when any neglect would be likely to be followed by danger to either life or property. Were this system to be fairly and honestly acted upon, I have no doubt the necessary result would be the appointment of an individual, to whom would be confided the *entire* and *uncontrolled* management of the whole of the *out-door* business of the railway. To him would be committed the whole charge of the selection, employment, pay, and superintendence of every engineman, fireman, guard, porter, rail-layer, and labourer on every part of the line, any of whom he should fine, punish, or dismiss at his pleasure, and on him, and him *alone*, should rest the responsibility, both with respect to the public and the Directors, of every hindrance or accident which might occur. In proportion to the success of his management he should be paid, and on his appointment it should be distinctly intimated to him, that in the event of his being found unfit for his office, or even *unfortunate*, no hesitation or delicacy would be observed with respect to his dismissal and the appointment of another in his room. Any person aware of the importance of the duties which would devolve on an officer of this description, would at once perceive that they could not be properly and efficiently fulfilled without his *constantly traversing every part of the line*, and by personal inspection and observation, making himself intimately acquainted with the respective abilities, character, and disposition of every man employed under him, obtaining accurate knowledge of the varying circumstances of the traffic, and of those parts of the railway, where danger was most to be apprehended, and by the foresight which, by this means, he would be enabled to exercise to prevent the confusion and accidents with which the present system is so rife. The influence, moreover, which an officer of this description would exercise over the men, would be instantly visible in their guarded and more careful conduct, the well disposed from a hope of reward or promotion, and the bad from the fear of detection and punishment. Energy, perseverance, and tact, combined with sobriety and habits of business, would be the chief requisites in his character. It would also be essential that, in addition to his being an experienced engineer, he should be *practically conversant* with the nature and details of every man's employment, especially that of the engine-men, as a more self-important and uncontrollable set of men do not exist, if they have reason to think that those who are placed over them are not perfect masters of their craft.

The first thing to which I should suppose a person placed in this situation would direct his attention and instantly prohibit, is the very common practice of making use of either line while travelling in the same direction, a practice so obviously fraught with danger, that I am astonished how any board of directors or superintendant can, for a ment, allow it, except under the most extraordinary circumstances, and most stringent and well defined regulations, whereas, on the contrary, there appears to be no instructions whatever on this important point, nor any farther discretion exercised in the practice of it, than such as the circumstances of the case, in the opinion of those present, seem to require. Indeed, throughout the whole system, the absence of *individual* and *responsible* management is glaringly evident, and in all cases of danger and emergency, every one seems to "do that which is right in his own eyes."

Then as regards the signals, there is a red light for danger, a green light which indicates neither "danger or safety," and a white one which it would appear means anything or nothing, as the engine-man can best make out, all of which are confided without check, and almost without instructions, to ignorant, forgetful, and sometimes careless men. Can any reasonable person for a moment expect, that with a complex and ill-defined code of signals like this, railways are likely to be free from danger, or would he not rather express his astonishment, that so *few* accidents should have happened. If the road *is* perfectly clear, what necessity is there for any signal whatever, if it *is not* so, what need of more than one? Instead of all this complexity, I would at once adopt the broad and intelligible principle, that *a signal of any kind, exhibited under any circumstances*, should *always indicate danger;* and in order to carry it out, I would render it imperative on *every train* to have a light in *front* and one *behind* from sunset to sunrise, placed at such a height from the ground that persons moving about could not intercept the view. *Similar lights* should be exhibited during the same period at all the stations, placed at the *same height*, and occupying the *same relative position*, as those in the trains, so that an engine-man could not be certain, on seeing the signal, that it was not a train in his way. But the improvement to which I should be disposed to attach the most importance, and from which I should anticipate the happiest results, would be to place the whole of the station signals on a machine, which should be so far self-acting as *always, when left to itself, to indicate danger*, and to *require an effort* on the part of the attendant, before that warning could be removed; from this very simple precaution would be derived the important result, that *neglect of* or *inattention to* the signals would *insure safety*, which is sufficiently evident, as, whether danger did or did not exist, the signals would always indicate it, and cause the coming train to stop until it should be removed. There are many more points connected with railway management, which are by no means brought to the greatest degree of perfection of which they are capable, but for the present, I will leave them for a future communication, should it be necessary.

I am, Sir,
Your's very respectfully,
November 24, 1840. A Railway Engineer.

REVIEWS.

Papers on Iron and Steel. By David Mushet.

(THIRD NOTICE.)

Continuing our remarks upon the subject of iron, we may remark that the ores from which the metal is derived are distinguished by the author into two principal classes, primary iron ores and iron stones. The primary iron ores are defined to be those found in the older formations, bearing little resemblance to those in the stratified planes, and have, in Mr. Mushet's opinion, been formed by secondary agency, although they differ widely from each other in their properties. Some are distinguished as being obedient to the magnet, and others the reverse, but this property is by no means dependent upon the quantity of iron contained in the ore, but on its being in the state of protoxide, united or not with a portion of peroxyde, as ore from the Isle of Elba yielding 70 or 80 per cent. is but slightly affected by the magnet, while many of the Norwegian and Danish ores with only 18 to 30 per cent. of metal are highly magnetic. Mr. Mushet well defines the magnetic property as a test rather of the presence of iron than of the probable quantity to be obtained. The principal localities in England for primary iron ores are Cumberland, and Furness in Lancashire, also in the island of Islay, Muirkirk, and other places in the north, Cornwall, Devon, &c.

The Cumberland ores which present a perfectly formed crystal seem to be formed by the agency of water, an opinion which is countenanced not only by the structure but by several remarkable circumstances, water having been found in cavities of this ore, which had been transported several hundred miles. This ore is generally found, as well as that of Furness, in caverns or churns of the mountain limestone in large masses, splinty and globulated, consisting of various kidney terms called hæmatites, striated and smooth, of bluish and reddish colours. The Lancashire ore is composed of smaller masses, softer and of a more greasy appearance, but highly crystalized. Both of these ores, in the kidney variety, contain fine specimens of graphite or fossil plumbago. The ores both of Cumberland and Furness are much sought after for the purpose of mixing with poorer ores, large quantity of the Furness ore being shipped from Ulverston for South Wales. An opinion has prevailed unfavourable to the working of these ores on the spot, where both coal and limestone are at hand; no effective method of reducing them having yet been employed, although the author of the work before us has on more than one occasion given his weighty testimony as to the practicability. The Islay ore is found regularly stratified, and resembling, in point of deposition, the Norwegian and Danish ores. The strata, as described, are almost vertical, and are found imbedded in a loose ochreous earth surrounded with soil. The ore is not smelted with advantage owing to the excess of silex it contains. In different parts of Scotland, in the West Highlands, at Muirkirk, Salisbury Craggs, La Mancha, Cranston, the Ochil hills, &c., small quantities of ore have been found, but no quantity sufficient to justify the working. The chief Cornwall ores found in the granite are those of Lostwithiel, much mixed with quartz and manganese, and averaging about 48 per cent., and those of Fowey, a brown hæmatite, with 58 per cent. Those of Devon are the ores of Haytor, containing about 45 per cent. and lying in a schistose formation. We may also notice here the alluvial Minehead, in the new red sandstone, yielding 41 per cent., and at Brixham, yielding 62 per cent. The Devon and Cornwall ores are used extensively in South Wales, as also a rich hæmatite from the neighbourhood of Bristol, containing from 45 to 60 per cent. The iron of ores of the Forest of Dean are found like those of Cumberland in the carboniferous limestone: brush ore is one of the principal varieties, a hydrate, with protoxyde of iron, containing frequently from 60 to 65 per cent. of iron, the leaner ores containing a great deal of calcareous matter in the shape of spar, and so yielding only about 15 or 25 per cent. The Forest of Dean ores are the only ores worked alone, and instead of being treated with limestone, require a mixture of burnt argillaceous schist, as on account of their containing limestone, they are refractory and infusible.

We now come to the iron stones—these are commonly found in horizontal strata, subject to the same acclivity and declivity as the other stratified substances under the surface; their inclination varying according to the nature of the ground, and the disposition of the incumbent strata. They are supposed to be of aqueous origin, and are generally found imbedded in schistous clay more or less compact, which moulders away on being exposed to the atmosphere, and frequently accompany coal and limestone, in immediate contact with the coal. The ores are of two principal forms, in strata from half an inch to twelve inches thick; regularly connected strata called bands, and strata of detached stone found in distinct masses, from the size of a small shot up to a weight of several hundred pounds. The smaller masses being called in Scotland ball stones, and the larger lunkers (qv. lumpers). Band ironstone accompanying limestone is most commonly of inferior quality, its component parts being chiefly calcareous, and the quantity of iron contained being small, while ball iron stones accompanying lime are of much superior quality. The iron stones are divided by Mr. Mushet into four classes. 1. Argillaceous ironstone, which has clay for its chief component earth, and this clay comparatively pure and free from sand. 2. Calcareous ironstone, possessing lime for its chief mixture, and this lime also comparatively destitute of sand. 3. Siliceous ironstones, uniting clay and lime, and containing large proportions of silex. 4. Mixed ironstone, containing nearly an equalized mixture of clay, lime and sand. Each of these classes requires a different treatment dependent on its constituent parts, which with the quality of the fuel are the causes of the great diversity of processes which prevail in the manufacture of iron. Besides these four classes must be mentioned the Mushetstone or Blackband, a carboniferous ironstone, partaking much of the nature of coal as generally it contains carbonaceous matter enough to torrify the stone and make it fit for the furnace. Its exact geological position has not yet been determined, but is supposed by its discoverer to be in the lower part of the coal field near the millstone grit. The usual criterions by which ironstone is judged are—1, the degree of tenacity with which it adheres to the tongue after torrefaction; 2, its colour; 3, the obedience to the magnet when pulverized: 4, by depriving of its iron a given weight of the ore in the assay furnace. The first and third of these methods are peculiarly liable to error, as the degree of adhesion to the tongue will be more in proportion to the quantity and kind of clay contained in the stone, than to its real contents of iron, and the influence of the magnet as before remarked, is equally deceptive. The test by colour, although an empirical method, is one far more to be depended upon. A correct chemical analysis, however, although the surest test, is scarcely ever used, from the ignorance of the manufacturers. Mr. Mushet complains loudly and truly of the deplorable state of scientific knowledge of this class, which is as slow in acquiring instructions as in adopting improvements. He asserts that to his own knowledge the grossest mistakes have been made, and cites one case of iron ores of 30 per cent. having been sold for and smelted as ores containing 60 per cent. Detection it appears in such cases is difficult, as the charge of the furnace often consists of an association of iron ores, iron stones, and scoria from the forge and mill. Nor does the case appear to be much better among those professing some knowledge, as from want of proper instruction they are also open to gross errors. Instruction of this kind therefore seems to be a legitimate object in schools of mining and engineering, the inculcatiob of which would be of more good than all the attempts at teaching practice by theory.

A Practical Treatise on Locomotive Engines. By the Comte de Pambour. London: J. Weale, 1840.

We feel much gratification in being enabled to recommend to the notice of those of our readers who are interested in the theory or practice of locomotive endgines, a second edition of this excellent and truly valuable work. The former edition, although conveying, in the form of experiments, more practical information relative to locomotives than any other work which has appeared on the subject, and embodying the results of those experiments in a theory, which, though no perfect, was nevertheless calculated by the soundness of the reasoning in general, to throw much light on the true theory, was still defective in several points. The resistance of the air to the motion of the trains, and that of the extra pressure of the waste steam on the back of the pistons, caused by the blast-pipe, did not enter into the evalution of the work done by the engines. To supply these deficiencies, the author undertook, in the month of August, 1836, some experiments on the Liverpool and Manchester Railway, from the results of which he has deduced formulæ for determining those quantities which had previously been neglected in the calculation of the resistance overcome.

These experiments comprise also several other researches, such as the vaporization of boilers in different circumstances of rest and motion, the effects of different proportions between the fire-box and the tubes on the total vaporization of the engine, and on its consumption of fuel, &c.

In the first edition the loss of steam by the safety valves had been very incorrectly measured: this has suffered a material alteration in the edition now before us, but how far the new determinations are to be depended on, remains yet to be proved. It is an investigation which demands that the experiments should be conducted with the utmost nicety, and in the greatest possible variety of circumstances.

The table of experiments on the quantity of water carried over with the steam in the liquid state, differs in some respects from that which was published in our Journal for December, 1839, and to which we appended a note explaining our reasons for not putting implicit confidence in the results obtained. Two different experiments with the Star engine have been substituted in the work under consideration, for those contained in the table which was published in the Journal, and in all the other experiments which are the same as in that table, we observe that a different deduction has been made for the loss by blowing through the safety-valves during the ascent of the plane. The first of our objections is removed by the indirect statement that there was no loss by leakage during the experiments given in the table, the second in some measure by the corrections in the determination of the loss through the valves, and the last by the declaration, that the mean is only intended to be adopted approximatively for engines that have not been directly submitted to experiment in this respect. This mean has been corrected from 0·68 to 0·76.

The second chapter, which treats of the laws which regulate the mechanical action of the steam, is the same as the corresponding chapter of the "*Theory of the Steam Engine*," by the same author, which was published last year. It has been introduced here in order to save the reader the trouble of recurring to another work, besides which, it has the advantage of rendering unnecessary the purchase of that work to those who are only interested in steam engines in as much as they are applied to the purpose of locomotion on railways, and whose means may be too limited to justify such an addition to their libraries.

We are compelled, for want of time, to postpone a more particular examination of this very interesting work until next month, in the mean time assuring those of our readers who are desirous of making themselves more thoroughly acquainted with the effects of locomotive engines, that they cannot do better than possess themselves of this second edition of Comte de Pambour's Treatise; for those who were unable to obtain the first edition, will be amply recompensed for their disappointment, by the superiority of the new one, and those who possess the former, will find it almost equally necessary to purchase the latter, since it can scarcely be considered as a reproduction of the same work, but almost rather as a continuation of it, so many and important are the corrections and additions which have been introduced.

REPORT ON THE REMOVAL OF THE WEIR AT THE BROOMIELAW BRIDGE, GLASGOW.

By William Bald, F.R.S.E., M.R.I.A., &c., Engineer of the Clyde.

To the Trustees for Improving the River Clyde and the Harbour of the City of Glasgow.

My Lord, and Gentlemen,

In conformity with the remit transmitted to me, dated the 6th instant, I have read over the Report of Captain Johnstone and Mr. Russell, Harbour Masters. It has been drawn up with great care; and from the facts therein stated, is of great value, and merits deep attention. I have no hesitation in signing their report, so far as it treats of the many advantages which would arise from the opening up the spaces between the bridges for the accommodation of the small steamers, sailing craft, &c. But there are other points, in my opinion, of vital importance, connected with this subject, which have not been mentioned in their report; and which I beg leave to lay before your lordship and the trustees.

The removal of the weir at the Broomielaw Bridge, and the deepening and clearing of the space upwards to Stockwell Bridge, containing nearly 14 acres, would give much additional tidal water; thereby increasing the currents not only through the harbour, but also to some extent in every part of the Clyde downwards; thus aiding and assisting that scouring force which acts so powerfully in freeing and keeping clear all river estuary channels from banks and shoals—the great obstacle to navigation. In the improvement of the navigation of tidal rivers, no expense or pains should be spared to increase this scouring force, arising from that uniform and constant tidal flow and run of currents ascending and descending alternately, and which are so eminently distinguished by their beneficial effects in preserving navigable channels, as compared to those violent land-floods, which, in many instances, so frequently carry down immense masses of matter, forming shoals, banks, and bars in them, extremely injurious to the navigation, and involving great expense in keeping them clear.

The removal of the Weir at the Broomielaw Bridge, and the additional receptacle for tidal water between the Bridges, would have a tendency to sweep and scour away all those impurities which are at present discharged into it by the city sewers. The removal of the weir, and the deepening and clearing away of the channel of the river, would also have the effect of lessening the miasma which arises from the present condition of the bed of the Clyde between the bridges, and would render the atmosphere of that part of the city much more pure and healthy.

It is noble and praiseworthy to erect hospitals and asylums for the relief of those who may unfortunately be afflicted with fever; but how much more advantageous would it be to cut off and destroy the sources from which that contagion arises, by the removal of all offensive matter? In this respect, the attention paid by the Dutch to many of their cities and towns, offers an excellent example to the people of other countries.

At present, the harbour of Glasgow is a receptacle, not only for a large portion of the *debris* which the Clyde sends down during floods, but it is also a reservoir for almost the whole of the matter discharged by the city sewerage. The quantity delivered into the present harbour from those two sources is immense.

The flood of last August left a deposit on the steps of the upper ferry-stairs, on the south side of the harbour, as follows:—On the upper step, reached by the flood, a depth of 2 inches; on the descending steps, $2\frac{1}{8}$, $2\frac{3}{8}$, $2\frac{5}{8}$, $3\frac{1}{8}$, $4\frac{3}{4}$, and 5 inches. The last step was about 3 feet 4 inches below ordinary high water line. It has been alleged, that the River Clyde leaves little or no deposit; but the above facts prove the fallacy of such a statement. Besides, no experienced observer could have a doubt on this subject, who has seen the extremely discoloured state of the water of the Clyde during a flood, by the quantity of alluvium held in suspension, and which is deposited in the bed and sides of the Clyde, wherever the tranquillity of the water is not disturbed by a current sufficient to carry it away;—and it should always be recollected, that, in the improvement of the navigation of a river, and the widening of a harbour through which it runs, a velocity of 3 inches per second at bottom will work on fine clay; that 6 inches per second will lift fine sand; 8 inches per second, sand as coarse as lintseed; 12 inches per second will sweep along fine gravel; 24 inches per second, gravel one inch in diameter. These established facts ought to govern the engineer as to the width which should be given to rivers, and to harbours through which rivers flow, so as to regulate the velocity of the water and prevent them from being silted up with alluvial matter, or involve a serious expenditure in keeping them clear by the artificial means of steam-dredging; therefore, no exertion or expense should be spared to increase the natural force of the scouring power, by the descending currents through river harbours and river navigations.

It may be observed, that to keep the harbour of Glasgow clear, and sufficiently deep for vessels sailing out and in, requires at least the power of two steam-dredges constantly working; the annual approximate expense of which is as follows:—

Expense of one dredging-boat per annum, including repair of wear and tear, and interest on capital, at . . .	£1368	9	4
Steam-power drawing the punts	500	0	0
Discharging the material and carrying it away . .	1200	0	0
Expense of one dredging-vessel	£3068	9	4

Then, the annual expense of two steam dredging-vessels will be about £6,136 18*s.* 8*d.* The area of the wide part of the harbour between Messrs. Todd and Higginbotham's mill, and the Weir at the Broomielaw Bridge, is about twenty-one acres, which requires to be operated on constantly by two steam dredging-vessels: this is nearly equal to the rate of 300*l.* per acre of harbour surface per annum.

Immediately below the Weir, and within the Port, spaces have been cleared and deepened to 10 feet below low-water line, but which have been filled up in the short period of a few months to 2 feet above it; thus filling up a space of 12 feet in height. Looking at the vast expense of keeping the harbour clear—and again, at the great inconvenience to the shipping by a reduced depth of water, arising from shoals and banks being so rapidly formed within it, so extremely detrimental to its free navigation—I am impressed with a more full conviction, that the most active and the most energetic steps should be adopted to diminish those evils as far as practicable. Therefore, the clearing away immediately of the Weir at the Broomielaw Bridge, the widening of the mouth of the Harbour, and the deepening of the River up to Stockwell Bridge, would tend partly to remove the evils here stated, because those operations would increase the tidal currents through the harbour, and equalise them at its mouth.

The matter discharged from the city sewers on the north side into the harbour, might be entirely removed by the construction of a large sewer, commencing near the Jail, and running parallel with the river down to below Barclay's Slip, where it would enter the Clyde. This sewer would receive the whole of the drainage which at present falls into the harbour from the city of Glasgow on the north, and would consequently free the port from considerable deposits which are discharged into it.

The peculiar construction of the present harbour of Glasgow, with its narrow entrance, its head barred by a stone weir extending across from side to side, over which the high tide only sometimes rises but a few inches, so that there is scarcely any perceptible tidal current upwards through it during the whole period of flood tide, until the water has reached above the top of the weir at the Broomielaw Bridge; the water sent up by the tide of flood, as well as the river water descending and falling over the weir into the harbour, remains in a quiescent state, except during the times of floods. Thus, the alluvium contained in the descending waters of the river, the silt carried in by the city sewers, and the fine particles of matter held in suspension by the tidal water flowing up—all meet in the harbour of Glasgow—at every tide, forming immense deposits, undisturbed by any tidal current for more than four hours; which fully accounts for the rapid manner in which the harbour of Glasgow silts up, and the great expense which is constantly required to keep it clear and open by steam dredging-vessels. But if that part of the river between the Broomielaw Bridge and Stockwell Bridge, were deepened, it would receive the river *debris* before it could reach the harbour, and it could be dredged up there as cheaply as any where else, and without any inconvenience to the shipping.

What can be compared to a fine navigable river flowing free and unfettered, without lock or dam, through a city, laying open, by its upper reaches, the rich mineral wealth of the interior country to the enterprise and industry of the people; while, on the other hand, the lower reaches of the river waft the ships to the ocean, that highway to all the regions of the world!

It must be manifest to any person who has observed the immense business which is carried on by small craft, on the waters of the Thames at London between the bridges, on the Seine in Paris, and on many other rivers which run through cities and towns, and the clearing away of the weir at the Broomielaw Bridge, and making the river Clyde navigable through the city, would be a work of the greatest public utility, conferring advantages of the most beneficial kind, not only on the shipping interests, but also on the whole population of Glasgow.

The Govan Railway delivers at the harbour of Glasgow annually from 60 to 65,000 tons of coal; and although this railway will, in my opinion, continue to increase in its traffic, yet I am confident that the opening of the upper navigation of the Clyde would be the means of sending down by water considerable quantities of coal and other minerals, &c. to the shipping in the harbour; and it may be observed, that the descending tidal and river currents—a power which costs nothing—would offer every facility to the transmission of coal and other articles downwards, which could be shipped at once from the barges or punts into the ships and steamers lying in the harbour, without encumbering and occupying so much of the quays, or wearing the streets by the constant cartage of such vast quantities of coal, which are not only required for exportation, but also for the supply of the numerous steamers on the Clyde, and those plying to the ports of England and Ireland. Coal-lighters, carrying about 100 tons, descend the Mersey, enter the docks of Liverpool, and supply the shipping. The facilities to river navigation which the Clyde offers, from the harbour to a considerable distance above the city, into the coal and iron districts, are extremely inviting for the carrying on of a similar traffic.

The space, as already mentioned, between the Stockwell and Broomielaw Bridges, contains an area of nearly 14 acres. The deepening and the construction of wharves within it, would be less expensive, and would afford comparatively more accommodation to the small shipping craft, than any other place which could be found anywhere within the vicinity of the harbour. The expense of the contemplated works will be nearly as follows:—

Masonry, in wharves and quay-walls, 1350 feet long .	£17,287	11	6
Deepening channel, paving, cranes, pauls, &c . .	8,047	17	0
Securing Stockwell Bridge	1,234	11	8
Total	£26,570	0	2

It may be proper to observe, that the deepening between the bridges to two feet below low water line, will not, in my opinion, disturb the foundations of the existing quay-walls in the harbour.

In concluding, it is to be hoped that the space between the Broomielaw and Stockwell Bridges, which is now waste and useless, without a raft of timber, or even a small boat, to adorn its surface, will very soon be covered with numerous classes of small vessels, presenting a scene of a busy maritime trade nearly in the middle of the city. And now that railways are about to compete with the steam-boat passenger trade, what immense advantages would it confer on the steam navigation of the river, if the weir were removed, thereby enabling the steamers sailing to all the lower parts of the Clyde, to arrive and take their departure from between the bridges, or even from the Broomielaw Bridge, which would be so extremely convenient and central to the inhabitants of the city.

BRITISH MUSEUM.—FUNEREAL MEMORIALS OF ROME.

(From the Times.)

There are, perhaps, few rooms in the British Museum whose contents deserve or attract more inquiry and observation among the generality of its visitors than the one appropriated to the funereal memorials of the Romans, and of which less account is given in the meagre synopsis of the institution; the other remains of Grecian or Egyptian antiquity which fill its halls, although possibly placed with sufficient taste and judgment, yet having no connexion with the scenery, if it may be so called, of the localities in which they are contained necessarily lose much of the effect they are calculated to produce. To the artist who contemplates the beauty and boldness of their designs, or the excellence of their execution, and takes them as models for his study, this is perhaps scarcely felt; his taste may discern their value; like the lapidary, he is equally aware of the brilliancy of the gem when it first meets his view, whether disguised by the crust that nature gave it, or set off with all the splendid adjuncts which art or study can devise. Still, even the genius of the artist may become cramped and clouded in its development from contemplating the master-pieces of antiquity isolated and unconnected from the architecture to which they appertain, and when, instead of viewing them as part of a magnificent whole, he sees them but in a state of chaotic vagrancy and isolated decay. In contemplating the minutiæ of beauty displayed in the dilapidated or even in the more perfect remains of antiquity, apart from the designs of which they form but a portion, the imagination necessarily becomes concentrated and confined by that which it contemplates, and however much the taste of the observer may be improved, and however excellent may be the work he in consequence produces, yet in his productions that sense of unity and grandeur of thought is often found wanting, which is the distinguishing feature of ancient art. To this, perhaps, may be attributed those anomalies of design which are to be seen in almost all the classic monumental sculpture of our cathedrals, and also in most of the modern architectural elevations of the Greek and Roman school. The different parts or sections of one or the other will often be found perfect, but few there are that taken as a whole will bear comparison with the edifices or monuments of antiquity. We mention this, because, in the chamber we are about to describe its architecture and decorations, with the exception of the northern side, form a perfect representation of a Roman columbarium, or place of family sepulture; the urns which are in the niches of the walls originally occupied similar positions; the sculptue of few of them possesses pretensions to excellence, and had they been placed in a room among a generality of sculptures, they probably would have caused no observation, or if any, contempt; yet in this chamber, fitted up in resemblance of those in which they were found, they acquire consequence, and well worthy are they of the observation they attract. It is the only part of the Museum in which the sculptures are in connexion with the edifice, and which, from that connexion, give a true idea of the purposes for which they were designed; in the contemplation of them the spectator, without much stretch of imagination, might almost fancy himself in a family sepulchre of ancient Rome, surrounded by the ashes of its members.

This saloon is entered from a door in the northern side of the statue gallery; it is 16 feet in length by 10 in breadth, and the height 10 feet; the roof is vaulted and divided into compartments; the colour gray. On either side, cut in the depth of the wall in lines one above the other, are niches, in which are placed the funeral urns of a family, and on the pavement on the eastern and western sides are some of greater magnitude, and also some smaller ones placed on votive altars; almost all of them are richly sculptured, and the various designs have an allusion either to the mythological dreams of the ancients, or represent some domestic scene: none of them possess that character of awful simplicity which distinguish the last receptacles of our Gothic ancestors. Beneath some of the niches are marble tablets, bearing inscriptions, and where this is the case within the thickness of the walls are enclosed earthen jars, with covers, in which the ashes of the deceased were placed. The floor is formed of Mosaic.

The niche No. 35 contains a sarcophagus, on the front of which the marriage of Cupid and Psyche is sculptured. Of this Apuleius gives the following description:—"The bridegroom in the centre is lying on a couch, Psyche '*gremio suo complexus*;' Jupiter and Juno are in the centre behind in a sitting posture, and all the gods according to their rank are standing around; a bowl of nectar is passing from one to the other. Jupiter has a particular cupbearer to himself to attend and fill. Bacchus waits on the others, while Vulcan cooks the supper; the loaves are strewed with roses and other flowers, and perfumes are scattered over all by the graces: '*Musæ voce canora personabant!*' Apollo sings to the lyre, while Venus dances in time to soft music, and the graces sing in chorus; the pipe is blown by a satyr, and Pan plays on the reed. The whole of this is a representation of the rites by which Pysche is conferred on Cupid." In this piece of sculpture the principal figures shown are Cupid and Psyche, with their immediate attendants; they are sitting on a couch, in front of which is a small tripod table, on which is a fish; around are the attendants playing on musical instruments in honour of the bride, and bearing to her wine, fruit, and presents: the companion of each of these attendants is represented as a Cupid or a Psyche, for the ancients had many Cupids and more than one Psyche. The ends of the sarcophagus are rounded, the length of it is 4 feet 6 inches, the breadth 18 inches, and the height 15; it was brought from Rome.

No. 33 is a sepulchral urn of an oblong form: three fluted spiral columns and two pilasters divide the front into four compartments, in each of which is a door ornamented on the top with pendant garlands of laurel; there are four tablets passing across the upper part, one of which has the following inscription on it:—"2 C. Magio, F.. Pal. Heraclidæ V. A. xviii.;" the others are blank. The lid resembles those found on the Etruscan tombs; it is like two lids joined together lengthways; in the centre is an ornament of a rabbit feeding on fruit from a basket, on each side of which ornament is a deer, which a serpent and a dog are attacking in front and rear. The doors are supposed to be the portals of the abodes of departed spirits, they are remarkable as having their pediments of the shape generally chosen for the covers of sepulchral monuments. At the end of the urn are two spears crossed, which probably had some allusion to the youth to whom it is dedicated, who perhaps took delight in the sports of the chase, and who appears to be according to the incription—C. Magius Heraclidæ, of the Palatine tribe, the son of Quintus; it has a handsome pediment, in which are figures of dogs hunting.

The niche which is marked 21 contains an exceedingly curious cinerary urn of baked clay; the bas relief on the front represents the hero Echetles fighting at the battle of Marathon for the Greeks, his arms are a ploughshare. Upon the cover is a female figure asleep in a recumbent position; beneath her head is a pillow. Pausanias gives the following account of the circumstances of the combatant who used so singular a weapon:—"It happened in this battle (as they say) that a man dressed and having the appearance of a peasant, and armed with an agricultural weapon, should appear when the barbarians were prevailing, who when he had slain a number of them should vanish; no one knew him as an Athenian, but others said, according to the oracle, that he was a native of Echedæum." On the border of the urn there is an inscription over the bas relief, which is slightly cut, and has not been painted. The whole of this urn is exceedingly well designed: there is great spirit shown in the attitude of the figure who has been forced down by the strength of the rustic weapon the effort it is making to rise is true to nature; the figure with the helmet has the arms of a Roman legionary, but the shields of all the combatants are Grecian; much vigour and spirit is displayed in the *melée* of the combat.

No. 13 is a sarchophagus, on which a family is represented mourning over the body of the dead; the corpse is that of a female lying on a couch, which is surrounded by the friends and relations of the deceased: they are exceedingly well grouped, and the expressions of grief are well designed. Beneath the couch are seen the sandals of the departed, as also a wreath which has been used as an ornament to the hair: a dog, probably a favourite, is also introduced, and appears as a mourner. On each side of the sarchophagus is a griffin, resting on its hind legs; the lid and plinth are modern. It formerly stood in the Caprinaca palace at Rome, and has been several times engraved. Montfaucon mentions the sculptures of this monument, as illustrating the Roman manner of lamenting the dead; the two figures close to the couch with their arms extended are alluded to in the passage of Lucan—"*Exacte ad sævas famularum brachia planctus*," and represent a singular part of the Roman ceremony, the "*exclamatio*," or calling aloud, on the name of the just departed, intended either to arrest or call back the flight of the soul, or to rouse the dormant spirit in case death should not actually have taken place, that the person might not be exposed to neglect or placed upon the funeral pile while any breath of life might still remain. It might be curious to inquire if the singular custom of the death wake, still so pertinaciously adhered to by the Irish peasantry, and to perform which *dacently*, as they call it, the poorest will sacrifice all they possess, and the non-performance of which is looked upon as a sacrilege committed, derived its origin from the custom of ancient, or the priestcraft of modern, Rome. At each end of the sculpture the father and mother of the deceased are standing; an old man at the extreme end holds one hand to his eyes, in the other is a funeral cake. On each side of the female are two children. Altogether there are ten figures in the group. The father is sitting on a stool and the mother in a curule-shaped chair; the head of the father is wrapped in a veil.

No. 34 is an Etruscan cinerary urn of baked clay. The bas relief in front represents the single combat of Eteocles and Polynices, who were both slain in the combat; the first from a wound in the groin, and the latter from a stab in the breast. The female figures standing by the combatants are furies; each hold a torch in one hand, while the other is extended over the antagonist encouraging and inflaming the combat; at each end, on a pilaster, is an Etruscan inscription, which is written from the right to the left in red letters. All the figures have been painted, and some of the colours yet remains. Upon the cover of the monument is a female figure asleep. The action of the whole group is excellent; the warrior who is down has lost his helmet; his hair is curled in the Etruscan fashion. His opponent is more completely armed, and the manner in which he forces the shield from his opponent, and drops his own while he stabs him to the heart, is masterly designed. The expressions on the countenance of each are different; extreme anguish in that of the fallen, and the exultation of victory in the other, are strongly defined; the figure of one of the furies is sandalled, while the other is bare. The representation of the combat as here given exactly corresponds with the account of it by the poet Statius, and it is not unlikely that he was indebted for it to these figures. It is highly probable that this contest was by no means an uncommon subject among the ancient artists. Pausanias says that the representation of it made one of the subjects which ornamented the sarchophagus in which the tyrant Cypselas, of Corinth, was deposited: in that the same author mentions that Polynices is represented as having fallen on his knee, which is the exact attitude here represented"—"*Ex Œdipi filius Polynicem* *in genu vilay suu frater Flecch orpe:*" Take this sculpture as a whole, it is one of the most splendid specimens of sepulchral urn in existence.

No. 13. This is a sepulchral urn of a square form: in the centre of the front is a tablet, on which is the following inscription:—

" Dis manibus
" Peliæ. Philtatæ
" M. Pilius. eucarpus
" Convgi. B. M.
" fecit, et sibi."

At each of the four corners is an eagle; the lid resembles a pointed roof; in the centre of the face of the urn is a bust of Pelia Philtata, and at the corners are the usual ornaments of honeysuckle flowers. The particular for which this urn is remarkable is a peculiarity in the lid, which is occasioned by a singular custom of the ancients, and sometimes practised in honour of the deceased. When the funeral rites were performed it was the custon at stated periods to visit the ashes of their friends, and to adorn their urns with flowers and garlands, and to offer sacrifices of oil and wine to their manes. In some cases these visits arose from friendship or affection, but the performance of them was often strictly ordered by the will of the deceased, and funds provided for it. In this, in order that it might with greater convenience be complied with, on the top of the lid of the urn a patera is formed, in the bowl of which is an opening through which the wine, oil, and ointments were poured upon the ashes. Propertius says—"Adfert hao unguenta mihi, sertisque sepulchrum ornabit, custos ad mea basta sedens." Ovid in mentioning libations to the funeral urn says:—

" Jam tamen extincto cineri sua dona ferebant,
" Compositique nepos busta piabat avi."

On the left side of the doorway as you enter is a sepulchral urn dedicated by Flavia Dada, and by Fortunatus, a freed man of the Emperor, to the memory of her deserving husband, and his most worthy father, Admetus, a superintendent of the furniture of the Imperial Palace, and also a freed man. Above this inscription is a bas relief representing the "cœna feralis," or funeral feast. Naked to the waist is the figure of Admetus reclining on a couch; in his left hand he holds a large cup or vessel, and in his right a wreath; according to the Roman custom at feasts, his head is decorated with a garland; two children naked are sitting at his feet; behind is a female attendant, who is supporting his body; the hair of this figure is singularly bound on the front of the head in a knot. All these attendants are dwarfish in their proportions, as was frequently the case when inferior persons or slaves were represented on the ancient sculptures. These representations of the funeral feast are curious and interesting: it is impossible for us to enter into the feelings which dictated them; yet the custom of offering the funeral cake and wine at the present day may have derived its origin from it; we know not in what light the ancients regarded a future existence, but these sculptures sufficiently indicate their hopes, though they show the indistinctness of their ideas; here are the monnied dead, represented as exercising the animal functions of life; elegances are displayed to please the eye, food and wine to gratify the taste, often music to charm the ear, and garlands to perfume the air, and to these enjoyments are added the presence of their friends who are yet in existence; thus the living and the dead, the spiritual and the material world, are associated together in one common act; circumstances are represented in the history of which we can hardly participate or understand, but by which we may perceive that the ancients did entertain notions, though inaccurate and ill-defined, of a future state. The urn is ornamented at the top with garlands, which take the shape of volutes, the ends of which terminate in a rose. The præfericulum and patula are sculptured on the sides of the urn. The top has never been separated from the body; it has a large circular excavation in the middle, about seven inches and a half in diameter.

On the north side of the room, in the niche, the third as you enter, is an urn different from most of the others, and very rarely met with, being square, and of an upright shape; it is enriched by a festoon of laurel leaves. On it is this inscription in four lines:—"Vernasiæ Cycladi. Conivgi optima, vix. ann. xxviii. vitalis, Aug. I. scrib. cv. B." The figures of a man and his wife are represented as standing beneath a portico, the roof or which resembles that of a sepulchral urn; they are in the act of joining hands; between them are the letters F. A. P. Lighted torches, placed in an upright position, form the corners of this urn, each side of which is embellished with a laurel tree; a wreath is placed on the centre of the lid, and a dolphin at each corner. The intention of the portico on the monument is in allusion to the entrance of the habitation of departed spirits, where the wife must take a long farewell of her partner. Among the Romans in the earlier times of the empire their funeral ceremonies were always performed at night, which was formerly also the custom in this country, and the torches at the corners allude to it; and even at a later date when the funerals took place in the day time, lighted ones always formed part of the accompaniment; those placed here are of the sort called "tædæ," being the semblance of a number of fine slips tied together with thongs. The dolphins relate to that superstition of the ancients which supposed that the spirits of the dead were conveyed by them across the seas to the happy abodes of the blessed. Vitalis, who by the inscription erected this monument to the memory of his beloved wife, Vernasia Cyclax, seems to have been a freed man of the Emperor, and a favourite, as he held an office similar to that of private secretary; the letters "F. A. P.," between the figures, denote that the tomb was erected by order of the Œdiles. No. 6, is a small slab let into the wall, it shows the manner in which the memory of the favoured dependents of a family were preserved: on it is this inscription—

ANNIOLENA T. F. MAXIMA	SERVILIA IRENE.

Within the wall which it faces are two ollæ or circular vases of earthenware, somewhat of the shape of the alabaster one near the centre on the south side of the room, in it were deposited the ashes of the two persons whose names are recorded on the slab in front. The lids of these vases alone are visible, which can be taken off, to allow libations to be poured which the pious affection of surviving friends might offer to the memory of the departed. Sometimes in family tombs four or more excavations were made in each niche, in general they are found sufficiently large at the top to allow the urn to be taken out, but occasionally, as in this, they are so constructed at the mouth that the space does not allow of the removal.

In the centre of the room is a mosaic pavement, which in the year 1805 was found on making some repairs under the south-western angle of the Bank of England, about 20 feet west of the westermost gate, opening into Lothbury; it was 11 feet beneath the surface, the design is handsome and well executed, but the workmanship is evidently inferior, and probably that of a native artist. The outer border is composed of pieces of brick. It is not sepulchral, nor is it connected with the other objects here: it evidently, from the cross in the centre, was made after the introduction of Christianity into the island.

On the south side, near the centre compartment of the room, placed on an altar, is a sepulchral urn without either inscription or decoration; it has handles and a cover, the shape is exceedingly elegant, the material of which it is made is the alabaster of the ancients, which is of a yellowish colour with pinkish stripes; near it there is another of the shape of a truncated cone, which has a cover and very small handles; the stripes on it are more strongly defined; the colour is the same, as is also the substance of which it is composed; the height of it is 20 inches, the diameter at the top $8\frac{1}{2}$, and at the bottom 12.

The saloons containing the Elgin and Phigalian marbles have lately, after a variety of trials, been coloured in imitation of rose-coloured Egyptian porphyry, and the roof of grayish granite; time may in some degree reduce the luxuriancy and brilliancy of the colour; at present, perhaps, the rosy warmth which it throws over the apartments somewhat hurts the effect of the sculptures. The brown and dark appearance which time has given to these master-pieces of antiquity is compromised by the blooming walls by which they are surrounded and supported, their look of youthful pretention and roseate bloom but badly harmonizes with the severity of age. The monstrosities of Egypt in the adjoining halls would have been more in keeping with that mythias of colour by which their neighbours in a great degree are eclipsed and overwhelmed.

ON DRY ROT.

I was desirous of taking only a partial view of this subject, and of confining my observations to that species of Dry-rot which is common in new buildings; without encountering what is known by that name, which at one time threatened the extermination of the British Navy, and is by some attributed to the Fungi Sporotrichi, but I attempted in vain to make the distinction.*

The rot which I allude to, might be more properly called the damp-rot, or wet-rot, than the dry-rot, for it appears to arise from *confined moisture;* and the prevention as well as the cure for it, I believe, may consist in merely giving the confined moisture an opportunity to escape, by the admission of air. I do not mean to say that atmospheric air is a specific, by the administering of which rotten wood can be made sound; but I do mean to express my belief, that the introduction of air, even in small quantities, will effectually arrest the destructive progress of the dry-rot.

I will mention two instances now existing of this dry-rot in two new churches, namely, that of Trinity Church, Oswestry, and the New Church at Aberystwith. The former is built of rubble-stone of the neighbourhood, from Sweeney Mountain, which is a free-stone, with a large proportion of mortar: the latter is built of rubble-stone of that neighbourhood, which is of a slaty quality, with a large proportion also of mortar. In both these cases the ends of the pews are closely fitted with framed panels of deal upon damp walls, good oak floors in the former, and I think in the latter also, and risers of deal under the pew doors. The effects of this dry-rot have become very conspicuous in both instances, by an extensive destruction of the wood work, against the walls, and under the doors of the pews: upon removing the panels &c., it was found that a parasitic fungus has made extensive ramifications, and the deal is very much decayed, but the oak has as yet suffered comparatively little injury. I believe, that if a perforated plate containing apertures equal to three or four square inches had been inserted in the upper panel, fixed to the wall in each pew, and the like under each door, the mischief would not have happened; and that if these means of ventilation were resorted to now, they would stop the progress of the dry-rot. But I do not know any thing more certain to produce the dry-rot than what I have just noticed, and consequently nothing could put any expedient for the prevention or cure of the evil to a severer test than to have thus impounded the moisture. A pretty little gothic pattern, weighing three-quarters of a pound, has been

* The following Fungi are considered as the cause of dry-rot:—Boletus lachrymans, Merulius lachrymans, Polyporus destructor, and the genus Sprorotrichum.

prepared and partially put up in Trinity Church, for ventilating the parts affected with dry-rot.

The growth of the parasitic plant, and the decay of the wood coming into contact with it, seeming to be in a great degree contemporaneous, I am not prepared to say which is the cause, and which is the effect of the other; but I think that the growth of the plant takes precedence of the destruction of the wood.

I shall relate two or three facts which have come within my knowledge, because they strengthen my conviction as to the most effectual means for the prevention and cure of the dry-rot.

The usual manner of preparing the walls of a house for skirting-boards, and fixing them, is likely to produce the dry-rot, as thus:—a coat of mortar mixed with pounded glass fills up very closely the space behind the skirting-boards, to prevent mice from having a run there, and a moulded cap of wood is rabbeted and put up for receiving the plain board: on the floor is sprigged down a rib of wood, of about one inch square, for the whole side of a room, without any intermission, and the skirting-board is then scribed and closely fitted to the floor, &c.

In a new house the walls and the plaister may not be perfectly dry, and the same mischief which has been described in the pews of a church is likely to occur, and does so continually, in the decay of the skirting-boards, particularly on the ground floor; but I think that it happens less frequently when there are arched cellars below, which may carry off some of the moisture. A little of the water in washing the floor, the skirting-board being in a dry state, will find its way behind it, and increase its liability to decay, by impounding a little more moisture.

I have observed this to take place to some extent in fifteen or twenty years after a house has been built, but not perceived till the damage was considerable, because the paint will conceal it. In replacing the skirting-board instead of a continuous rib of wood sprigged on the floor, I have taken pieces of a foot or foot and half in length, leaving a vacant space of two or three inches between them, and not fitting the skirting-boards very closely to the floor, so that a small circulation of air may be preserved; and no decay has occurred in a similar period, at least I can answer for a term of thirty-five years from the erection of the building.

When a new mansion house is to be built, it often happens that a certain quantity of sound timber from an old house is to be made use of, in the shape of beams, joists, &c., and the old beams and joists are apt to be immediately applied to the ground floor, which is a great mistake. An instance of this having occurred within my knowledge, I must give a minute account of facts and consequences in order to bring them to bear on the points which are under consideration.

The front of the house faces the west, and consists of two principal rooms extending length-ways to the right and left of an entrance room, the floors being three steps above the ground; and I am pretty sure that the joists, if not the beams also, were of old timber: the boarded floors were of the best Baltic oak, prepared and finished in the most careful manner. Beneath these front rooms there are no cellars, but arched cellars extend under all the back rooms, which appear to have prevented the evil that I am about to describe as having occurred in the floors of the two principal rooms.

In the course of twenty or twenty-five years from the building of the house, the deal skirting-boards on the outward walls were found to have decayed, particularly on the west, and the floor sunk nearly an inch in some places from the skirting-boards. It was evident that the joists had failed at their insertion into the outward walls. The floor was then taken up for an opening sufficient to admit a man with a lighted candle, who crawled on his hands and knees under the floor, to ascertain the extent of the mischief: the parasitic plant or the dry-rot had got so great a footing, that it became a question whether the whole of the two floors ought not to have been taken up: but it was at length resolved to try the effect of a less expensive operation, which at the present time, after a lapse of ten or fifteen years, seems to have answered perfectly well. Several new oak joists were placed crossways beneath those which had partially failed, and as nearly as conveniently might be to the decayed ends of those joists which had wholly or in part lost their holds upon the outward walls, propping the new joists with bricks, slates, and stones; and the skirting-boards were then replaced in the manner before described.

But the thing on which the greatest reliance is to be placed was the preparation to be made for the circulation of air beneath the floors: plates of iron were cast three inches square, perforated with many holes of a quarter of an inch diameter, four of these plates were applied to each of the two rooms, two distantly from each other, at the two outward sides of the walls, below the floors, and two on either side of the fire-places in the floors, whereby a continual circulation of air was established, and has ever since been kept up; and I conceive that the progress of the dry-rot is stopt, while the supply of air required for the fires is materially assisted.

The disagreeable mouldy smell of dampness accompanying the dry-rot was evident enough as soon as the floor was opened, and continued to be less and less perceptible for months, or perhaps years, through the small grates; but those near the fire-places were covered occasionally: the grates had better have been made of brass one-third or one-fourth of an inch thick. I shall bring forward only one more instance, to prove that confined moisture is the cause of the dry-rot, and I must again be very minute, that I may be the better able to support my suggestions when I attempt to apply them to general purposes.

About the year 1820, or a little later, there was occasion to build a new sitting-room at a farm-house, and the site fixed upon was over a cellar, then roofed as a shed or lean-to: the new floor was approached by four steps out of the kitchen, the walls were built of rubble-stone eighteen inches thick, the size of the room is 14 ft. 9 in. by 11 ft. 6 in.—the floor over a slope, and from four to two feet above the ground, while a grate of seven inches square ventilates the cellar from the north.

The object of this is to show in how short a time the new floor was totally destroyed by the dry-rot, without in any way accounting for it, but from the floor itself. The joists were cut out of sound poplar, probably the upper or inferior parts of trees, and between the joists were nailed ribs of wood to support short pieces of boards for groating in the usual manner of counter-ceiling, the floor was neatly laid with inch poplar boards well seasoned, planed, and of the best quality.

In the course of a few months, I believe, the floor joists, boards, &c. were entirely decayed, excepting a few feet near to the door out of the kitchen, which were only partially so. Although, I believe, that the decay was very rapid, I can only assert from recollection of some other particular occurrences, that in the course of three years the room was built, the one floor laid, that floor decayed, and a new floor put up, which is perfectly sound at the present time, after a lapse of more than 17 years.

The present floor is made of oak beams and joists, and very good poplar boards, without any ceiling or laths and plaster under them.

The way I would account for this extraordinary instance of dry-rot is, that the walls were damp when the first-mentioned floor was laid, and that the counter-ceiling was very damp, that the boards were dry and closely fitted, that a fire was rarely (if ever) used in this room, and that the progress of the dry-rot was extremely swift, as it would be in any case under similar circumstances of confined moisture.

I may mention chamber floors of poplar boards at the present time, over a considerable extent of kitchen and other offices, which have been laid down for thirty-five years, and are as sound now as they ever were; although I have seen poplar boards used as window shelves in inferior apartments, and in some other ways, which have gone into complete decay, grub-eaten or otherwise, in the course of a few years.

The reader who may have waded through the details of facts, which I have thought necessary for my purpose, may wish to have the conclusions drawn from them recapitulated in a few short sentences, as thus:—That wherever joiner's work is to be fitted to newly-built walls, there should be means taken for the circulation of a little air. That the beams and joists used for the ground floor of a house should be of British oak, birch, or best foreign deal. That the ends of beams or joists inserted into the outward walls of a new house, on the ground floor, should be cased with sheet lead, zinc, or cast iron, all impervious to moisture, but not too tightly fitted, for fear of the sap's producing confined moisture; or they might be secured at their ends with cases made on purpose of fire-brick clay, or other clay impervious to moisture. I have used cast-iron sockets and fire-brick cases very satisfactorily. That the wooden ribs upon which the lower edges of the skirting boards are to be nailed should not be in continued lengths, without some intermission. That wherever floors are laid with stone bricks, or slate flags, the skirtings should be made of slate-flags from three-quarters of an inch to one inch in thickness, with one sawed edge. That in servants' halls and other offices, where it may be desirable for the skirting or dado to extend to the height of three feet or more, slate-flags of three-quarters of an inch or one inch thick, might very properly be preferred to wood, but capped with a grooved ledge of wood; these slate-flags being worth only about 9*d.* the square yard.

Many of the particulars respecting the rooms which have been affected with dry-rot may, as I have observed before, appear trivial, or even ludicrous; but when it is recollected that we have been alluding to facts that occurred fifteen or twenty years ago, and which engaged attention only for the moment, I wish to state what is still to be seen; and more particularly to show, that there was nothing in the position nor dimensions of the room last-mentioned, neither door, window, chimney, nor any other circumstance, whereby such an effect of dry-rot could have been produced or promoted, excepting only by the *confined moisture*, and to which alone the dry-rot is to be attributed.

A simple remedy for any grievance is sometimes unpopular, and you may be advised to poison unwelcome vegetation as you would rats, without considering that poison, like gun-powder or steam, is not a thing to be played with.* Is it not more reasonable to trace a mischief, if possible, to its cause, and by removing or counteracting the cause, endeavour to prevent or arrest the progress of the effect? Suppose that a ship may be liable to dry-rot, from confined moisture and the sap (juice) of unseasoned timber,† the natural remedy would be to give a change and circulation to the stagnant atmosphere by ventilation: I see no reason why dry-rot in a ship might not be prevented or arrested by a sufficient number of small grates, which have been used so successfully about the floors of the two rooms as above described.—*Salopian Journal.*

ON THE ECONOMY OF RAISING WATER FROM COAL MINES ON THE CORNISH PRINCIPLE.

At the annual meeting of the members of the Manchester Geological Society, held at their rooms, on Thursday, the 29th October, Mr. Fairbairn read a communication "On the Economy of raising Water from Coal Mines on the Cornish Principle." In introducing his paper to the meeting, Mr. Fairbairn, after explaining the sections of the engine and pumps made by him for some Belgian coal mines, said, that the improvements introduced of late years into the Cornish engines, were of so important a nature as to be highly worthy the attention of the miners of this district. They had not, till very lately, the slightest conception of the great saving effected by the performance of

---

* Corrosive sublimate is the only known specific, mineral or vegetable, for preventing the growth of the dry-rot fungi, and which, I believe, has formed the basis of Mr. Kyan's patent.

† Oak would require less seasoning, and be much fitter for use, if it were cut down in winter instead of in spring. I recollect, some fifteen or twenty years ago, observing a sound oak plank in the gable end of a house which was under repair: some of the sap (alburnum) and bark was still on the oak, and very slightly grub-eaten, although it might have been in the building an hundred years, perhaps, or more, on the inside of an outward wall, nogged with bricks, and never had been covered with plaister nor colour of any sort.

the [illegible] the pressure of steam in the cylinder, which [illegible] 7,500 [illegible] per square inch, would raise nearly double the [illegible] of any of the neighbourhood, chiefly from the advantages of the expansive principle adopted in the Cornish engine. Mr. Fairbairn then proceeded with his paper, of which the following is an abstract.—

"The steam engine performs so important a part in almost all the transactions of men, where great power is required, that the progressive improvements of this mighty agent, indispensable to the miner, must be regarded with interest by all. By the geologist its improvement will be looked at with additional pleasure, since by its means he is enabled to explore the earth to a much greater depth than he otherwise could have done. For this reason, I have thought it might not be out of place to give here some account of the progress of the steam engine during the last 120 years, mentioning the dates of its leading improvements.

"From the time of Savery and Newcomen, in 1707, to that of Beighton, in 1717, it remained stationary, till 1769, when Smeaton introduced considerable improvements upon atmospheric engines, the average duty from fifteen of which amounted to 5,590,000 lbs., lifted one foot high by a bushel of coal.* These improvements continued; and the duty, in 1772, was raised to 9,450,000 lbs.

"Mr. Watt's improvements commenced in 1776, when the average duty was declared at 21,600,000—more than double that of Smeaton's; and, during the years 1778-9, it was still further increased.

"In 1779, and from that to 1788, Mr. Watt introduced the improvement of working steam expansively, which raised the duty to 26,600,000. From 1788 to 1812, few, if any improvements were made in the Cornish engines; and, provided we except the plunger pole, which was introduced about this time, I question whether the Cornish engineers and miners did not retrograde rather than advance during a period of twenty-four years.

"In 1814 considerable advances were made, which raised the duty to 32,000,000 lbs. During that year, Woolf's engine, with two cylinders, was introduced, which again advanced the duty to 54,000,000 lbs.

"Mr. Woolf, above all others, did most for the Cornish engines, by showing the advantages peculiar to high pressure steam, and prepared for subsequent improvements, which led to the present effective system of expansive working.

"During a period of six years, from 1814 to 1820, Woolf's double cylinder engine maintained its superiority, and gave a higher duty than any other.

"Woolf's engine, in process of time, gave way to others of a better construction. They were introduced by Captain Samuel Grose, whose experiments upon the generation and preservation of heat led to great improvements, and ultimately established a new era in the history of the Cornish engine.

"In 1826, Captain Grose's engine, at Wheal Hope, attained a duty of 62,000,000 lbs.; and, in July of the following year, one of Mr. Woolf's single cylinder engines performed the unprecedented duty of 67 million.

"From this time Captain Grose's improvements were appreciated, and generally introduced; they led to a still greater advance in the duty, which this year reached as high as 87 million lbs.‡

"Messrs. Lean and Brothers report the duty of a few of the Cornish engines at this time as follow.—

	Millions lbs.
Wheal Towan Engine	87·0
Wheal Hope	74·8
Consols....................................	67·6
Binner Downs............................	63·5
Consols	61·7
Consols....................................	61·3
Wheal Vor..............................	61·1
Wheal Towan, (Druce's)..................	59·4
Consols....................................	58·4
Poldice.....................................	57·8
Wheal Vor	51·9

These give a mean duty of sixty-four millions of pounds.

"Nothing remarkable took place till 1834, when the duty was raised to 90 millions lbs. Since then, it has continued to increase in the ratio of 90, 100, and 110 millions: and during the last meeting of the British Association, at Glasgow, Mr. Taylor reported the present duty at the unequalled performance of 123, 300,593.

"Having briefly stated the progressive improvements that have taken place in the Cornish system of pumping, I would now direct the attention of the society to the important results which these improvements have produced.

"The quantity of coals consumed by all the engines working at the mines in Cornwall, in the year 1835, was, according to Messrs. Lean and Brothers, 1,669,421 bushels. Now, if we compare this with the number of bushels which would have been consumed to produce the same power in 1814, we should have, for the consumption at that period, 4,049,878 bushels, making a saving of 99,186 tons; which taken at 17*s.* per ton, (the price of coal in Cornwall,) we have the enormous saving of £81,308.

"From the above facts, it cannot be doubted, that the improvements in steam engines, and the consequent saving thus effected in the consumption of fuel, are matters of deep importance. Even in districts where coal is cheap, it is a consideration well worthy of attention; and we are assured by geologists, that the coal of this country, although abundant, will not last for ever."

In the course of a very interesting discussion which followed the reading of the paper, Mr. Fairbairn said, he might mention that so great was the saving from the improved system of working the Cornish engines, that it was not improbable that, in this neighbourhood, we might come back to the old system of power for factories. If the duty performed by the Cornish engine was so much more than that of the [illegible] factory engines in this district, it might be desirable to have a Cornish engine connected with a water-wheel to drive the machinery."

Mr. Boothman.—Why not apply it to rotatory motion?—Mr. Fairbairn said, that it would not apply to any thing where the force required was constant. The value of the thing lay in overcoming the inertia of matter. The Cornish engine first raised a weight, and then, by the descent of that weight, it raised the water. That was the whole secret of the Cornish engines.

Mr. P. Clare asked if Mr. Fairbairn had made a calculation of the effective force of the factory engines in this neighbourhood, so as to afford a comparison as to the combustion of coal by them with that of the Cornish engines?—Mr. Fairbairn said, he had done so. The consumption of fuel in our best condensing engines here was 10 lbs. to 12 lbs. per horse power per hour, while the consumption of fuel by the best Cornish engines was only 2¾ lbs. per horse power per hour. In other words, we consume four times more coal than the Cornish engines in producing the same effect. The circumstance was most extraordinary; but the facts were before the meeting. The returns of the duty performed were regularly registered in Cornwall, and published monthly, so that any gentleman might see them, in reference to any period: and it would be found, that the performance of the best Cornish engines (for he did not, in reference to this question, speak of the average duty) did not exceed a consumption of 2¾ lbs. of coal per horse power per hour.

A Member asked whether there was not some doubt as to the accuracy of the calculations of the duty performed by the Cornish engines, and as to the mode of estimating them?—Mr. Fairbairn said, that the calculations were made upon the area of the bucket and the length of the stroke. He was aware that doubts had been expressed as to the accuracy of the calculations; but they were backed by such authorities, and the returns were so numerous and regular, that he thought their general accuracy could not well be doubted.—The Member observed, that a small quantity of air coming up the pumps would make a difference.—Mr. Fairbairn: No doubt; but still the engine has to lift this great weight of all the pumps and iron work, and the plungers, which must be lifted by the force of steam. He had a return from Mr. Wicksteed, of the East London Water Works, which was not a pit at all; but the Cornish engine there was used to raise water for the supply of the eastern part of London—which return gave a duty of 118,552,475 lbs. raised one foot high; the consumption of fuel being 2·4 lbs. of coal per horse power per hour. Of course he did not speak of the duty performed by these Cornish engines from his own knowledge, but he had every reason to believe the returns substantially correct.—The Member said, he believed some doubts had been repeatedly thrown on the method of calculation.—Mr. Fairbairn said, that some years ago he had been present at a discussion on the subject in the Society of Civil Engineers, when great doubts were expressed, but further documents were brought forward to prove the accuracy of the calculations. However, taking the consumption of fuel by the Cornish engines to be 3 lbs. per horse power per hour, that was a very great difference, as compared with our factory engines.

Mr. Eaton Hodgkinson thought there had undoubtedly been great improvements made in the Cornish engines, chiefly the result of the adoption of the expansion of steam, which they had not been used to any great extent in this neighbourhood, at least till very recently. Whether the returns were quite accurate or not, no one could doubt that the improvements were immense. He thought the plan of making the engine to lift the pump-rods only, and then the descent of the pump-rods lifting up the water, seemed to be a considerable improvement in adaptation. Again, whether Mr. Woolf's plan of the expansion of steam, or that of Mr. Watt, expanding it in the same cylinder, and cutting it off when at a distance of one-fourth or one-fifth down, were adopted, (and it was a question as to which plan was the best,) in both cases there was a great improvement upon former methods. These improvements had a strong bearing upon geology, for were it not for these engines, they could not investigate the strata in mines, for the water would drive them out or drown them. These engines, by draining lakes, might enable the geologist to obtain a great deal of information he must otherwise be without.

* Duty is a term first used by Mr. Watt for ascertaining the comparative merits of steam engines. In Cornwall it is used for determining the number of millions of pounds of water lifted one foot high by a bushel of coal, (94 lbs.;) the time of lifting it not being considered.

‡ See Mr. Wicksteed's report in the Journal for January last, page 7.—Ed. C. E. and A. Journal.

PROCEEDINGS OF SCIENTIFIC SOCIETIES.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

TENTH MEETING.—*September*, 1840.

(From the Athenæum.)

SECTION G.—MECHANICAL SCIENCE.

Mr. James Milne gave an account of an instrument termed *a Gas Regulator*, of his invention, by means of which the length of the flame is equalized, notwithstanding the variations of pressure that occur, and a considerable saving in the consumption of gas is effected.

Mr. Coles *on Railway Carriages.*—Mr. Coles proposes to introduce friction wheels; and that, excepting the first and last carriage in the train, the carriages should run on *two* wheels. He also proposes a step-rail at the curves or bends.

"*On the Turbine Water-wheel.*" By Prof. Gordon.

The fundamental principle upon which the construction of the *Turbine-Fourneyron* is based, is that by which the maximum of useful effect is obtained from a given fall of water, depending on the relative velocity of the water and its recipient, which ought to be such that the water enters the wheel without shock, and quits it again without velocity. A notion of its construction may readily be formed, by supposing an ordinary water-wheel laid on its side, the water being made to enter from the interior of the wheel by the inner circumference of the crown, flowing along the buckets, and escaping at the outer circumference. Then centrifugal force becomes a substitute for the of gravity. A drawing was here exhibited of a Turbine of about 5 horse force power, the fall being 3 feet, and the expenditure of water 20 cubic feet per second. It was explained that the Turbine consists essentially of—1. A reservoir, the bottom of which is divided into radial compartments by curved plates, serving to guide the water to take a particular direction of efflux. 2. A circular sluice, capable of nicety of adjustment. 3. The wheel with curved buckets, on to which, when the sluice was raised, the water entered at every point of the inner circumference, and flowing along the buckets, escaped at every point of the outer circumference. This latter is a characteristic feature in the Turbines of Fourneyron. Reference was made to the principal Turbines erected in France and Germany,—particularly to that at Inval, near Gisors, and those at Müllbach and Moussay, as illustrative of their use for falls varying from 9 inches to 10 feet. And, again, to those at St. Blasier, in the Black Forest, as instances of high falls,—the one being $70\frac{1}{2}$ feet, the other 345 feet; the one expending 5 cubic feet per second, the other 1 cubic foot per second; the one being 56 horse power, the other very nearly 60 horse power; the one giving an efficiency of upwards of 70, the other of upwards of 80 per cent. of the theoretical effect. A drawing of the latter was exhibited—full size. It is $14\frac{1}{2}$ inches diameter. Its extreme depth or *breast* is ·225 inch, or less than $\frac{1}{4}$. It makes 2,200 to 2,300 revolutions per minute. It serves a factory, in which are 8,000 water spindles, 34 fine and 36 coarse carding-engines, 2 cleansers, and other accessories. The conclusions drawn by Morier from his experiments on these wheels with the Break dynamometer, or friction strap, are these:—1. That Turbines are with equal advantage applicable for high and for low falls. 2. That their net useful effect equals 70 to 78 per cent. of the theoretical effect of the power. 3. That they may work at speeds varying from

$$n = \frac{3{\cdot}3\ V}{R} \text{ to } n = \frac{5{\cdot}6\ V}{R}$$

Where n = number of revolutions; V = velocity due to fall; R = extreme radius. The useful effect still not differing notably from the maximum. 4. That they work at very considerable depths under water, the relation of useful to theoretical effect not being thereby much diminished.

Mr. Smith (Deanstown) said, there was much in the principle for very high and very low falls, and for varying falls. The principle had been long applied in Perthshire, but in that part of the country a great velocity is obtained at a great expenditure of power.—Prof. Gordon stated, that for all falls above 50 and below 10 feet, the Turbine is to be preferred.—Mr. Fairbairn: The common water-wheel at Gisors, in France, was made by himself and comparative trials were made with it against the Turbine. Mr. Fairbairn was quite satisfied, by Arago's experiments, and otherwise, that the Turbine is a very important machine, and gives a result of 70 to 75 per cent. of the theoretical effect.—Mr. Smith proposed, that as he had peculiar facilities for experimenting on the subject, he, along with Prof. Gordon and Mr. Fairbairn, should investigate the comparative merits of the Turbine and other water-wheels before the next meeting of the Association.

"*On producing True Planes or Surfaces on Metals.*" By Mr. Jos. Whitworth.

Surface plates were exhibited, intended to illustrate the proper mode of preparing surfaces where great accuracy is required. If one be put upon the other, it will float, until by its weight it has excluded some of the air, when they will adhere together with considerable force. These surfaces were got up without grinding. The only operations performed upon them were those of planing, filing, and scraping. Practically, the excellence of a surface consists in the number and equal distribution of the bearing points; the more numerous these are, and the nearer together, the more perfect is their action. But, if a ground surface be carefully examined, the bearing points will be generally found lying together in irregular masses, with extensive cavities intervening. The cause of this irregularity is evident in the unmanageable nature of the process. The action of the grinding powder is under no control. There are no means for securing its equal diffusion, or for modifying its application with reference to the particular condition of different parts of the surface; while the practical result is, that the mechanic neglects the proper use of the file, knowing that grinding will follow, to efface all evidence either of care or neglect. In various departments of the arts and manufactures, the want of improvement in this respect is already felt. The valves of steam engines, for example, the tables of printing presses, stereotype plates, slides of all kinds, require a degree of truth much superior to that they now possess, for want of which there is great waste constantly accruing in time, in steam power, in wear and tear, and, above all, in skill misapplied. The improvements so much to be desired will follow upon the discontinuence of grinding, The surface plate and the scraping tool will then come into vogue, and a new field will be opened to the skill of the mechanic. Supposing him to be provided with a true surface plate, he will find no difficulty, after a little practice, in bringing up his work to the required nicety. For this purpose he will find it advantageous to employ a scraping tool made from a three-sided file, and carefully sharpened on a Turkey stone, the use of which must be frequently repeated. A light colouring matter, such as red chalk and oil, being spread over the surface plate, and the work in hand applied thereto, friction will cause the prominent places to be marked, which will instruct the experienced mechanic where and how to operate to the greatest advantage.

Mr. Scott Russell presented the Report of the Committee *On the Form of Vessels*: the members of this Committee were Sir John Robison, Mr. Smith, (Jordan Hill), and himself.

Since their appointment by the Association, the Committee had been constantly engaged in carrying out the various investigations committed to their charge; and it had been their earnest desire to discharge their duties in such a manner as conclusively to settle the many important practical questions in naval architecture which were matters of uncertainty and dispute, especially in reference to steam navigation. The importance of precise knowledge in constructing a mercantile navy, ships of war, and steam vessels, was reckoned so great, that in almost all civilized kingdoms experiments had been undertaken at the national expense, and Italy, Spain, Sweden, and France had obtained by those means a very superior knowledge of the principles of the construction of ships. In this country the labours of individuals had supplied the only experiments of this nature; and it was matter of regret, that these were not of such a description as to furnish the ship-builder with any certain foundation for rules of art. The new demand upon the invention of the naval architect by the introduction of steam power, had also contributed much to augment the disparity which already subsisted between the data of experimental hydrodynamics and the demands of the practical builder of ships. It had also been thought not improbable, that certain singular phenomena in hydrodynamics, recently discovered, might considerably modify the views hitherto entertained of the nature of fluid resistance; and the Association had, therefore, resolved on the appointment of this Committee, for the purpose of giving this subject a thorough and searching examination. The first subject of concern with the Committee, was the mechanism by which to conduct experiments on a scale sufficiently large to render the results of practical value, and at the same time sufficiently manageable to free the experiments, as far as possible, from elements foreign to the immediate subject of examination. It was desirable to obtain, for experiment, a force capable of moving the vessels subjected to experiment, through the water with an uniform force and velocity capable of being continued for a considerable interval of time over a considerable length of space. All the forms of apparatus hitherto adopted for the purpose of experiment, were examined with the view of adopting the best. None of them appeared fully to answer the end in view, and it became necessary to invent another and better apparatus for giving motion to the vessels. This had been found: a simple contrivance of Mr. Russell's had been adopted, by which a force, perfectly uniform, could be applied without inconvenience throughout any given space, free from the usual errors of friction, rigidity, &c., which had become interwoven with the results of former experiments. This apparatus he regarded as an engine of experiment so important to the future acquisition of knowledge of the resistance of fluids, that he was desirous to communicate it to the distinguished men around him taking an interest in the subject, in order that if it met their approbation, they might avail themselves of it in future investigation. He then proceeded to give a description, with illustrative drawings, of an apparatus by which experiments were made of from a small scale up to 100 feet in length, over a sheet of water from 100 feet to half a mile or a mile in length. For each scale of experiment, strings, cords, and ropes of various thickness were employed; and for the most delicate experiments, a slender Indian fibre, brought home by Sir John Robison, had been found most useful. Two chronometers by Robert, of Paris, also brought over by Sir John Robison, were employed with great advantage, as observations were obtained which could be depended on within two-tenth parts of a second. The next point to be determined was, the general method of conducting the experimental inquiry, so as to elicit the most valuable truths, and those most apposite to practical art. For this purpose the most eminent ship-builders were consulted, as to the points upon which they most wanted information, and were requested to point out what were the forms of vessel which they would wish to have tried. More than 100 models of vessels of various sizes, from 30 inches to 25 feet in length, had been constructed. These were drawn through the water with various velocities, and at different degrees of immersion, so as to determine the resistance of all the various forms that might be adopted in practice, and enable the builder to adopt the form best suited to his purpose. A large pile of papers, laid on the table, contained the results of the experiments, which were still continued. Of these experiments, different series were conducted with very various objects. One class regarded the transverse sections of ships; another the water-lines of the bow; another the water-lines of the stern; another the form of ribband-line and of buttock-line; another class, the place of greatest breadth, and so on. From these experiments it resulted that vessels might be made fuller than usual at some points and finer in others, with great advantage, A peculiar class of lines, called by Mr. Russell "wave lines," appeared best adapted for high velocities both in smooth water and at sea. It also appeared, that the manner in which the particles were displaced by a moving body, and replaced themselves after its passage, was very different from what was generally supposed. There also appeared to be three different conditions of fluid motion and resistance, accompanied with distinct characteristic phenomena: motion slower than that of the wave—motion on the wave—motion on wings of water. The last occurred only at very high velocities, and when two high and beautiful films of water spread themselves in the air, and carried the boat as on gossamer wings along the surface of the water. Mr. Russell concluded the report, by stating, that the experiments would soon be published, and submitted to the examination of those interested in the subject, in a form better adapted to use than that of verbal description. He hoped it would be found that their experiments had gone far to fill up one of the great desiderata of practical science.

Sir John Robison stated, that the whole merit of imagining and conducting the experiments belonged to Mr. Russell.—Mr. Arch. Smith made some observations, disputing the mathematical accuracy of one of the illustrations used by Mr. Russell.—Mr. Russell explained that the physical effect differed in that instance from the mathematical theory.—The Rev. Mr. Brodie had arrived, by calculation, at nearly the same results as Mr. Russell had by experiment. Mr. Brodie hoped Mr. Russell would direct his attention to the phenomena at very high velocities, such as from 25 to 30 miles an hour. Mr. Brodie's calculations have led to such curious conclusions, as to make him suspect some mistake: he was, therefore, anxious that Mr. Russell should prove their accuracy by his delicate experiments.

"*On the Economy of Railways in respect of Gradients.*" By Mr. Vignoles.

Mr. Vignoles stated that this was another subject, in addition to the former one on timber bridges, selected from a general work on the Principles and Economy of Railways, which he was preparing for publication. Looking to the great cost of railways, he had turned his attention to a comparison of the result of the working of railways, with the price paid for various degrees of perfection. He disclaimed asserting that sharp curves or steep gradients were preferable to straight and level lines, but he would endeavour to show that good practicable lines might be and had been constructed, on which trains sufficient for the traffic and public accommodation could and did move at the same, or nearly the same velocities and with little, if any, additional expense. On an average, the hitherto ascertained cost of the principal lines might be divided thus:—

Land	10 per cent.
Stations and carrying establishment	20 ,,
Management	10 ,,
Iron	10 ,,
Works of construction proper	50 ,,
	100

though, of course, these items differed considerably in various railways, but in general it might be said that the works of construction constituted one-half of the whole first cost. He left out, on the present occasion, all consideration of the saving of any of the items, except as to the works of construction; though it would not be difficult to show a reduction on these, to the extent of at least one-half. Mr. Vignoles stated that he had analyzed railway expenses of working, and had reduced them to a mileage,—that is, the average expense per mile, per train, as deduced from several years' experience, and observations of various railways under different circumstances, and with greatly different gradients, some of which lines were enumerated. The result on passenger and light traffic lines was, that the total deductions for expenditure from gross receipts was 3*s.* per mile per train; 2*s.* 6*d.* being the least, and 3*s.* 4*d.* the highest; and that this average seemed to hold good, *irrespective of gradients or curves.* Particular lines might, from local circumstances, differ in detail, but he was satisfied that the following detail was a fair average approximation:—

	s.	d.
Daily cost of locomotive power and repairs	1	6
Annual depreciation, sinking fund, and interest on stock, tools, shops, and establishment	0	6
Daily and annual cost in carriage department	0	4
Government duty, office expenses, police, clerks, guards, management, and maintenance of railway	0	8
	3	0

It was not found practicable to distinguish the additional expense, if any, arising from curves or gradients; but as three-fourths of railway expenses were quite independent of these curves, such addition must be small; especially as, on the North Union Railway, a line which had 5 miles out of 22 in the gradients of 1 in 100, or nearly 53 feet per mile, the total expenses were less than on the Grand Junction Railway, and several other lines. Mr. Vignoles then proceeded to illustrate, by diagrams, the mode in which the economy might be made in the works of construction, on what he called the *first system*, by the occasional introduction of inclines of 50 and even 60 feet per mile, if not of too great a length; and again, on the *second systeem*, by introducing entire series of severe gradients, such as those of 30, 35, and 40 feet. On the first system, he had executed the North Union Railway; and had also thus designed all the government railways to the south and west of England. On the second system was the Bolton and Manchester Railway, by the late Mr. Nimmo, Mr. Macneill's government railway lines to the north districts of Ireland; and that engineer had lately altered the Dublin and Kilkenny, and the Dublin and Drogheda Railways, from better but more expensive gradients, to those on the second system; and Mr. Vignoles was about to apply it to the Dublin and Kingstown Railway; and he had set out the whole extent of the Sheffield and Manchester Railway, for 40 miles, on an average gradient of nearly 40 feet per mile, mixed with occasional inclinations of 1 in 100, and with curves of one-third mile radius. That work was now under execution by Mr. Locke, who had succeeded Mr. Vignoles an engineer, and who fully concurred in the general principles,—which, as also the details, and the introduction of timber viaducts on a large scale for economy, Mr. Nicholas Wood approved. Mr. Gibbs had also adopted the second system on the first ten miles eastward of the Newcastle and Carlisle Railway. Mr. Vignoles went on to state, that, on either one or both of these systems, introduced as might be considered most advantageous by the directing engineer, lines of railway might be laid out so as not to exceed 10,000*l.* per mile, being particularly applicable where fertile, populous, and manufacturing districts, or the metropolis, with the extremes of the empire, had to be connected through difficult and unproductive districts. Mr. Vignoles concluded by remarking, that when a continued stream of heavy traffic justified the expense, he saw no reason to vary from the general rules adopted hitherto by engineers for laying out railways, or from his own former opinions and practice. But it was forced on him by daily experience, that, to accommodate the public convenience, the Post Office arrangements, and business in general, it was scarcely once in twenty times that a locomotive engine went out with more than half its load, and in general the engines were only worked up to two-fifths of their full power: he was, therefore, conclusively of opinion, that it was much cheaper to put on additional engines on extraordinary occasions; and on such principle railways should be constructed through the more remote parts of the country, so as to be made in the cheapest possible manner. The possession of all the *profitable* lines of railway by private companies, was likely to throw on the government the *onus* of constructing their lines through such districts, in which case economy was desirable: or, if not to be constructed by the government, then was economy still more important; for Scotland, Ireland, Wales, and western and eastern England would want railways, until some such system as those now promulgated could be brought to bear in the laying out lines of internal communication.

Mr. Roberts entirely concurred with Mr. Vignoles with regard to the gradients and curves, as also to the propriety of the economy of adopting timber bridges, and so reducing the price of conveyance to the public.—Mr. Vignoles being asked whether, in the gradients of 1 in 100, on the North Union line, any practical danger was to be apprehended, stated that no danger whatever was apprehended; and that, on these gradients of 1 in 100, the trains travelled *down* at full speed, or about forty miles per hour.

Mr. Jeffreys described a *fire-grate*, exhibited in the model-room, which may be placed, he said, so far forwards as to be quite out of the chimney, and radiate a two-fold quantity of heat into the apartment; and yet there shall be no tendency to send smoke into the room. By an addition, in accordance with the same principle, fresh air is introduced, comfortably warmed before it enters the room.

"*Timber Bridges.*"

Mr. Mitchell observed, that Mr. Vignoles having drawn attention to the subject of *Timber Bridges*, with reference to their application to the economical construction of Railways, he begged to report the result of some experience in works of this nature in the Highlands of Scotland. About twelve years ago he had erected a bridge across the Spey, consisting of an arch of 100 feet span; another about six years since of two arches of 100 feet span, with stone abutments and piers; a third across the Dee, of five arches of 75 feet span, with timber piers; besides a number of others of smaller dimensions. Economy was the chief object in building bridges of this material. It was found they were one-third less expensive; that across the Dee with timber piers less than half: the period of duration he found to be from thirty to forty years; the accumulated value of the saving being more than equivalent to rebuilding the structure. In his opinion, viaducts of this material might be beneficially applied in the construction of railways, of course being suitably constructed to resist the violent action and heavy weights of railway trains. He was glad to hear that Mr. Vignoles considered that railways might be constructed with gradients so much steeper than what has been hitherto considered practically advantageous. Of course, there could be but one opinion about the propriety of a level and direct line both for safety and speed: but the subject was of great importance to Scotland, where neither the country admits nor the traffic demands such perfect construction. He thought practical experiments should be made on the amount of locomotive traction at different inclinations, and with different rates of speed; it appears that hitherto engineers had acted more by theory than observation. One fact he would mention. On a railway recently constructed, he found, that with inclinations of from 1 in 70 to 1 in 100, locomotives travelled nearly at full speed, and at one point, an inclined plane of half a mile with a gradient of 1 in 22, a train of loaded carriages, with a gross weight of thirty-five tons, was drawn up with ease, of course at a reduced speed, but not such as to affect the general rate of travelling; the carriages also passed along curves with radii less than 500 feet.

"*On the application of Native Alloy for Compass Pivots.*" By Capt. E. J. Johnson, R.N.

Among those portions of a ship's compass which most affect its working, are the pivots and caps on which the needle and card traverse, and which, like the balance of a chronometer (but of far more importance to the practical navigator), should not only be fitted with the most scrupulous attention to accuracy, but be made of materials capable of maintaining a given form under the trials to which such instruments are necessarily exposed. Having examined a great variety of compasses which had been used at sea, wherein Capt. Johnson noticed that their pivots were generally injured, and often by rust, he searched numerous records of experiments for its prevention, and for improving the quality of steel in other respects, by means of alloys of platinum, palladium, silver, &c. (he alluded particlarly to the experiments of Dr.

Faraday and Mr. Stoddart; and Mr. Pepys having obligingly supplied Capt. Johnson with specimens of similar kinds of steel to those used by them, these examples, together with pivots made of the ordinary kind of steel, and hardened and tempered in the manner recommended by eminent instrument-makers, were placed in a frame for experiment; and to these again Captain Johnson added certain contrivances of his own, such as rubbing a steel pivot with sal-ammoniac, then dipping it into zinc in a state of fusion, and afterwards changing the extreme point. Some specimens he coated with a mixture of powdered zinc, oil of tar, and turpentine; and others again were set in zinc pillars, having small zinc caps, through which the extreme point of the pivot protruded after the manner of black lead through pencil tubes. The whole of the specimens were then placed in a cellar, occasionally exposed to the open air, examined from time to time during more than half a year, and their several states, as respected oxidation, duly registered. Without going into the details of this register, the general result was, that not any of the kinds of steel pivots used in this trial, except such as were coated with zinc, remained free from rust, while the pivot made of the "native alloy" which is found with platinum, completely retained its brilliancy. Captain Johnson then applied a more severe test to this singular substance, first, by placing sulphuric acid, and then nitro-muriatic acid upon it; but even under this trial he could not observe that any change had been effected, although the blade of a penknife, subjected to a similar process, was rusted to the centre. Having enumerated the facts respecting the trials to which he had subjected this curious material, Capt. Johnson stated the conclusion that he had come to, namely, that it is sufficiently tough not to break, and hard enough not to bend, under the trials to which it would be *fairly* exposed; and that being alike free from magnetic properties and liability to oxidation from exposure to the atmosphere, it possesses the requisite qualities for the pivot of the mariner's compass; and he could not but anticipate that, when fitted with a ruby cap to correspond, it would be found greatly to improve the working. Besides the application of this substance for compass pivots, Capt. Johnson stated that it might probably be found advantageous for other instruments, and especially for the points of the axes of the dipping needles fitted, on Mr. Fox's plan, for use on board ship.

Mr. Hawkins has used this "native alloy" for several years in tipping the points of pens, and not a single instance exists of any of these pens showing the least symptom of wear. He tried native alloy on a cap, in comparison with ruby, when he found that in the same circumstances, the ruby was ground away with diamond dust twice as rapidly as the native alloy. He had made engravers' tools of the same metal, and when made too sharp they cannot be blunted on the Turkey stone, but only by diamond dust.—Sir J. Robison could bear testimony to one of Mr. Hawkins's pens, which he had used for years, not being at all changed.—Mr. Hawkins stated that this alloy consists of native crystals of osmium and iridium in conjunction with platinum.

Mr. Lang "*On an Improvement on the Air Pump.*" A letter from this gentleman was read, but from some mistake, the paper itself had not been received.

INSTITUTION OF CIVIL ENGINEERS.

"*On the Properties and Chemical Constitution of Coal, with Remarks on the Methods of increasing its Calorific Effect, and preventing the Loss which occurs during its Combustion.*" By Charles Hood, F.R.A.S., &c.

It appears that, previous even to the invasion of the Romans, coal was used as a fuel in Great Britain; but such was the prejudice against it, that wood was the fuel generally in use among the higher classes until the eighteenth century, when the supply of it diminished so considerably as to render necessary the substitution of coal; and from that time the increase in its consumption has been immense.

Previously to the seventeenth century, the smelting of iron and all other metals was performed by charcoal; but the attempts of Sturtevant and Ravenson in 1612-13, and of Dudley in 1619, to introduce the use of coal or coke in blast furnaces having proved the possibility of success, the progress of the innovation, though slow, was certain, and led to the transfer of the iron works from many of the original positions in the midst of forests to the coal districts where they are now placed.

The author considers his subject under three heads:—1st, The chemical character and composition of coal; 2ndly, Its properties as a combustible; and 3dly, The nature and application of its various gaseous products.

1st. The opinion that coal is a compound of carbon and bitumen has been objected to by some chemists, on the ground that by no process hitherto pursued in analyses has it been possible to resolve it entirely into these two substances; even at a low temperature a quantity of gaseous matter is thrown off, and at an elevated degree of heat an evident decomposition of the bitumen takes place. Even anthracite contains a small portion of volatile matter, its component parts being carbon, oxygen, hydrogen, and nitrogen; the hydrogen being either combined with the oxygen to form water, or with a small portion of carbon to form carburetted hydrogen, which exists in a gaseous state in the pores of the coal. In bituminous coal, the hydrogen is combined with a larger proportion of oxygen and nitrogen; the mechanical difference being, that the bituminous and free-burning coals (more particularly) melt by heat when the bitumen reaches the boiling point, whereas anthracite is not fusible, nor will it change its form, until it is exposed to a much higher degree of temperature.

Two tables of the analyses of different coals are given from the authorities of Mushet, Thomson, Vanuxem, Daniell, Ure, and Reynault; No. 1 showing the proportions of carbon, ashes, and volatile matter, with the specific gravity of the coal and of the coke; and No. 2 showing the proportions of carbon, hydrogen, azote, and oxygen. These tables show that the largest quantity of carbon (92·87) is contained in the Kilkenny anthracite, and the least quantity (64·72) in Cannel coal; and that the nature of the volatile matter greatly affects the quantity of coke—the aggregate quantity of the gaseous products of coking, splint, and cherry coal, being very nearly similar; while the quantity of coke obtained from these different species varies more than 45 per cent.

The author then points out the continual presence of azote, which quits the base with the greatest difficulty; and also the affinity of sulphur, not only for the coal, but for the coke, as it is rarely found to have been completely expelled, even from the most perfectly made coke; the only coal found to be even partially free from it being anthracite, in some species of which no traces of its presence are found.

2dly. The application of coal as a fuel depends on the chemical change which it undergoes in uniting, by the agency of heat, with some body for which it possesses a powerful affinity. In all ordinary cases this effect is produced by its union with oxygen. When coal is entirely consumed, the carbon is wholly converted into carbonic acid gas and carbonic oxide, and the hydrogen into water in a state of vapour. The atmosphere supplies the necessary oxygen for this purpose; and in this state the products of the combination are nearly or quite invisible, both of them being almost colourless fluids; if, therefore, any smoke be visible, it is the result of imperfect combustion. Some calculations are given to ascertain the amount of loss that is sustained when the smoke escapes unconsumed; from which it appears, that with bituminous coal about 37 or 38 per cent. more heat is produced when the smoke is consumed than when it escapes freely. Many modes of consuming smoke have been attempted; those which appear to have been attended with the greatest success are—1st. Causing the smoke from the fresh coals to pass through or over that portion of the fuel which is more perfectly ignited; 2dly. Supplying heated air to the top of the fuel, as well as admitting cold air through the ash-pit in the usual manner; and 3dly, Throwing a jet of steam into the furnace or into the chimney. The various modes of carrying into effect these plans are briefly alluded to; from them a few may be selected. Robertson's plan was to use inclined furnace bars, where the fresh coals were placed close to the fire-door, and being there partially carbonized, gave out the gas, which, in passing over the mass of incandescent fuel, was ignited, and became active flame, thus economizing fuel and preventing smoke. In this and similar cases, by the slow distillation of the coal, a gas is produced, which not only inflames at a lower temperature than the dense olefiant gas produced by rapid distillation, but which only requires for its combustion a quantity of oxygen never exceeding double its own volume, or ten times its bulk of atmospheric air, while olefiant gas requires three times its own volume of oxygen, or fifteen times its bulk of atmospheric air. The elimination of a gas which burns with so small a portion of oxygen is, therefore, the principal cause of the non-production of smoke in furnaces of this description. The second mode of consuming smoke is founded on the necessity which exists for a large supply of air being requisite to inflame the gases given off from coal by a rapid and intense heat; and this is accomplished by introducing a quantity of heated air above the burning fuel. When a quantity of fuel is thrown into a furnace, the increased thickness of the mass opposes additional resistance to the passage of air through the bars; the temperature of the furnace is lowered, and an increased volume of gas is at the same time given out. If at this moment a quantity of air, heated to the temperature of the gas, be admitted, the gas immediately inflames, and that which would have produced a dense black smoke passes off in the invisible state of carbonic acid gas and vapour of water. Different gases require different degrees of heat to inflame them; and this explains the easy combustibility of the volatile products of coal when the heat is so managed as to produce those gases which inflame at the lowest temperature. A larger quantity of air is required at the time that the coal is first thrown on than at a subsequent period; therefore, when economy is studied, the supply of air should be gradually diminished as the mass approaches an incandescent state. The use of heated air has produced most important results in the manufacture of iron with bituminous coal, and also with anthracite; the latter fuel having been almost neglected until the recent application of this principle of employing heated air to promote its combustion, although it is known to be capable of producing perhaps a more intense heat than any other carbonaceous fuel. The rationale of the third plan of consuming smoke by injecting a jet of steam into the fire or the chimney, is less obvious than the others. In 1805, Mr. Davies Gilbert observed, that whenever the waste steam of one of Trevithick's engines was permitted to escape into the chimney, the smoke from the coal was rendered invisible. Subsequent experiments confirmed this fact; and it was supposed that the steam, being decomposed, furnished oxygen to support combustion. The author combats this opinion, and accounts for the effect by the increased draught of the furnace caused by the jet of steam into the chimney, by which means a larger portion of air is brought into contact with the burning fuel; thus supplying the previous deficiency of oxygen to the fire, and promoting the combustion. As steam is only about half the weight of air at a like temperature, and the power of all gaseous fluids to ascend is "*inversely* as the square roots of their specific gravities," the velocity of its escape by the chimney, compared with common air of the same temperature, is about as 1·4 to 1; therefore the compound mixture of steam, air, and carbonic acid gas, will escape with a considerably increased velocity, and more air must consequently enter the furnace. It appears that about 10 per cent. of the total quantity of steam generated is necessary to effect the combustion of the smoke by this means; therefore, unless the waste steam only be used, the saving of the fuel must be reduced by this amount. Brief mention is made of the experiments of Messrs. Apsley Pellatt, Parkes, and the Chevalier de Pambour, proving that a given quantity of oven coke will produce as much heat as the coal from which it was produced; and of the various kinds of artificial fuels which had been invented, especially that composed of resin and peat coke, of which the author remarks that its combustion probably produces a mechanical effect, as the hydrogen is converted into water in a state of vapour, which escapes through the chimney with a great velocity, and consequently a large quantity of air is drawn into the furnace, and a more perfect combustion of the fuel is the result. In the same manner he accounts for the necessity which exists for having the openings between the bars wider in a furnace in which coke is burned than in one used for coal. In opposition to the general opinion, he considers that less air is required for the consumption of coke than for coal; the carbon only requiring 2⅔ times its weight of oxygen for its combustion, while the hydrogen contained in coal requires 8 times its weight of oxygen; and the only reason that the openings between the bars are required to be wider in the former than in the latter case, is in consequence of the draught being so much slower during the combustion of coke.

3dly, "On the nature and application of the volatile products of coal." In treating this portion of the subject—many of the observations on which have been necessarily anticipated in the preceding sections—the author traces the application of carburetted hydrogen gas to the purposes of artificial illumination from the year 1798, when its first successful application was made by Murdock at Soho; he then proceeds to Dr. Henry's investigations of the phenomena of its production and combustion; the variation of the intensity of light obtained from carburetted hydrogen, due to the proportion of carbon contained in it; the difference in the gas obtained from different qualities of coal; the superiority of the illuminating power of the gas from Cannel coal; and the still greater power of that produced from the decomposition of oil, which is 2 to 2½ times greater than that of coal gas. He then mentions the other products of coal by distillation, such as ammoniacal liquor, carbonic acid and oxide, sulphuretted hydrogen, tar, essential oil, naphtha, petroleum, asphaltum, and other substances. The paper concludes by pointing out the advantages which would result from the production of such gas as is usually given out at the beginning of the distillation of coal, as it contains 2 volumes of gaseous carbon united with 2 volumes of hydrogen, and its illuminating power is consequently more than double that of ordinary coal gas.

Mr. Parkes observed, that the quantities of air required for the combustion of different fuels as determined in the laboratory and on the large scale of practice, were frequently very different. It might be quite correct that a given weight of coal would require more air for its perfect combustion than the same weight of coke. There was great difficulty in ascertaining the fact practically, under steam-boilers, as the gases given out by the coal must have air supplied to them distinct from that which passed through the grate to ensure their perfect ignition, and many circumstances prevented the consumption of air from being exactly measured. Generally, he had found it necessary to use wider spaces between the grate bars for coke than for coal. In some late experiments very carefully made on a boiler invented by Mr. A. M. Perkins, equal weights of coal and coke required the same time for their destruction on the same grate, the apertures of the damper and ash-pit door, which were used to govern the draught being precisely the same. Coke effected a greater evaporation than coal at similarly rapid and slow rates of combustion; and in every case the temperature of an oil bath at the foot of the chimney was higher with coke than with coal. It must, however, be remarked, that no process had been used to ignite the gases which escaped from the furnace uninflamed. He had tried different kinds of coke, coal, and anthracite at this boiler, and the same fuel in every instance performed a greater evaporative effect at a slow than at a rapid rate of combustion. He thought that much of the air which entered the grate of a boiler passed through the fire unconsumed, for want of time to effect a sufficiently intimate combination with the fuel. In some experiments lately made at Swansea on the properties of anthracite, Dr. Schafhäutl had found from analysis, that no less than 40 per cent. of the products of combustion taken from the chimney consisted of oxygen, yet he had effected the large evaporation of 11 lb. of water with 1 lb. of that fuel.

Mr. Field stated, that Mr. Cooper had expressed an opinion that in the use of coke as a fuel, a less portion of heat reached the chimney than with coal, on account of the large quantity of unconsumed air that passed through the fire, owing to the open spaces necessarily existing between the pieces of such a dry fuel as coke; whereas in a fire made of binding coal, nearly the whole of the air combined with the fuel in its passage through the body of fire.

Mr. Pellatt observed, that although in practice coke appeared to require more air to support combustion than coal did, yet long experience had taught him to believe that when coal was exposed to a rapid combustion, it required more air than coke.

In answer to an observation that some experiments lately made on the measurement of the quantity of air which entered the blast furnaces of Sir John Guest at the Dowlais Iron Works might bear on this subject—Mr. Farey objected to the application of such results to determine the question, as the air is injected with considerable force into a furnace; there is frequently a great reflux of blast from the Tuyere when the furnace is working close; whereas when it is working open the flame at the top shows that the passage of the air through the mass of burning fuel is very free, and that consequently a portion of it passes off unconsumed. He had found in his experiments on blast furnaces, that unless there was a redundancy of carbon, and a deficiency of oxygen, there was no chance of making good iron.

May 26th.—The PRESIDENT in the Chair.

The following were balloted for and elected:—Thomas Illman, Joseph Chessborough Dyer, and G. S. Saunderson, as Associates.

"*On a new Mode of Covering Roofs with Planking.*" By William Cubitt, Assoc. Inst. C. E.

The roof itself is framed in the usual manner with principals and purlins, but without rafters. The boards intended for the covering are cut, by means of a circular saw, from planks 7 inches wide by 2½ inches thick, in such manner that each plank makes two boards, the one tapering from its centre towards the edges, the other from its edges towards the centre. The hollow boards are laid side by side, at intervals of 4½ inches, and nailed to the purlins by their centres only, so as to admit of shrinking; the intervening spaces are then covered by the other boards, overlapping 1¼ inch on each edge, and nailed in like manner. The covering thus formed presents a series of alternate elevations and depressions, longitudinally from the ridge to the gutter, and consequently the rain falls off very rapidly, and a roof so constructed is easily kept water-tight. The author conceives this to be the most economical mode of using timber for covering, and he has adopted it extensively. The communication was accompanied by a model of the roof and specimens of the boards as they are left by the saw.

"*On Long and Short Connecting-rods for Marine Engines.*"

A letter was read from Ardaseer Cursetjee, of Bombay, inviting a discussion on the relative advantages of long and short connecting rods for marine engines. He was induced to make inquiry on this subject from some observations in a communication to the Institution, relative to the engines of the steam tug the "Alice" (Minutes of Proceedings, page 385). In that paper their superiority is in part attributed to the increased length of the connecting rods. This is the point upon which he requests information, as he conceives that the power of the piston upon the crank is the same whatever may be the medium through which it is transmitted, and the effect to be the same throughout a complete revolution, whether the connecting rod be long or short, except that from the increased angle of a very short connecting rod some additional friction is thrown upon the joints.

On the general construction of the engine of the "Alice," he remarks, that engines of similar form are now used for pumping at the Thames Tunnel under Mr. Brunel's direction; and that a pair of engines of this kind were built by Messrs. Seaward, 13 years ago, for the "Staadt Francfort" steam-boat, to ply between Francfort and Coblentz; in this instance, the cylinders were firmly fixed to the bed-plate and sleepers, with the cross bars above the cylinders, thus having one connecting rod only leading to the cranks, which he considers a superior arrangement to that of the engines of the "Alice."

A drawing of the engines of the "Staadt Francfort" accompanies the communication.

A letter was read from Mr. John Cooper, of Dover, describing the effect of the worm (*Teredo navalis*) on several kinds of timber which had been exposed to the action of sea water. The kinds of timber on which the experiments were made were fir, English oak, and African oak; specimens of each sort, some Kyanized and the others unprepared, having been tried under exactly similar circumstances on the piles of the south pier of Dover harbour. The results show that Kyanizing timber does not in any degree protect it; as, after exposure from December 1837 until May 1840, it was found that the worm made equal ravages among all the specimens. The author also tried the process of saturating timber with copperas water, but did not find any good result from it. In July 1835, he placed under water some 2-inch oak planks which had been prepared with copperas; and on examining them in May 1840, they were found to be as much attacked by the worm as the worst specimens of unprepared fir timber which had been exposed for a similar length of time. The African oak resisted the attack of the worm better than either fir or English oak.

It was stated that Teak timber resisted the attacks of the worm and of the white ant, which destroy all other kinds of timber. It is, however, liable to injury from the attacks of barnacles.

"*On the Corrosion of Cast and Wrought Iron in Water.*" By Robert Mallet, Assoc. Inst. C. E., &c.

This communication is one of those forwarded to the Institution in consequence of the Council having considered this subject a suitable one to compete for the Telford Premiums; and the author having been long engaged in making experiments on this subject at the request of the British Association, refers in the introductory part of this paper to the contents of that report, which may be viewed as a "*précis*" of the state of our knowledge on the subject to the year 1839, together with original researches forming the basis of the present results. This communication is accompanied by a most elaborate set of tables of results; but these laborious investigations being yet in progress, the author directs his special attention to so much only of the subject as may be necessary for their elucidation, divesting his remarks as much as possible of a purely chemical character, and confining them to those practical conclusions which are of immediate use and importance of the engineer.

The tables of results are altogether twelve in number. The first five contain the data and results of the chemical or corroding action of sea and fresh water on cast and wrought iron under five several conditions, during a period of a year and ten months; and these five series of experiments are so coordinate with each other as to form one connected and comparable whole, whence the relative rates and absolute amounts of corrosion of cast and wrought iron—by, 1. clear sea water, 2. foul sea water, 3. clear sea water at temperature 115° F., 4. foul river water, and 5. clear river water—may be ascertained. The corrosive action of water and air combined produces on the surface of cast or wrought iron a state of rust possessing one of the five following characteristics—1. Uniform, 2. uniform with plumbago, 3. local pitted, 4. local pitted, 5. tubular—or of two or more of these characteristic conditions in combination; these facts for 82 different specimens of British and Irish cast iron--together with their original external characters, mode in which they were cast, specific gravity, dimension and weight before and after immersion, loss of weight per square inch of surface, this loss referred to a standard bar, and the weight of water absorbed for clear sea water—compose Table 1. The four subsequent tables contain similar results for specimens of iron immersed under the other four conditions mentioned above. These five tables contain also the results of the corrosion of certain cast iron protected by either of ten several paints or varnishes, the results of which are comparable with those for the unprotected iron. Table VI. exhibits the general comparison of the results set forth in the preceding tables for specimens of iron one inch thick, and reduced to one common or equal period of immersion. Table VII. shows the *average loss* of all varieties of cast iron experimented on per square inch of surface. Table VIII. the average calculated amount of corrosion (assumed uniform) of various specimens of cast and wrought iron per superficial foot of surface at the end of one century. From these tables it appears, that the metallic destruction or corrosion of the iron is a maximum in clear sea water of the temperature of 115° F.—that it is nearly as great in foul sea water—and a minimum in clear fresh river water.

Iron under certain circumstances is subject to a peculiar increase of corrosive action—as, for instance, cast iron piling at the mouth of tidal rivers—from the following cause. The salt water being of greater density than the fresh, forms at certain times of tide an under current, while the upper or surface water is fresh; these two strata of different constitutions coming in contact with the metal, a voltaic pile of one solid and two fluid elements is formed; one portion of the metal will be in a positive state of electrical action with respect to the other, and the corrosive action on the former portion is augmented. The lower end of an iron pile, for instance, under the circumstances just mentioned, will be positive with respect to the other, and the corrosion of the lower part will be augmented by the negative state of the upper portion, while the upper will be *itself* preserved in the same proportion. From this theoretical view may be deduced the important practical conclusion, that the lower parts of all castings subject to this increased action should have increased scantling.

The increased corrosive action of *foul sea* water may be referred to the quantity of hydrosulphuric acid disengaged from putrifying animal matter in the mud, converting the hydrated oxides and carbonate of iron into various sulphurets, which again are rapidly oxidized further under certain conditions, and becoming *sulphates* are washed away. Hence the rapid decay of iron in the sewage of large cities, and of the bolts of marine engines exposed to the bilge water. The corrosive action being least in fresh water may be partly referred to this being a worse voltaic conducting fluid than salt water.

It appears also that wrought iron suffers the greatest loss by corrosion in hot sea water; which fact has led the author to inquiries, with reference to marine boilers, at what point of concentration of the salt water, whether when most dilute, after the common salt has begun to deposit, or at a farther stage of concentration, the corrosive action on wrought iron is the greatest, and he points out the important practical use which can be made of this information. It appears also, that the removal of the exterior *skin* of a casting greatly increases the corrosive action of salt water and its combined air, so that the index of corrosion under these circumstances is not much less than that of wrought iron, and in clear river water is greater.

It farther appears, that chilled cast iron corrodes faster than the same sort of cast iron cast in green sand, and that the size, scantling, and perhaps form of a casting, are elements in the rate of its corrosion in water. The explanation of these facts is to be found in the want of homogenity of substance, and the consequent formation of numerous voltaic couples, by whose action the corrosion is promoted. It is also observable that the corroded surface of all these chilled specimens is tubular.

It appears also that, in castings of equal weight, those of massive scantling have proportionately greater durability than those of attenuated ribs and feathers. Hence appears also the great advantage of having all castings, particularly those intended to be submerged, *cooled in the sand*, so as to insure the greatest possible uniformity of texture. The principles now stated afford an explanation of the fact often observed, that the back ribs of cast iron sheet piling decay much faster than the faces of the piles. It is also probable that castings in dry sand and loam will, for these reasons, be more durable than those cast in green sand. The general result of all these experiments gives a preference to the Welsh cast iron for aquatic purposes, and to those which possess closeness of grain. Generally, the more homogeneous, the denser and closer grained, and the less graphytic, the smaller is the index of corrosion for any given specimen or make of cast iron.

The author next proceeds to the important question of the protection afforded by paints and varnishes. White lead perishes at once in foul water, both fresh and salt; and caoutchouc dissolved in petroleum appears the most durable in hot water, and asphaltum varnish or boiled coal tar laid on while the iron is hot under all circumstances. The zinc paint, which is now so much noticed as an article of commerce, the author has analyzed, and states its composition as—

Sulphuret lead	9·05
Oxide zinc	4·15
Metallic zinc	81·71
Sesqui-oxide iron . . .	0·14
Silica	1·81
Carbon	1·20
Loss	1·94
	100·

It may, *a priori*, be considered likely to produce a most excellent body for a sound and durable paint under water. The black oxide of manganese has no advantages but that of being a powerful drier. The defects of all oil paints arise from the instability of their bases; the acids which enter into the constitution of all fixed oils readily quit their weakly positive organic bases to form salts with the oxides of the metal on which they may be laid. Hence we must look for improvements in our paints to those substances among the organic groups which have greater stability than the fat or fixed oils, and which, in the place of being acid or Haloid, are basic or neutral. The heavy oily matter obtained from the distillation of resin, called "resenien," and eupion, obtained from rapeseed oil, have valuable properties as the bases of paints.

Tables IX. and X. contain the results as to the corrosion of cast iron in sea water when exposed in Voltaic contact with various alloys of copper and zinc, copper and tin, or either of these metals separately, per square inch of surface. It appears that neither brass nor gun metal has any electro-chemical protective power over iron in water, but on the contrary promotes its corrosion. This question is only a particular case of the following general question: viz. if there be three metals, A. B. C., whereof A. is electro-positive, and C. electro-negative, with respect to B., and capable of forming various alloys, 2 A + C. . . . A + C. . . . A + 2 C; then if B. be immersed in a solvent fluid in the presence of A., B. will be electro-chemically preserved, and A. corroded, and *vice versa*. If B. be so immersed in the presence of C., B. will be dissolved or corroded, and C. electro-chemically preserved; the amount of loss sustained in either case being determined according to Faraday's "general law of Volta-equivalents." The tables show that the loss sustained by cast iron in sea water, as compared to the loss sustained by an equal surface of the same cast iron in contact with copper, is 8·23 : 11·37; and when the cast iron was in contact with an alloy containing 7 atoms of copper and 1 of zinc, the ratio was 8·23 : 13·21; so that the addition in this proportion of an electro-*positive* metal to the copper produces an alloy (a new metal, in fact) with higher electro-negative powers, in respect to cast iron, than copper itself. The author discusses many results equally remarkable, and is therefore enabled to suggest by its chemical notation the alloy of "no action," or that which in the presence of iron and a solvent would neither accelerate nor retard its solution, one of the components of this alloy being slightly electro-negative, and the other slighly electro-positive, with respect to cast iron. These results will also enable some advances to be made towards the solution of the important problem proposed by the author in his former report, viz. "the obtaining a mode of electro-chemical protection, such that while the metal (iron) shall be preserved, the protector shall not be acted on, and the protection of which shall be invariable."

Table X. exhibits especially the results of the action of sea water on cast iron in the presence of copper and tin or their alloys. It appears that copper and tin being *both* electro-negative with respect to cast iron, all their alloys increase or accelerate the rate of corrosion of cast iron in a solvent, though in very variable degrees; the maximum increase is produced by tin alone, thus indicating that this metal (contrary to what was previously believed) is more electro-negative to cast iron than copper. Hence the important practical deduction, that, where submerged, works in iron must be in contact with either alloy, viz. brass or gun metal; common brass, or copper and zinc, is much to be preferred. These experiments will also serve to demonstrate the fallacy of many of the patented so-called preservatives from oxidation, which are brought before the public with so much parade.

The author lastly proceeds to the subject of the specific gravity of cast iron, tables of which are added to the preceding. The specific gravities here recorded were taken on equal sized cubes of the several cast irons cut by the planing machine, from bars of equal size, cast at the same temperature, in the same way, and cooled in equal times. Many of these results differ considerably from those given by Dr. Thompson and Mr. Fairbairn; which the author refers to the probability that those of Dr. Thompson were taken from pieces of the raw pig, and those of Mr. Fairbairn by weighing in air equal bulks cut from the mass by the chisel and file, by which latter process the volume is liable to condensation. The experiments of Mr. Fairbairn and Mr.

Eaton Hodgkinson seem to show that the ultimate strength of cast iron is in the ratio of some function of the specific gravity dependant upon the following conditions: viz. 1. the bulk of the casting; 2. the depth or head of metal under which the casting was made; 3. the temperature at which the iron was poured into the mould; 4. the rate at which the casting was cooled.

Table XI. All the irons experimented on are arranged in classes, according to the character of the fracture; for which purpose the terms—1. silvery, 2. micaceous, 3. mottled, 4. bright grey, 5. dull grey, and 6. dark grey, have been adopted by the author as a sufficient basis on which to rest a uniform system of nomenclature for the physical characters of all cast irons, as recognisable by their fracture; and it is to be wished that experimenters in future would adopt this or some other uniform system of description, in place of the vague and often incorrect characteristics commonly attached to the appearance of the fracture of cast iron.

The twelfth and last table contains the results of a set of experiments on the important subject of the increase of density conferred on cast iron, by being cast under a considerable head of metal, the amount of which condensation had not been previously reduced to numbers. It shows this increase of density in large castings, for every 2 feet in depth, from 2 to 14 feet deep of metal.

A very rapid increase of density takes place at first, and below 4 feet in depth a nearly uniform increment of condensation.

The importance of these results is obvious; for, if the ultimate cohesion of castings is as some function of their specific gravity, the results of experiments in relation to strength, *made on castings of different magnitudes, or cast under different heads*, can only be made comparable by involving their variable specific gravities in the calculation.

The following were balloted for and elected:—Lieutenant T. H. Sale, B.E., and George Larmer, as Associates.

June 16—The President in the Chair.

The following were balloted for and elected:—William Jory Henwood, as a Member; John Thomas Cooper and John Oliver York, as Associates.

"*On the Action of Steam as a Moving Power in the Cornish Single Pumping Engine.*" By Josiah Parkes, M. Inst. C. E.

In this communication, the author presents a detailed analysis of some of the facts collected and recorded by him in his former communications, with the special object of ascertaining from the known consumption of water as steam, the whole quantity of action developed—the quantity of action had it been used unexpansively—the value of expansion—the correspondence between the power, and the resistance overcome—and, finally, a theory of the steam action, with a view of determining the real causes of the economy of the Cornish single pumping engine.

The data employed for the purposes of this investigation are those obtained from the Huel Towan engine by Mr. Henwood, from the Holmbush by Mr. Wicksteed, and from the Fowey Consols, and recorded in the author's communications in the Transactions of the Institution of Civil Engineers, Vols. 2 and 3.

Steam may be applied in one or other of the two following modes: expansively, that is, when admitted into the cylinder at a pressure greater than the resistance, and quitting it at a pressure less than the resistance; or unexpansively, that is, when its pressure on the piston is equal to the resistance throughout the stroke. By the term *economy* in the use of steam, is meant the increase in quantity of action obtained by the adoption of that mode which produces the greatest effect.

The weight of pump-rods, &c., which effects the pumping or return stroke in a Cornish engine is greater than the weight of the column of water, by the amounts necessary to overcome the friction of the water in the pipes—to displace the water at the velocity of the stroke—to overcome the friction of the pitwork, and of the engine itself. The absolute resistance opposed to the steam, consists of the weight which performs the return stroke, plus the friction of the engine and pitwork, and the elasticity of the uncondensed steam.

The water-load in the Huel Towan engine was very accurately ascertained as 11 lbs. per square inch on the piston; and it is shown that the additional resistance amounted to 7 lbs. in the Huel Towan, and to 6 lbs. in the other engines, so that the whole resistance in the Huel Towan engine is 18 lbs. per square inch of the piston. Now, the elastic force of the steam at the termination of the stroke, and before the equilibrium valve is opened (ascertained from the ratio of the volumes of steam and water consumed), is only 7 lbs. per square inch, that is, 4 lbs. less than the water-load alone. The corresponding results for the other two engines are equally remarkable, and show most distinctly that, at the termination of the stroke, the pressure of the steam is far below the water-load, as had been previously observed by Mr. Henwood and others.

The next step in the analysis is to determine the portion of the stroke performed when the pressure of the steam in the cylinder is just below the resistance, and then to separate and estimate the spaces through which the piston is driven respectively by steam of a pressure not less than the resistance, and less than the resistance. These facts being ascestained, the virtual or useful expansion, and the dynamic efficiency of the steam, during the two portions of the stroke, are known; and it appears that there is a deficiency of power, as compared with the resistance overcome, of above 3 lbs. in the Huel Towan, and more than 4 lbs. in the other engines, per square inch on the piston.

From these startling facts, and a careful examination of Mr. Henwood's indicator diagrams, the author was induced to inquire whether the piston had not been impelled by a force altogether distinct from the continuous action of the steam upon it, namely, by a force which is to be referred to the sudden impact on the piston when the admission valve is so fully and instantaneously opened, as it is in these engines, and a free communication established between the cylinder and the boiler. To this instantaneous action on the piston, the author, for the sake of distinction, assigns the term *percussion*; and, proceeding to analyse the authentic facts under this view, it appears that the space of the cylinder though which the piston was carried by virtue of this percussive action was about 21 inches in the Huel Towan, 27 inches in the Holmbush, and 33 inches in the Fowey Consols engines.

The results thus unfolded, which are facts independent of any hypothesis, appear less startling on a full consideration of the circumstances under which the steam is admitted into the cylinder. The engine has completed a stroke, and is brought to rest by the cushion of steam between the piston and the cylinder cover; a vacuum is formed on the other side of the piston; the elastic force of the steam in the cushion then nearly balances the resistance. A communication is now suddenly opened between the cylinder and the boiler containing steam of a high elasticity; and the piston, being ready to move with a slightly increased pressure, receives a violent impulse from the steam's instantaneous action. The piston having started, the influx of the steam is more or less retarded by the throttle valve, and its elastic force, though at first greater than the resistance, is soon reduced considerably below it, the mass of matter in motion acting the part of a fly wheel, absorbing the excess of the initial power over the resistance, and discharging it by degrees until the stroke is completed.

The indicator diagrams, which are the transcripts of the piston's movements, show that such may be the nature of the action on the piston, and the discussion of numerous well-established facts and phenomena, for the Cornish engines, strongly confirms this view of the case. Whatever may be the theory of the steam's action, the fact that the sum of those actions has carried the piston through its course, is certain; and it seems equally certain that the quantity of water as steam which entered the cylinders was insufficient alone to overcome the resistance.

The author then investigates the amount of useful action due to the steam imprisoned between the piston and the cylinder cover, and recovered each stroke, which, for its use in bringing the engine to a state of rest at the end of the return stroke, he terms the *cushion*. This quantity, though small, is appreciable, and its value is assigned for each engine.

The author treats lastly of the evidence furnished by the diagrams of the indicator, and of its utility as a pressure gauge. The communication is accompanied by elaborate tables of the results of the analysis, and an appendix with the calculations worked out in detail.

SCIENTIFIC SOCIETY.

The opening meeting of the present Session was held by the Scientific Society on Thursday evening, Nov. 19, at their rooms in Great Russell-street, Bloomsbury. In the absence of the President, one of the Vice-Presidents, John Stevens, Esq., delivered the annual address, in which, after adverting to the advanced position of the institution, he explained, at some length, its characteristic features, and the peculiar objects which it is designed to promote. The great and known want of adequate facilities for collecting and registering scientific observations, seriously impeded the progress of inductive generalization,—facts are lost for want of channels through which they may be brought to a common centre, and there has never yet been formed a Museum of recorded and classified data, to which the scientific inquirer may resort for evidence to support or subvert theoretical views. The leading purpose of the Scientific Society is to supply this deficiency, but they can only hope to succeed in so arduous an undertaking, by the most active individual exertion, and by the friendly co-operation of those who are interested in the advancement of science. After the address a paper was read on a new discovery in Electrotype. The meeting was numerously attended, both by members and visitors, which evince the interest taken in the proceedings of the society.

KING'S COLLEGE.

We understand that regretting the necessity of refusing many applications for admission of students, whose age and previous character were not sufficiently advanced, into the civil engineering department—and feeling at the same time the advantage of having their previous education directed to those studies, which would ground them in the subjects of the more extensive readings of the senior class, and convinced as well, that even to a general studen would be useful, some knowledge of the principle and nature of that mechanism and machinery which is now becoming the subject of every day remark and conversation, without which the education of the gentleman is scarcely complete, the council of the college have established a junior class for students of 14 years and upwards.

ARCHITECTURAL SOCIETY.

The Tenth Session of this Society was opened on the 3rd ult., at their apartments in Lincoln's Inn Fields, with a conversazioné. The President, William Tite, Esq., F.R.S., the Architect of the New Royal Exchange, took the Chair at nine o'clock; when the Secretary, Mr. Grellier, proceeded to read the Report of the Committee, which stated the arrangements made for the lectures and papers of the ensuing session, and announced five prizes for the competition of the student-members, upon the following subjects :—The best architectural composition; the best measured drawing of the front of St. George's Church, Bloomsbury; the best series of architectural sketches produced during the season; the best notes of the lectures delivered at the several meetings of the Society; and the best drawing in chalk or pencil from the plaster figure.

The President then read an elaborate essay on the history, chemistry, and uses of bitumen and its compounds, tracing the facts of their application from the earliest times, with illustrations from the Bible, from Herodotus, Diodorus Siculus, Josephus, Dioscorides, Vitruvius, and Pliny. The lecturer then described the various kinds of bitumen, beginning with its most liquid state of naptha, and descending to petroleum, mineral tar, mineral pitch (sometimes called maltha), and then to the compact bitumen known as asphaltum, elastic bitumen, or mineral caoutchouc, mineral wax, and mineral tallow. This part of the dissertation was illustrated by specimens of most of these substances on the lecture table, and by references to the principal sources from which they are derived in the present day. It appears that, for the purpose of commerce and the arts, they are now obtained from the mines of Avlona in Albania, of Lobsaun in Alsace on the left bank of the Rhine, from Pyremont, which furnishes the asphalte of Seyssel, known in England as Claridge's, besides the asphaltes of the Landes known as the Bastenne and Gaujac. Bitumens, in various states, are also found in great abundance at Rangoon, in the Birman Empire, at Coxitambo in South America, in the famous Pitch-Lake of the Island of Trinidad, in the celebrated Naptha Wells at Baku on the Caspian, in Persia, in Greece, Sweden, Gallicia, Moldavia, Sicily, England, and, in fact, in all parts of the world. In many cases, the varieties are found pure; and in others, as at Seyssel and Lobsaun, they are mixed with argillaceous sands, calciferous bitumens or bituminous grits or shales: all the deposits appear to belong to the tertiary formation. There are various opinions as to their origin; their chemistry, however, would seem to indicate that they must have been derived from the destructive distillation of vegetable matter, the produce of ancient forests. Among other curious facts stated by the lecturer, it was mentioned that the streets of Parma are lighted with petroleum from the mines of Avlona; and that a kind of purified bitumen had been, for some centuries, used in Paris for greasing the wheels of carriages, under the name of *graisse noire.*

The introduction of bitumen into mastic, for the purposes of paving, lining tanks, &c., though recently revived in Paris as a novelty, does not appear to be so. Mr. Tite noticed upon this subject, a Tract in the British Museum, entitled, "Dissertation sur l'Asphalte, ou ciment naturel, decouvert depuis quelques années au Val Travers, dans la Comté de Neufchatel, par le Sieur Eirini d'Eyrinys, Professeur Grec, et Docteur en Medecine. Avec la manière de l'employer, tant sur la pierre que sur le bois; et les utilitée de l'huile que l'on en tire." Paris, 1721, 12mo. From this tract the following extracts were read; from which it would seem that the proportions and applications of bitumen in mastic were known more than a century since. "Pour former le ciment, et le mettre en état d'être employé, il faut prendre la mine toute pure, et la bien pulvériser. Pour le faire avec moins de peine et de frais (car elle est fort dure), on peut l'attendrir en la mettant devant le feu, ou à see dans un chaudière. Dès qu'elle sentira la chaleur, on la broyera très facilement; il vaut, cependant, mieux la piler froide, parecqu'en la chauffant, l'huile s'évapore, et elle perd beaucoup de sa qualité et de sa force.

"Quand elle est absolument écrasée, et réduite comme du terreau, on prend de la poix de Bourgoyne blanche ou noire (la blanche est la meilleure) on la fait fondre a petit feu dans une chaudière de cuivre ou de fer; quand la poix est entièrement fondue, il faut prendre garde que le feu n'y prenne; on y mêle peu à peu l'asphalte en le remuant continuellement avec un bâton ou spatule, jusqu'à ce que l'incorporation soit faite, on le voit parceque l'asphalte doit être liquide comme de la bouillie; la doze de la poix est la dixième partie, c'est à dire, qu'il faut neuf livres de mine et une livre de poix pour former le ciment dans sa perfection."

After giving an account of the manner of employing the asphalte as mortar, the author continues,

"L'on pourroit encore faire des bassins, réservoirs, citernes et terrasses, même sans employer des pierres de taille, et cette façon, qui couteroit moins que les autres, servit aussi solide, et auroit sa beauté, &c. &c."

His recommendations of the invention are warm :—

"Quand le ciment d'asphalte est fait éxactement, il resiste également au chaud et au froid; la plus grande ardeur du soleil, ni la gelée la plus forte, n'y peuvent faire aucun dommage. Je crois avoir trouvé la chose du monde la plus avantageuse pour le public, principalement pour Paris, &c. &c."

The lecturer exhibited tables showing the chemical analysis of various substances from recent woody fibre down through the lignites, coals and jets to the most compact anthracite, and from the recent turpentine through the napthas, pitches, &c., down to the asphaltes. He pointed out the chemical analogy or isomerism of many of these substances, as contrasted with their uses and appearances. In the course of the lecture, reference was made to the ruins of Babylon and Nineveh, as well as to the ancient Oracles and Nymphæa connected with the springs of Naptha, and particularly to the ruins of Avlona, which seem to connect the ancient Nymphæum spoken of by Strabo and Dio Cassius, on the banks of the Aias, or Aous, the modern Viosa, with the mineral pitch formation of Selenizza, furnishing the modern asphalte of Avlona.

Mr. Tite explained, at some length, the composition of the asphalte mastics, recommending to the notice of the architects present a careful consideration of their application and introduction.

The lecture was received with the strongest marks of approbation from a very large auditory, including many of the leading members of the Royal Society, the Society of Civil Engineers, the Society of Arts, and the Institute of Architects; and, after the announcement of various donations to the Library and Museum of the Society, the meeting separated.

INTERESTING EXPERIMENTS WITH LOCOMOTIVE ENGINES, ON THE HULL AND SELBY RAILWAY.

On Tuesday, the 10th ult., a course of five days' experiments commenced with the engines of the above Railway, originating through the following circumstances :—

About the commencement of the present year, six engines, somewhat similar to those on the Leeds and Selby line, were in a greater or less state of forwardness for the Hull and Selby Railway, at the works of Messrs. Fenton, Murray, and Jackson, of this town, when the Hull and Selby Railway Company resolved to have six other engines, on the most approved construction which experience up to that period could produce, from the previous working of locomotives on the various Railways. Four objects were particularly kept in view, namely, *safety, simplicity, accessibility* of the various parts, and *economy*, the whole combining general *efficacy* and *durability* of the engine throughout.

The first object is secured by giving a more extended *base* for the action of the springs in supporting the weight of the engine, being about six and a half by eleven feet, whereby a remarkably steady motion is secured at thirty miles per hour. It is not at all a matter of surprise that the four wheel engines of several Railways now in use should every now and then go off the road, and in an instant, when it is recollected the extreme base of their springs for supporting the engine is only about three three quarters by about six feet; hence their rocking, serpentine, and pitching motion, which without any other cause than a slight increase of speed, literally lifts the flanges of the wheels above the surface of the rails, and in three or four seconds the engine is turned end for end, upset in the act, and the train with it; whilst the stability of the engine is effectually secured through an extended base upon the front and hind wheels. By means of a new combination, the best properties of the four-wheeled engines are also completely applied, by resting the weight on the crank shaft immediately within the wheels, which experience has for years proved to be the place least likely to injure it, and thereby avoid the alarming accidents which have so often taken place by the breaking of the shaft, through placing the weight on bearings outside of the wheels; the centre of the engine being a sort of neutral axis, there is very little power over its motion in that part, and this advantage, by placing the weight on the crank inside the wheels, is, in consequence, got without a sacrifice of stability.

Secondly,—In addition to the safety and simplicity of having only *two* inner frames, instead of three or four, with as many bearings on the crank shaft, the space under the boiler is still further stripped of machinery by a new valve motion, which gives a high degree of openness and facility of access so desirable in examination, cleaning, &c, of the working parts.

Thirdly,—The steam being used expansively by the valve motion above alluded to, a great saving in fuel is effected, as will be seen on examining the results of the experiments, and as the excessive wear and tear of locomotive boilers arises from intense heat, it is not improbable this decided step towards removing the cause will prevent the effect, namely, the rapid destruction of the boiler. The action of this valve motion is perfectly smooth, being worked by eccentrics (which are also of an improved construction), and any quantity of steam from 25 to 90 per cent. on the stroke can be admitted into the cylinders with the most ready and complete control, at any speed the engine may be going; if a high wind or an incline oppose the progress of the engine, a greater quantity of steam is admitted; if wind or gradients be favourable, the steam is still admitted at full pressure into the cylinders, but shut off at an earlier period, propelling the pistons the remainder of the stroke by its elastic force, similar to driving a time-piece by the uncoiling of the main spring.

Lastly,—A combination of dimensions and proportions have been gleaned from the best results of locomotive engines of various constructions, and in use in different parts of the country. The driving wheels are 6 feet diameter, length of the stroke 2 feet, diameter of cylinders 12 inches, inside dimensions of fire-box, 2 by $3\frac{1}{2}$ feet, tubes, 94 in number, by $9\frac{1}{2}$ feet long, and 2 inches diameter. The general diminution of machinery in the construction has given room for ample dimensions in the principal working parts, and thus the whole arrangement has a close bearing on *safety, simplicity, accessibility, and economy.*

Circumstances led to those engines being ordered of Messrs. Shepherd and

Todd, Railway Foundry, of this town. The Hull and Selby line was opened with the engines of the former order, but the public and the company being so much annoyed by hot cinders from their chimneys, burning whatever they lighted upon, and rapidly destroying the smoke boxes themselves, three of those engines were altered, and succeeded to a considerable extent in diminishing the nuisance, whilst the engines performed better, and with less fuel. That fact, however, being questioned, and two engines of the *improved* construction having got to work, Mr. John Gray, the engineer of the locomotive department, and patentee of the improved engines, urgently requested a most rigorous and simultaneous trial of the different engines, and to be witnessed for the parties concerned by persons above suspicion. Mr. J. Miller and Mr. T. Lindsley represented Messrs. Fenton, Murray, and Jackson; Mr. J. Craven and Mr. J. Barrons represented Messrs. Shepherd and Todd; and Messrs. E. Fletcher, W. B. Bray, J. G. Lynde, jun., J. Farnell, and J. Gray, were the repreaentatives of the Hull and Selby Railway Company. The arrangements for the experiments were, that the gross load should include engine, tender, carriages, and every thing in the train.

The steam was got up in the respective engines to the pressure of from 56 to 66 lb. per square inch; the fires filled to a certain level at the starting in the morning, and filled to the same level on finishing the last trip at night. The pressure of steam at starting was generally up to 66 lb. and was at about half that pressure at the end of each trip. There were *fifty* experimental trips made in all, namely, twenty-four trips with the *Collingwood, Andrew Marvel*, and *Wellington*, the unaltered engines of Messrs. Fenton, Murray, and Jackson. Their average gross load was 53·4 tons, or 1656 tons, over one mile: consumption of coke 1013 lb. or 0·611 lb. per ton per mile; water, 6500 lb. or 3·90 lb. per ton per mile. There were ten trips made with the other three engines of Messrs. Fenton, Murray, and Jackson, which were altered at Hull, namely, the *Exley, Kingston*, and *Selby*. Their average load was 49·16 tons, or 1524 tons over one mile; consumption of coke, 635 lb. or 0·416 lb. per ton per mile: water, 4264 lb. or 2·79 lb. per ton per mile.

The *patent* engines made by Messrs. Shepherd and Todd, viz. the *Star* and *Vesta*, made sixteen trips, and their average loads, &c., were 55·4 tons, or 1718 tons over one mile; coke consumed, 465 lb. or 0·271 lb. per ton per mile; water, 2874 lb. or 1·62 lb. per ton per mile. The average gross load of all the fifty trips is 53·2 tons, or 1649·4 tons over one mile, and taking that as a standard load, the consumption of fuel and water performing exactly equal quantities of work, is represented in the following tables :—

Class of Engine.	Load in tons conveyed over one mile, in lbs.	Elsecar Coke used per trip of 31 miles, in lbs.	Coke used per mile, in lbs.	Coke used per ton per mile, in lbs.	Water used per trip of 31 miles, in lbs.	Water per mile in lbs.	Water per ton per mile, in lbs.
Patent	1649·4	446·98	14·41	0·271	2672	86·19	1·62
Altered	1649·4	686·15	22·13	0·416	4601·6	148·43	2·79
Unaltered	1649·4	1007·78	32·59	0·611	6432·8	207·5	3·90

The financial annual result of the three classes of engines for coke and boilers, with such a traffic as that of the Hull and Selby line, will be about—

£4,500 for the unaltered engines.
£3,250 for the altered ditto; and about
£2,000 for the patent engines.

In conclusion, it is deserving of remark, that *all* the attesting witnesses expressed themselves highly satisfied with the manner in which the experiments had been conducted, and with the facilities which the Company so readily granted to enable them to come at correct results. Probably no experiments were ever made under similar circumstances where the parties concerned displayed greater independence, impartiality, and good feeling than on the present occasion.—*Leeds Mercury.*

PATENT LAW.

An Important Case of Patent Law regarding the Amendment of Specification was heard in the Rolls' Court, on Friday, Nov. 6.

IN THE MATTER OF JOHN SHARP'S LETTERS PATENT.

The petition of Joshua Wordsworth, of Leeds, machine-maker, for expunging from the memorandum of alterations in the specification of Sharp's letters patent "for machinery for converting ropes into tow, &c.," such portions as were in substance descriptive of the same machinery as was invented by the petitioner Wordsworth, was resumed, and Mr. Bacon for Mr. Sharp followed Mr. Hill against the petition, and Mr. Pemberton, in behalf of Wordsworth, the petitioner, replied.

By statute 5 and 6 William IV., c. 73, "to amend the law touching letters patent for inventions," it is enacted "that any person having obtained letters patent for an invention may enter with the clerk of the patents (having first obtained the leave of the Attorney or Solicitor-General) a disclaimer of any part of his specification, or a memorandum of any alteration therein which is to be deemed part of such specification." Wordsworth's petition stated that letters patent were granted in October, 1836, to Sharp to make and vend his invention, part of which the petitioner stated was applicable to the preparing cotton wool and silk for spinning. The specification was enrolled in April, 1837. In May, 1838, letters patent were granted to the petitioner Wordsworth for an invention of improvements in machinery "for heckling and dressing flax, hemp, and other fibrous materials," and in November following the specification was enrolled. The petition then stated, that after this enrolment he (Wordsworth) discovered that Sharp had, in September, 1838, obtained from the Solicitor-General a certificate that Sharp had applied for leave to enter with the Clerk of the Patents certain memorandums of alterations of parts of his specification, and that the Solicitor-General had directed him to advertise the alterations, which was done; and, no objection having been made, the Solicitor-General granted leave to Sharp to file the memorandum of alterations, which alterations the petitioner stated were a new arrangement of machinery, and extended Sharp's patent to what were in substance his (Wordsworth's) inventions, as described in his specification. The petitioner submitted that the statute did not authorize the addition to a specification of any description of new machinery, and prayed for expunging the memorandum of alterations.

For the petition it was argued by Mr. Pemberton and Mr. James Russell, that the Master of the Rolls (in whose custody the rolls of the Court in Chancery were) had authority to permit alterations to be made in the rolls, and his jurisdiction for that purpose remained unimpeached by the act of William IV. The jurisdiction originally inherent in this court had been acted upon under the Municipal Corporation Act in question respecting the authority given to the Lords of the Treasury of interfering with the rolls of the court in the cases of "The Attorney-General against the Corporation of Liverpool," and against the Mayor of Poole, where it had been laid down by the Lord Chancellor, that to exclude the jurisdiction of one court there must be not only another tribunal created, but an absolute exclusion of all other authorities enacted. In a case of charitable trusts, which were to be exercised in such manner as the Lord Chancellor should direct, there was an appeal from the direction to the House of Lords, in which the question whether that house had jurisdiction was not decided, but the opinion expressed was that they had not. In "the Attorney-General against Norwich," the judges were unanimous against the jurisdiction of the house. To exclude the jurisdiction of this court there must be an express legislative exclusion; and the mere giving an authority to another tribunal would not have that effect. Where a clerical mistake was established that might be corrected. Every court had an entire control over its own records, as the Court of Common Pleas had over fines and recoveries; whether the error were clerical or otherwise, it made no difference, for the record was not in the state it ought to be. The rolls of this court were under the control of the Master of the Rolls, and the state in which the records ought to be was subject to his determination, which must control the opinion of the Solicitor-General. The memorandums of alterations were filed with the specification and became part of it. Had there been an alteration by erasure and substitution of other words, a difficulty would have been created; but there was no difficulty here in ordering the memorandum to be taken off the rolls. The act had not given the Solicitor-General power to decide conclusively and without appeal what should or should not be on the rolls, nor had it excluded the jurisdiction of the judges of the court over its rolls. Suppose *per incuriam* or by mistake in his clerk a fiat for an inconsiderate alteration had been given, or suppose the fiat had been attached to a wrong memorandum, the Solicitor-General would have no authority after he had given his fiat to correct any mistake or fraud, nor would there be any means of making such correction if the jurisdiction of this Court were taken away. The effect of the fiat was merely that certain things should be placed upon the record, subject in all respects to the same conditions as the other records were. If the memorandum were not warranted, the Court could take it off. Had the statute made the fiat absolute, that could not have been done, but the fiat left the jurisdiction precisely in the same state it was in before, and it was for his Lordship to determine whether the memorandum of alterations ought or ought not to remain a record of the Court, and if not, his Lordship had jurisdiction to order it to be removed. He did not contend that his Lordship could order a patent to be taken off the rolls of the court on the ground that the invention was not new, but whether his Lordship was to decide whether such circumstances had existed as could justify the memorandum being put upon the rolls. The question was not to be determined by the law officers of the Crown without the control of any other authority. The act had not declared their fiat conclusive, nor had it extended any right given by the letters patent. The Legislature prevented the record being altered at the mere will of the parties, enacting that there must be the leave of the Attorney or Solicitor-General. Their fiat was not to extend the exclusive right granted by the letters patent, but this fiat extended those rights; therefore the memorandum of alteration was not such as the act allowed, and if so, the fiat was good for nothing. It might be said, that if the memorandum is not warranted by the act, the objection might be taken in an action at law; but the answer to that would be, that the alteration is incorporated into the letters patent, and alters the specification; and although the petitioner in an action at law might say the invention as specified in the alteration was neither new nor useful, he could not say it was no part of the specification, and he might have a right to have his action tried upon the original specification. If the fiat were conclusive, the alterations could not be averred to be no part of the record, for the statute had made them part of the record so long as the fiat remained. Unless the court had jurisdiction, the fiat would, in altering the records of the Court, be conclusive not only against the Court, but against the Attorney and Solicitor-General themselves, for the act had not provided a mode of amending any mistakes they might have been led into. Where surreptitious or forged documents were discovered to be placed upon the rolls of the court, it would be no answer to an application for their removal to say that an action could not be brought upon them. The Court would order an invalid instrument to be delivered up, on the ground that it formed a cloud upon the title of the individual whose interest was sought to be affected by it.

Mr. Hill and Mr. Bacon, for Mr. Sharp, against the petition, said the arguments for the petition were, that the specification with the alteration was a record of the court, that such records might be amended by his Lordship, that the prayer was in substance for an amendment, and that the petitioner had that interest in the question which authorized him to make the application. The specification with the alterations might for many purposes be a record, but under the colour of that general term inferences not quite sound had been drawn. The patent was granted upon a proviso that the patentee should at a certain time enrol a specification; but that proviso did not give the specification any of those high attributes of records which had been claimed for it. A record imported verity, and if the petitioner's argument was well-founded, no person could defend an action in which the patentee could prove an infringement of his patent. But from the statute of James I. these records had been treated only as the statement of a party who was bound to prove every averment he made, as that there was an invention, that he was the first inventor, &c. The patentee could not hold up his specification, and say "Here is a record, you are estopped from saying I am not the first inventor; my case was determined before we came into court." Nothing of that sort could be said. The specification was not a record in the sense and for the purposes for which that word had been used, nor was the memorandum incorporated in the specification such a record. In one of the cases cited (Redmond's) there was a clerical error, and that which had been intended was not done. If that had been the case here, his Lordship might, but with considerable trepidation, go back and bring the intention and the act which had parted company into agreement again; but his Lordship had been required to erect the Court into a court of appeal over judgment of the Solicitor-General, and to do what that officer might have done had he viewed the matter in a different light. Such a procedure would not come within the doctrine of amendments. It might as well be said that the reversal by writ of error of a judgment at common law was an amendment of the record; it was confounding things entirely different; it was not an amendment of the record, but the correction of the errors of an inferior court. In analogy to the practice of the common law, there must be something to amend by. The present was not a question of amendment. Before the statute of William IV. there was no authority that could enable a patentee to disclaim any part of his patent; it was a new power given to the Crown, and vested in its legal officers. By the common law the Crown had great powers in granting monopolies, which by the statute of James were restricted to new inventions, and to the term of 14 years, and where the patentee by his specification had made his claim too large, it was fatal to his patent; but the late act had given the Attorney-General power to permit the patentee to disclaim a portion of his patent. When a power was created by the Legislature and vested in a certain tribunal, then no other court had jurisdiction. The invention was only one condition—the inventor must have a patent and specification. The memorandum remaining on the files of the Court decided nothing but that the memorandum was authentic; it did not decide that there was an invention, or that the patentee was the inventor. The alleged invention might not be new, but that would be no reason for taking the memorandum off the files of the court. A bill in equity was not taken off the files of the court because it contained false allegations. If a judgment were erroneous, it would be a reason to appeal from it, but no reason to take it off the rolls of the court. The difference was between what was genuine and what was authentic. He did not argue that all was necessarily genuine, but he did say it was all authentic, and the question was to try the authenticity. The argument for the petition went to change the whole course of proceedings in patents from the time of James I., and he would advise his friend, who was the inventor of the doctrine, to get a patent for it. Whether it would stand as a new machinery for trying the validity of patents by their specification before the Master of the Rolls, would be a question. It was said that whatever had any vice would be taken off the rolls of the court, which would not bear anything on its rolls which contained an erroneous allegation. The question was, who was the new inventor? An issue could not be granted to determine the question of amendment. The Solicitor-General required advertisements to be made of the application to him, and gave it two hearings; so that the fiat for filing the memorandum of alterations was not granted in haste, but after due consideration. The validity of patents ought not to be decided in the present mode of proceeding. The mode of trying those questions had been settled for years, and ought not to be altered.

Mr. Pemberton replied. As long as the memorandum of the alterations with the fiat of the Solicitor-General remained as part of the rolls of the court, it would not be competent for any person to deny that the memorandum was a part of the specification on which the patent was granted. The statute did not authorize the memorandum to be placed on the rolls, for the memorandum did not form part of the specification. He would ask, had the Crown granted letters patent with the alteration? If it had, the objection that his Lordship had no power to interfere would be good; but if the memorandum were improperly placed, then it formed no part of the grant, and his Lordship would remove it from the record, as he would remove a forged specification or correct a clerical error.

Lord Langdale said, it was his duty to receive the records of the court, and in his character of recipient he had no doubt of his jurisdiction. He was to receive such documents as parties presented as the records of their own acts. If it were shown that documents had been presented which were not an accurate record, it would be his care to discover where the error arose, and to satisfy himself that it was an error. He would see what had been done upon former occasions.

Mr. Pemberton.—The question was not whether his Lordship could alter a record, but whether the enrolment as it stood was a record.

NEW INVENTIONS AND IMPROVEMENTS.

An improved method of retarding and stopping railway trains; patented by Henry Montague Grover, of Boveney, Buckingham, Nov. 7.—Claim first.—The application of electro or other magnetism, for the purpose of retarding or stopping railway trains.—A magnet, of the ordinary horse-shoe form, is let into a block of wood, and fixed by sustaining rods in such a position that its ends are a short distance from the face of the tire of one of the wheels. A galvanic battery is placed on the bed or platform of the carriage, and a connection of the magnet and the face of the tire of the wheel formed when necessary, by means of connecting wires, which will cause the wheel to be retarded or stopped. These magnets may be applied to any number of wheels in this manner, or through one magnet to a lever, and by cranks or other apparatus, indirectly to the wheels.—*Inventors' Advocate.*

An improved apparatus or process for producing sculptured forms, figures, and devices, in marble and other hard substances; patented by William Newton, of Chancery-lane, Middlesex, (being a communication from a foreigner residing abroad), Oct. 22.—These improvements consist, first, in the construction of a mould, die, or matrice, of metal or other hard substance, in which the counterform of the figure or device intended to be sculptured has been made, and its application to the stone or marble intended to be cut.—Secondly, in the means by which the sculpturing is effected; viz., by the repetition of slight but rapid blows of the mould, or die, struck against the face of the stone, by which the surface becomes abraded, and particles are gradually broken off, leaving the stone ultimately in a form, or figure, corresponding to the mould or die which has been working upon it.—Claim.—Application of a mould or striking die, which being by any arrangement made to strike a rapid succession of light blows on the substance to be sculptured, shall abrade or wear away the superfluous parts of the surface of the material under operation, and produce a form, or figure, corresponding with the mould or die.—The mould must be mounted in any convenient mechanical apparatus capable of holding, raising, and depressing it, that it may strike very light but rapid blows on the face of the block to be sculptured, which must be supported upon firm stationary bearings; the mould or die is securely attached to a lever, which is a strong frame of iron, mounted on pivots, which are made adjustable, in order to regulate the height of the frame, from the block of marble or stone; to the outer end of the lever a staple also adjustable by a screw and nut is fixed, to which is attached a cord, also connected to a series of cranks and rods, which are mounted in a horse-shaped frame; a crank in the lower end of this series is acted upon by stops, notches, or teeth, in the periphery of a tappet or rachet wheel, which is acted on by a pulley being made to revolve on its axis driven by a band from any first mover; so that on a rotary motion of the tappet wheel, its teeth will act against the arm of the lower crank, and produce a slight reciprocating motion in the series of cranks and rods, which will be communicated through the cord to the lever which holds the mould, thereby causing a rapid succession of slight blows to bear upon the surface of the block, and in a short time to abrade all those parts of the stone against which the mould or die strikes. The process will be facilitated by the introduction of sand, emery, or diamond dust, with water, at an early stage of the work, and may be introduced by a simple inclined plane, or in any convenient manner; towards the end of the process a finer powder should be used and the work will leave the mould in a highly-finished state. This invention applies to busts, statues, and groups of figures, even the most complicated and extensive, and finishes them with the greatest delicacy, only it is necessary to employ several small moulds instead of one, and it will act equally well on crumbling stone, that would not bear the chisel, as upon a solid mass.—The inventor claims no particular arrangement of apparatus for causing the mould to strike the face of the block, although he considers that above described suitable and appropriate for the purpose.—*Ibid.*

A composition for the prevention of corrosion in metals, and for other purposes; patented by Arthur Wall, of Bermondsey, surgeon, October 15, 1840.—This composition is prepared in the following manner:—20 lb. of strong muriatic acid are diluted with 3 gallons of water and placed in a shallow cast iron vessel; 112 lb. of steel or iron filings are heated to redness and quenched in the diluted acid to effect their oxidation; to facilitate this action, the pan is placed on a furnace or sand-bath, and the contents repeatedly stirred for about 24 hours, or until ebullition takes place, the liquor is then drawn off, and the foregoing process repeated with such portion of the filings as remain unoxidized. The oxide thus obtained is exposed on a red hot iron plate, till all the moisture has been driven off, and the oxide assumes a red appearance When cold, 16lb. of quicksilver are to be added to the mixture, by sifting through a fine sieve, and afterwards intimately incorporated in a mortar; enough water to cover the surface is then poured over it, and from 8 to 9 lb. of strong nitric or nitrous acid added; this mixture is to be placed in a sand-bath till all the moisture is driven off. When the mass is dry it is to be well pounded in a mortar till it assumes a uniform state of blackness. All the finer particles are to be separated by washing in water, and left to settle, the sediment is to be placed in a crucible or earthen retort, with a receiver attached to collect any chloride or mercury that may come over. When red hot plunge it into fresh boiling water, stir it well and leave it to settle, then draw off the water and add any chloride that may have come over into the receiver. Then add one-fourth of its weight of common black or red lead, according to the colour desired. This composition is to be mixed with boiled linseed oil with one fifth of spirits of turpentine, and applied as thinly as possible with a brush to the sheets of metal to be protected. The metal coated in this manner is to be dried by the application of heat, beginning with a low temperature, and gradually raised to about 300° of Fahrenheit, so as to make the metal "*imbibe*" the preparation. The claim is, for the invention of the composition prepared as above described, for the prevention of corrosion in metals, and for other purposes.—*Mech. Mag.*

STEAM NAVIGATION.

The Clyde.—There was launched, on the 27th October last, at Clyde Bank a new steam dredging vessel for the River Clyde trustees. This vessel is the largest of the kind which has yet been built on the Clyde; she is 100 feet long and 22 feet broad; she is to carry an engine of 24 horse power, and to work effectively in 18 feet depth of water. The engine for this vessel has been constructed by Mr. John Neilson, of Oak Bank Foundry, in accordance with the specification drawn up by Mr. Bald, engineer of the Clyde. This vessel is now in the harbour of the Broomielaw, for the purpose of receiving the engine and machinery on board. A very beautiful model of this vessel, on a scale of one foot to an inch, was exhibited in the model room of the British Association, and which was constructed under the direction of Mr. Bald, before the steam dredge-boat was built.

Navigation of the Mersey.—The *Warrington*, a new iron steamer, of 200 tons burthen, builder's measurement, built entirely (engines and hull) by the Warrington Bridge Foundry Company, made her first experimental trip down the Mersey to Liverpool and back on Wednesday, 11th ult. On her downward voyage she sailed remarkably well, and took in tow several flats bound for Liverpool. On her return home, she steamed from the Old Quay Pier, Liverpool, to the Old Quay, at Runcorn, in one hour and twenty-two minutes, towing one of Messrs. John Hodson and Company's flats. From Runcorn to Warrington, a distance of ten miles and a half, her speed was put to the test. In spite of a heavy fresh, and the disadvantage of getting up her speed after stopping at Runcorn, she completed the distance in forty-seven minutes. As far as the navigation of the Mersey is concerned, all difficulties thrown in the way of Warrington one day becoming a bonded port have now been made to disappear.—*Liverpool Times.*

The Mammoth Iron Steamer at Bristol.—A gentleman who has recently seen the immense iron steamer building by the Great Western Steam Ship Company at Bristol, informs us that she will *register* about 3,000 tons, but that her actual tonnage will exceed 3,600 tons, or about 600 tons more than any ship ever built. An immense saving in stowage will be gained in consequence of the adoption of iron for her hull, whilst her draught of water will be comparatively small, owing to the great buoyancy possessed by iron vessels. She will consequently be able to carry coals sufficient both for her outward and homeward passages,—a most important point, when the inferior quality of coals obtainable in America, and consequent diminution in speed, is considered. Her engines, we hear, are to be of 1000 horse power, and it is confidently expected that the average voyage across the Atlantic will be reduced to ten days. She will carry a vast spread of canvass, so that in all probability the engines will frequently be at rest. In consequence of the adoption of Smith's Screw Propeller, this stupendous ship, the greatest experiment in steam navigation ever made, will, we believe, be able to pass the present locks at Cumberland Basin, and discharge her cargo in Bristol Harbour. We congratulate our Bristol neighbours upon the enterprise which they are displaying. Two magnificent steamers are now building at Bristol, by Messrs. Acraman, for the Royal Mail Company; and, altogether, the ancient port seems to be "going a-head."—*Gloucester Chronicle.*

Iron Steamer.—On Saturday the 21st ult., was launched from Messrs. Ditchburn and Mare's building yard, at Blackwall, a wrought iron steam vessel of 160 tons, named the "Mermaid," to be propelled by an engine on an entirely new principle, of 50 horse power, invented expressly to drive the Archimedes screw without the aid of geering-wheels. Should its power equal its simplicity, it is likely to cause a change in steam engines. The engine is making by Messrs. Rennie's.

Prevention of Steam Packet Collisions.—The Corporation of the Trinity House has deemed it right to frame and promulgate the following rules, "which, on communication with the Lords Commissioners of the Admiralty, the Elder Brethren find have been already adopted in respect of steam-vessels in Her Majesty's service." Rule first—"When steam-vessels on different courses must unavoidably or necessarily cross so near that by continuing their respective courses there would be a risk of coming into collision, each vessel shall put her "helm to port," so as always to pass on the larboard side of each other." Rule second—"A steam vessel passing another in a narrow channel must always leave the vessel she is passing on the larboard hand."

Steamers Wanted.—We had hoped that the cry of "steamers wanted" which we have continually kept up for the last two years, would before this have been responded to by the arrival of steamers from England; but as we see that that the subject was alluded to in several London and Liverpool papers of November and December last, we still hope that many months will not elapse before several steamers arrive in the colony. The following steamers are now urgently wanted, in fact we are suffering much from the want of them:—Two large steam-boats to run from Port Philip to Sydney; a large boat to run from Sydney to New Zealand; a second to be added in about 12 months; three boats to run to Hunter's River; a boat to run to William's River; a boat to run to Brisbane Water; a couple of small boats to run between Newcastle and the different towns on the Hunter, Williams, and Paterson. Besides the above, a boat will be required to run to Twofold Bay very shortly, as the country between there and Manaroo, called the Bija country, is beginning to attract attention; boats for Jervis's and Bateman's Bay will soon be required. We consider the above boats are required at once, in addition to those now here, for there will always be some of the vessels meeting with accidents, and otherwise requiring repair, and it is of the greatest importance that boats should run regularly. Although the above are urgently required, we believe that the only boats that can be depended upon, as sure to arrive during the present year, are two for the Hunter's River Company, and one for Port Philip. Half a dozen vessels of different burdens sent to this colony would be a splendid speculation.—*Sydney Herald*, May 15.

PROGRESS OF RAILWAYS.

America.—There are now 2,270 miles of railroads completed, or nearly completed, in the United States, besides 2,346 miles of railroads in progress of construction, making a total (when finished) of 4,616 miles.—*Times.*

Greenwich Railway.—Tenders as delivered on Tuesday, 3rd November, for widening the Greenwich Railway, from the Croydon Junction to Tooley Street, (extending *nearly a mile* for the present contract.)

Mr. Jackson	£34,900
Messrs. Grissell and Peto	37,791
Messrs. Baker & Son	38,734
Messrs. Little & Son	38,800
Mr. Lee	38,850
Messrs. Piper & Son	39,300
Mr. Bennett	39,972
Messrs. Ward	43,320
Mr. M'Intosh	43,500
Mr. Grimsdell	46,596

Taff Vale Railway.—We are glad to perceive that the promoters of the prosperity of this town, are not unmindful of the inducements which its great natural advantages hold out for the accomplishment of railway communication with other districts of the kingdom, as well as the importance of meeting other places in the race of competition by the aid of this grand achievement of modern science. The progressive commercial importance, and the exhaustless mineral wealth of Newport and its neighbourhood, have been so frequently the theme of observation in this journal, that it would be superfluous at present to dwell on facts, admitted by all, as incentives to action during the railway undertakings now completed or in course of operation through the leading districts of the kingdom. Our position is commanding, our advantages great, and our exertions should be commensurate to obtain a participation in the benefits for our town and port, and for the county at large, that railway communication with the great arteries of the traffic of the kingdom, is now diffusing. A railway is projected between Newport and Gloucester, taking the circuit of Monmouth and Usk. We understand that Mr. Barber, late of the Taff Vale Railway, a gentleman highly spoken of as possessing great talents in his profession, is directing his best energies to the subject, and with the support he has already received, we augur well for the maturity of his plans. The question shall be resumed in our columns.—*Monmouthshire Merlin.*

South-Eastern Railway.—This great undertaking is now proceeding with the utmost vigour; all the works between Tunbridge and Redhill are in a state of great forwardness, it being the intention of the directors to open the line as far as Tunbridge, with the least possible delay. The tunnel, near the village of Bletchingly, which is a particularly arduous and heavy structure, is also progressing considerably. This is one of the most interesting works upon the line, particularly to the geologist, as it passes under ground near the foot of Tilburston-hill, which it is well known has been subjected to some powerful subterraneous action, the strata upon some parts of the hill being singularly distorted. All the phenomena observed by the engineer in the progress of the work shows this spot to have been peculiarly subjected to the upheaving and disturbing powers which, at some remote period, have been in active operation. Mr. Simms, the engineer, who resides at Bletchingly, is in possession of several interesting fossils, which he has found in the progress of his work.—*Sussex Express.*

Gloucester and Monmouthshire Railway.—Agreeably to our promise, we this week recur to the subject of a railway from Newport to Gloucester. It appears that two lines have been surveyed, the one by Usk and Monmouth, the other by Chepstow and Newnham; and it is a matter of the greatest moment to arrive at a sound conclusion, as to which line will best subserve the interests of the public, and of the districts through which it passes. We have been long impressed with the importance, and indeed, the necessity for a railway communication through this rich and greatly improving district; and having attentively considered the subject, it appears that there can be but one opinion as to the eligibility of the central line, and of the impolicy of allowing a trifling difference of cost, to weigh in the consideration of a question involving results of such paramount advantage The line proposed, to follow the banks of the Severn, is open to so many objections from its being parallel with a fine navigation, and with a probability of another railway from Gloucester to Bristol being carried along the opposite bank, that we think it will not bear comparison with a line embracing towns of importance, and laying open a splendid district of country, greatly needing the facilities of railway communication. The traffic from the important districts of Pontypool, Abergavenny, Brecon, &c., largely flow into the line near Usk, and the City of Hereford would doubtless communicate near Ross. The central character of this line affords a guarantee that traffic will be derived on every side. We have had the pleasure of inspecting the plans of the line surveyed by Mr. Barber, and as our readers feel great interest in the subject, we will endeavour to obtain the details of its course.—*Bristol Paper.*

Proving Steam-Engine Boilers in Belgium.—By a decree of King Leopold, dated Oct. 28, it is ordained :—"That every boiler in which the steam is required to have a pressure of more than one atmosphere shall be submitted to a proof of treple the force it will be required to support. This pressure to be determined by the difference between the authorised pressure of the steam in the boiler and atmospheric pressure.—Considering that tubular boilers of locomotive engines may safely be exposed to less rigorous proof, on the report of our Minister of the Public Works, we have decreed.—Article 1. That the boilers of locomotive engines intended to run on railroads shall be submitted to a proof of twice the amount those engines are required to support.—Art. 2. The permission to make use of locomotives belonging to the state will be granted after the trials prescribed by the articles of the first and second decree, by the director of the railroads now in operation.—Art. 3. The proof of the locomotive engines shall be renewed at least once a year; they shall take place after every important repair of the boiler. The boilers that are injured during the proof shall not be used.—Art. 4. The director of the railroads in operation shall address to our Minister of the Public Works a duplicate of the permission to use the engines, and of the declarations of proof."

Thames Haven Dock and Railway.—Considerable exertions are being made for pushing forward this important undertaking in the ensuing spring.

MISCELLANEA.

Mast Conveying.—It has been usual of late, since it has been considered objectionable to immerse made masts in the water, to send them from the mast-houses on trucks, a process which does them no good, and occupies a whole day when a line-of-battle ship's lower mast is to be dealt with. A method, however, was tried on Tuesday last with the Indus's foremast, and it answered admirably, to convey it by water, without wetting it, in the following way :—Two flat-bottomed boats, placed side by side, and having strong skids laid on their gunwales, were brought to the slipway, at the back of the mast-houses, and properly placed; the mast was then launched out until it projected beyond the boats, and over the centre of the skids until its heel end rested upon them; the launching of the mast was then continued, the boats bearing it, and another pair of flat-bottomed boats, similarly fitted with skids, were brought and placed under the mast towards its head, which, as it descended the slip, presently rested on them, as the heel had done before, upon the skids of the boats first placed; the tressel trees were then bolted on, and the flats with their burden were towed away to the sheers, where the Indus was waiting for, and very soon received, her foremast, which had thus been conveyed perfectly dry. This novel operation was carried into effect under the superintendence of the officers of the mast-house; for the idea, however, and also the details of the scheme, the service is indebted to Mr. Whettem, an intelligent and zealous inspector in the mast-making department.—*Times*, Nov. 2.

A steam fire-engine has been invented at New York, by Captain Erichsen. It weighs only $2\frac{1}{4}$ tons, and will throw 3,000 pounds of water per minute to a height of 105 feet, through a nozzle of $1\frac{1}{8}$ inch diameter.—*Times.*

Patent Wire Rope for Standing Rigging.—Last week a series of trials of Smith's Patent Wire Rope was made at the Corporation testing-machine, in Trentham Street, Liverpool, in presence of a number of nautical gentlemen and others interested in improvements in navigation, and the result was highly satisfactory. The patent consists of improved methods of forming a rope from any number of wires that shall be flexible, is served with hemp, and can also be spliced or knotted. The rope is tarred in the usual way, so as to exclude the water; and a chemical preparation is employed to prevent oxidation. The rigging with wire rope is smaller and lighter than of hempen rope, and as it offers much less resistance to the wind, is of great advantage in beating to windward. The cost, too, is much less, and the durability greater. In the trials we have alluded to, the following results were ascertained :—

1-inch rope broke at	2 tons	1 cwt.
$1\frac{1}{2}$	.. ..	5 ..	0 ..
$2\frac{3}{8}$	.. ..	8 ..	14 ..

other sizes were also tried with proportionate success; and it should be remarked, that a *three inch* hempen rope of the best quality broke at 2 tons 1 cwt. The weight or traction borne by each piece of different sized rope far exceeded that fixed in the scale of the patentee, thus showing great superiority in the workmanship of the manufacturers, Messrs. Fox and Co. of London and Birmingham. According to the scale alluded to, the weight to be sustained by $1\frac{1}{2}$ inch wire rope is 3 tons 10 cwt., and so in proportion. Another good quality of the wire rope is its elasticity, which, though not of course equal to that of hemp rope, is quite sufficient to counteract the effects of a sudden jerk while a vessel is rolling heavily at sea. One comparatively short length of rope that was tried, stretched $18\frac{1}{2}$ inches before it broke. A very short length of $1\frac{1}{2}$ inch stretched 6 inches. The machine on which the tests were made is very ingenious, and of tremendous multiplying power; it is that on which iron cables for the largest ships are put to their utmost tension of many tons. The gentlemen present took a deep interest in the operations, and were at once gratified and astonished to witness the immense weight or traction sustained by lengths of wire rope so comparatively small and light. It should be added, that this patent rigging has been tested at sea upwards of five years, and that amongst the ships fitted with it in our own port are those crack steamers the *Oriental* and the *Liverpool*. The new light ship, the *Albert*, destined for the Victoria Channel, is also rigged with it, and it has hitherto been highly approved by practical men.—*Liverpool Standard.*

Survey of the Northern Counties of England.—We have much satisfaction in conveying the gratifying intelligence that the secretary of the Manchester Geological Society has received a communication from the Lords of the Treasury, announcing their intention to conduct the survey of the six northern counties of England, on an enlarged scale of six inches to the mile, instead of two inches, the size adopted for the other counties, and that they are to commence with Lancashire forthwith. This is a matter of very great importance to the landed interest, as well as to the proprietors of mines, coal mines, and quarries, and hence to the community at large, in this thickly peopled district. For this important improvement in the survey, we are indebted to the exertions of the Geological Society of Manchester, with whom the idea originated. They memorialised the Treasury, and influenced other scientific societies to follow their example, and thus paved the way to this important result. This fact alone proves the high importance of the Geological Society, seeing that their first acts are directed to the prosperity of the county and its varied mercantile interests. It is, therefore, the duty of the gentlemen of this and the surrounding towns to become members of this society, and by increasing its funds enable it to pursue its useful and laudable exertions with increased vigour.—*Manchester Chronicle.*

Ancient Window.—An ancient stained glass window of the 15th century, which formerly belonged to a convent at Mechlin, has just been placed in the church of St. George's, Hanover Square.—*Times.*

Improvement of the Severn.—The *Bristol Journal* has the following remarks upon the proposed improvement of the navigation of the river Severn :—"In the trading interests of Bristol, this long-wanted improvement must be of the greatest advantage in developing and carrying out those vast enterprizes which our fellow citizens have of late projected with such laudable spirit and liberality; thereby securing to them the readiest and cheapest conveyance of the vast mineral products and the produce of the potteries of Staffordshire, the salt of Droitwich, and the various manufactures of Birmingham and its neighbourhood, through the Worcester and Birmingham canal; nor will the port of Gloucester, and more particularly those of Newport and Cardiff, in South Wales, be less benefitted. In the present migratory state of commerce and manufactures, with competition every where taking place, and in which the minutest fraction in cheapness and certainty of conveyance will turn the scale, we do consider the contemplated improvement of first-rate advantage to Bristol. The great wonder is, that such an anomalous state of things, in these days of commercial enterprise, should so long have been suffered to exist."

LIST OF NEW PATENTS.

GRANTED IN ENGLAND FROM 2ND NOVEMBER TO 25TH NOVEMBER, 1840.

John Duncan, of Great George Street, Westminster, Gentleman, for "*improvements in machinery for cutting, reaping, or severing grass, grain, corn, or other like growing plants or herbs.*" Communicated by a foreigner residing abroad.—Sealed November 2; six months for enrolment.

Elijah Galloway, of Manchester Street, Engineer, for "*improvements in propelling railroad carriages.*"—November 2; six months.

Josiah Humphrey, of New Tower Row, Birmingham, Brass Founder, for "*certain improvements in machinery to be employed in the manufacture of wire hooks and eyes.*"—November 2; six months.

Henry Wimshurst, of Limehouse, Ship Builder, for "*improvements in steam vessels, in communicating power to propellers of steam vessels, and in shipping and unshipping propellers.*"—November 2; six months.

James Heywood Whitehead, of Royal George Mills, York, Manufacturer, for "*improvements in the manufacture of woollen belts, bands, or driving straps.*"—November 2; six months.

Henry Charles Danberry, residing at Boulogne, Esquire, for "*an improvement in the making and forming of paddle-wheels for the use of vessels propelled on the water by steam or other power, and applicable to propel vessels and mills.*"—November 25; six months.

Thomas Barratt, of Somerset, for "*improvements in the manufacture of paper.*"—November 25; six months.

Junius Smith, of Fen Court, Fenchurch Street, Esquire, for "*certain improvements in furnaces.*" Communicated by a foreigner residing abroad.—November 25; six months.

Charles Grellett, of Hatton Garden, for "*new modes of treating potatoes in order to their being converted into various articles of food, and new apparatus for drying, applicable to that and other purposes.*"—November 25; six months.

William Henry Bailey Webster, of Ipswich, Surgeon, for "*improvements in preparing skins and other animal matters, for the purpose of tanning, and in the manufacture of gelatine.*"—November 25; six months.

Oliver Louis Reynolds, of King Street, Cheapside, Merchant, for "*certain improvements in machinery for producing stocking fabric or framework knitting.* Communicated by a foreigner residing abroad.—November 25; six months.

Nathaniel Batho, of Manchester, Engineer, for "*certain improvements in machinery, tools, or apparatus, for planing, turning, boring, or cutting metals, and other substances.*"—November 26; six months.

Frederick Theodore Philippi, of Bellfield Hall, Calico Printer, for "*certain improvements in the art of printing cotton, silk, and other woven fabrics.*"—November 25; six months.

James Lee Hannah, of Brighton, Doctor of Medicine, for "*an improvement or improvements in fire-escapes.*"—November 25; six months.

Robert Roberts, of Bradford, Blacksmith, for "*a new method or process for case hardening iron.*"—November 25; six months.

Henry Walker Wood, of Chester Square, Gentleman, for "*an improvement in producing an uneven surface in wood and other substances.*" Communicated by a foreigner residing abroad.—November 25; six months.

TO CORRESPONDENTS.

Notice.

The present Number concludes the Third Volume. The Title, Preface, and Index will be given extra with the next month's Journal.

Vols. I, II, and III, may be had, bound in cloth, price £1 each Volume.

"A Constant Reader." *We have not seen the carriage.*

We have received two other letters besides the one inserted respecting Mr. Mansel's proposition for using marbles to check the lengths of the chain; we think it unnecessary to publish any other than the one by a "*Surveyor.*"

James Inglis's *letter commenting on our remarks, regarding his conduct, in last month's Journal, we must decline publishing. We are at all times disposed to lend our aid in crushing plagiarism; in doing so we must be supported by facts, and no part of the statement should contain any matter but what could be fully proved in a court of law, to which we render ourselves liable to be brought, when vindicating any particular interest, or exposing piracy. Mr. Inglis stated in his letter, that his assertions could be supported by written documents, which, upon investigation, turned out not to be the case. We therefore cannot allow any further correspondence on the subject of* "*Tide Gauges,*" *unless it is the wish of either Mr. Mitchell or Mr. Bunt.*

A Road Engineer. *We shall attend to the Report on Turnpike Roads next month.*

Books received:—Lecount on the London and Birmingham Railway; Parsey on Perspective; Williams on Combustion; Pambour on the Steam Engine.

Communications are requested to be addressed to "The Editor of the Civil Engineer and Architect's Journal,' *No. 11, Parliament Street, Westminster.*

Books for review must be sent early in the month, communications on or before the 20th (if with drawings, earlier), and advertisements on or before the 25th instant.
